Hydrogel swelling is determined by polymer properties and cross-link density determining the retractive forces which oppose the dissolution effects of mixing and in the case of charged gels—ionic repulsion effects. It is apparent from the simulations and literature data reported above that pH-sensitive gels show much higher swelling ratios than neutral or bio-responsive gels. In membrane applications they will be more suited to a pore gating role in microporous membranes where the gel acts as a valve to control convective flow [45]. While increases in mesh size with swelling will increase gel phase diffusivity, the high swelling ratios seen with many pH-sensitive gels limit their mechanical strength for applications in a diffusive membrane form.

**FIGURE 16.17** Effect of competitor concentration on transmembrane flux showing competing effects of increased mesh size and increased membrane thickness.  $(C_D - C_R) = 1$  M. (a) Zero covalent bonds per chain, (b) 5 covalent bonds per chain, (c) 10 covalent bonds per chain, and (d) 20 covalent bonds per chain.

Conversely, for responsive gels based on ligand–receptor interactions, where swelling and mesh size changes result from changes in cross-link density, changes in swelling ratio are usually much smaller. While this makes them less suitable for pore gating applications, they are potentially more attractive for use in a diffusive membrane construct.

As described above, diffusive systems fall into two categories: (1) diffusive systems that are based on a sol/gel transition [28,29,51,53] and (2) diffusive systems that are based on changes in mesh size [30,46,48,54]. In the sol/gel systems, the gel state results solely from reversible interactions between ligand and receptor; thus increases in competitor concentration will initially lead to increase in transport rate resulting from increases in mesh size, as the gel changes to a sol viscosity effects will predominate (Figure 16.4). In gels which contain both reversible and covalent interactions, gel structure is retained even at saturating competitor concentrations. In both systems, a cross-link density high enough to give a mesh size less than the radius of the solute to be delivered will be required if zero delivery is to be achieved in the absence of competitor (Equation 16.15). This requires a high cross-link density and ideally a polymer with a low molecular weight and short repeat unit (Equation 16.12). Thus when polymers are chosen, the monomer size, covalent cross-link density, and achievable degree of ligand and receptor substitution need to be assessed to ensure that the resulting mesh size is compatible with the molecular weight of the solute to be delivered.

## 16.5 APPLICATIONS OF RESPONSIVE MEMBRANES: INSULIN DELIVERY

In many clinical situations, controlled drug delivery systems, which deliver drugs at a predetermined rate, are replacing conventional drug formulations. However, in diabetes mellitus, there is currently no entirely effectively system for continuous control of blood glucose levels. The treatment of insulin-dependent diabetes requires the provision of insulin in response to increases in blood glucose concentration. Although a conventional oral route would be preferred, this is not practical for the systemic delivery of peptide and protein drugs, including insulin [72]. The consequent required daily injection of insulin may cause discomfort, and can lead to several long-term complications associated with diabetes mellitus such as retinal damage and cardiovascular disease. Therefore, an insulin delivery system capable of mimicking the pancreas and delivering insulin in response to increases in blood glucose would be highly attractive [73]. It is for this reason that many of the responsive hydrogels described above have targeted the controlled release of insulin in response to changes in glucose concentration.

As described previously, the specific interactions between enzymes and lectins with carbohydrates have been evaluated for use in insulin delivery systems based on responses to chemical and biochemical stimuli. These include pH, changes in specific ion concentration, and specific molecular recognition events [15].

An extensively studied approach has been the use of ConA/glucose derivatized polymer mixtures to form reversible sol/gel system, which is sandwiched between two porous membranes [29,51,53]. Gelation is reversible in response to changes in environmental glucose concentration such that the diffusion coefficient for insulin changes with degree of gelation. In earlier studies, the gels were based solely on soluble components. However, leakage of ConA through the membrane during gel–sol transition led to revised systems with ConA coupled to the polymer.

While reducing leakage, coupling of ConA to the polymer still results in a system that is in a soluble form in the presence of glucose [51,52]. Thus, support membranes are still required, leading to increased complexity and slow diffusion rates (Figure 16.5). To address these problems, the covalently cross-linked hydrogels containing glucose moieties and either boronate or lectin-binding groups were developed [30,31,50,54].

## 16.6 PERFORMANCE MODELING

The overall response of the patient to an insulin delivery system can be modeled using compartmental analysis to allow the performance of the release system and its interdependence with factors affecting the physiological response of the patient to be systematically assessed. Several such models have been published [74,75] to describe the response to a bolus input in a glucose tolerance test, but need to be combined with models of responsive gel performance to describe *in vivo* glucose and insulin levels over an extended period in the face of varying levels of input and demand. The ultimate goal is a model that can be used in the validation of control strategies for a gel membrane release system, *i.e.*, the production of a chemical control system analogous to the electronic systems proposed for pump-based closed loop delivery systems [76].

## 16.7 OUTSTANDING ISSUES

Despite considerable research on the development of responsive membranes for drug delivery there are significant hurdles to be overcome before techniques developed in the laboratory are made suitable for *in vivo* use. In insulin delivery, three response mechanisms have been investigated as described above: (1) a catalytically induced pH shift using glucose oxidase, (2) mesh size changes induced by displacement of ConA-mediated gel cross-links, and (3) mesh size changes induced by displacement of boronate-mediated gel cross-links. All three approaches require gel components which are either toxic, immunogenic, or

both. Therefore, these mechanisms pose a significant risk to patient health if membrane components were to leak from a delivery system.

In the glucose oxidase system, dissolved oxygen concentration as well as glucose levels will influence delivery response requiring close control of mass-transfer limitations. For both systems containing a protein component, stability factors may limit operational lifetime. This may be particularly severe in the case of glucose oxidase where the reaction product  $H_2O_2$  will accelerate enzyme denaturation unless it is rapidly removed by diffusion or reaction with a second enzyme (peroxidase or catalase).

In terms of insulin release, catalytic systems offer the advantage of failing safe, i.e., for transport to increase, pH must be actively reduced by the enzyme-catalyzed reaction. Loss of enzyme activity leads to a reduction rather than an increase in release. Conversely, in binding displacement systems protein denaturation will lead to an increase in release as the number of cross-links is reduced.

For extended operation, insulin release systems will need to require many times the lethal dose of insulin. Therefore, in addition to failure of the responsive element, there is a significant risk associated with accidental release resulting from a mechanical failure. This requires careful consideration of the mechanical design of a unit intended to operate as an implant.

Finally, the issue of biocompatibility and location needs to be considered to ensure response is triggered by a local glucose change representative of the wider levels and that release is not compromised by fouling or cell growth over the release surface. For these reasons little work has yet to be carried out in vivo systems. However, Taylor et al. [77] have demonstrated a pharmacological effect using a ConA-based responsive gel to deliver insulin in the rat, highlighting the potential of responsive membrane systems if the technical and safety issues can be resolved.

## NOMENCLATURE

$A$	membrane area ( $m^2$ )
$C$	competitor concentration (M)
$C_D$	Donor compartment concentration (M)
$C_R$	receiving compartment concentration (M)
$C_n$	Flory characteristic ratio
$D_{gel}$	diffusate diffusivity in the gel phase ( $m^2s^{-1}$ )
$D_l$	diffusate diffusivity in the liquid phase ( $m^2s^{-1}$ )
$fb$	force per bond (N)
$I$	ionic strength (M)
$J$	Flux ( $M s^{-1}$ )
$k_r$	dissociation rate constant ( $s^{-1}$ )
$k'_r$	apparent dissociation constant under applied stress ( $s^{-1}$ )
$l$	the unit length along the polymer back bone (m)
$L_{tot}$	immobilized ligand concentration (M)
$k_b$	Boltzmann constant ( $J M^{-1} K^{-1}$ )
$K_a$	dissociation constant for acid (M)
$K_b$	dissociation constant for base (M)
$K_C$	dissociation constant for competitor/ligand (M)
$K_L$	dissociation constant for receptor/ligand (M)
$\bar{M}_c$	number average molecular weight between cross-links ( $kg M^{-1}$ )
$\bar{M}_n$	number average molecular weight of the polymer ( $kg M^{-1}$ )
$nb$	number of bonds
$P$	polymer concentration in the gel (M)
$Q$	ratio of the swollen gel volume to the dry gel volume
$r$	hydrodynamic radius of the solute (m)
$[RC]$	receptor/competitor complex concentration (M)
$[RL]$	receptor/ligand complex concentration (M)
$R_{tot}$	immobilized receptor sites concentration (M)
$sr$	swelling ratio
$v_1$	partial specific volume of the polymer ( $m^3$ )
$v_{2,r}$	polymer fraction of the gel after gel formation
$v_{2,s}$	polymer fraction of the gel at equilibrium swelling
$V$	volume of receiving compartment ( $m^3$ )
$V_1$	molar volume of water ( $m^3 kg^{-1}$ )
$Y$	fraction of immobilized ligand bound to receptor

$\delta$	membrane thickness (m)
$\xi$	mesh size (m)
$x_1$	Flory polymer-solvent interaction parameter
$\gamma$	bond interaction distance (m)

----------------	-----

Biological membranes have long been known to be crucially important in cellular homeostasis and metabolic-energy transduction. They not only control cellular transport processes but also regulate various functional characteristics of multicellular organisms. Recent studies on bipolar membranes have provided a better understanding of the mechanism of ionic transport in cellular systems and have also led to new developments in highly selective membranes with such characteristics as permselectivity for monovalent ions, rectification, and water splitting. These discoveries are indeed harbingers of new heights to be attained in the field of bioseparations.

Developments in synthetic membranes and their utilization are more recent. Industrial applications of membrane-based processes in bioscience and technology have accelerated over the last four decades. The membranes are now used in numerous diverse fields extending from production of potable water and separation of gases, to drug delivery and cold sterilization of beverages and pharmaceuticals. It is often a method of choice for concentration and separation of different components of a macromolecular mixture or solutions, especially if they are sensitive to high temperatures. The physical and chemical make up of these membrane material are exploited to create a selective barrier for separation of species of different size, shape, electrical charge, and related properties. Porous membranes affect separation primarily by discrimination of size and shape, and hydrodynamic sieving; while nonporous membranes depend on sorption and diffusion. There has been tremendous progress in our understanding of how components pass through a membrane; both on the basis of thermodynamics of solubility and kinetics of diffusion that together constitute what is called permeability.

The utility of a membrane system is dictated by the degree of desired separations achieved and the rate of separation. The degree of desired separations is measured in terms of solute selectivity or rejection, while the rate of separation is evaluated by a combination of flux and fouling. The performance of a particular membrane and its replacement frequency will affect operation and maintenance cost, and invariably dictate the process selection. Some of the most attractive features of membranes are already listed in Chapter 1. Among few drawbacks, high initial capital costs, fouling, achievable product purity, and limited durability often pose limitations to their widespread utilization. Nevertheless, numerous industrially significant processes in the food processing and biotechnology industries continue to capitalize on the many products made using membrane-based processes. Some of the current examples include water desalination and purification, and cold sterilization of beverages; recovery and fractionation of proteins from cheese whey; clarification of fruit juice, wines and beer; removal of bacteria from water; effluent treatment for removal of heavy metals and organic materials; separation of oil/water emulsions; removal of VOCs from air; controlled release of drugs; separation of plasma from blood; dewatering of suspended solids such as slurries, among many others.

The statement made by Drioli and Romano in 2001 [1] on performance of various membrane-based installations in France is given as below:\*

It is interesting to mention that statistical analysis carried by Electricité de France on 174 different membrane installation in France using MF, UF, RO, and ED mainly in small- and medium-sized industries found a normal percentage of satisfaction between 70% and 95%, one of the highest positive responses received in this kind of analysis. This result is, in part, surprising because of the high innovative content of the technology and the lack of education still existing on their basic properties. It is, however, consistent with the important contributions that membrane operations can make in terms of cost reduction, quality improvement, pollution control etc.

The potential of membranes to provide nonthermal energy conversion through fuel cells is widely recognized and has received support from governmental agencies. Numerous research teams are working extensively across the world to develop different types of membrane-based fuel cells and a large number of publications have come out in recent years in this area. This clearly indicates that future research will be aimed at commercializing fuel cells as an alternative to current power sources.

The continuous interest and growth of the various new industrial processes related to the life sciences will also require significant contributions from membrane engineering. It is hoped that future research would provide deeper insight on the precise mechanisms involved, which would show new direction for research in membrane science and applications. It is, however, important to recognize that applicability of electroporation has been demonstrated in a variety of bacteria, yeast, and mammalian cells and some applications are ready for exploitation while many new technologies seem potentially possible.

It is indeed impossible to capture all current and future applications, and uses in any one publication. What follows here is a selective presentation from the large number of possible membrane-based processes of relevance to bioprocess industries.

Ultrafiltration-based protein bioseparation is the subject of Chapter 18 and how it can, by judicious choices of operating parameters, significantly reduce the number of purification steps currently in use. Membrane distillation, which is a relatively new and emerging area of application for concentration of dilute aqueous feedstock in which a microporous hydrophobic membrane is used, is covered in Chapter 19. Membrane-based separations in the brewing industry are discussed in Chapter 20 and a variety of uses ranging from beer clarification and cold sterilization to tank bottoms recovery, alcohol removal, as well as water and effluent treatment are detailed. Chapter 21 summarizes the principles of operation of monopolar and bipolar membrane and their applications in food and chemical processing, pollution control, and resource recovery with specific details on electrodialysis. The current state of research and development in the sprawling industrial use of membranes in the dairy industry for various processing purposes is presented in Chapter 22.

Chapter 23 is devoted to one of the most critical medical applications and discusses the principle and design of microporous membrane blood oxygenator that are used to ensure that oxygen-rich blood reaches the cells in the body during cardiopulmonary operations. In Chapter 24, the design, synthesis, characterization, and applications of nanotube membranes in bioextraction and biocatalysis are discussed. The physicochemical properties and modeling of emulsion liquid membranes and their uses in chemical and biotechnological separations are elaborated in Chapter 25. Chapter 26, goes into the mechanics and biophysical aspects of cell membrane and the current understanding of the dynamics involved in electropore formation and molecular transport, which have numerous promising implication to human health. The last chapter of this section, Chapter 27 deals with developments in polymer electrolyte membrane fuel cells, covering the principles, types, transport modeling, and their applications.

It is hoped that the Chapters 18 through 27 would well serve the needs of professionals, both researchers and practitioners, interested in the depth and breadth of membrane-based technologies of utility to them.

## 18.1 BIOSEPARATION

Bioseparations engineering deals with the large-scale purification of biological products such as proteins that are used as biochemicals, pharmaceuticals, foods, food additives, nutraceuticals, and agrochemicals. Biological products can be categorized in different ways. One way is to classify them based on their applications (see Table 18.1). Developments in the field of bioseparations engineering have largely been fueled by the rapid growth in biotechnology. More and more biological products are now required to be purified in sizable quantities. The separation of biological products from their respective starting material (i.e., biological reaction medium or tissue extract) is technically difficult and expensive and can frequently be the critical limiting factor in biological manufacturing. In many cases, the bioseparation cost is a substantial component of the total cost of production. Manufacturing cost is perhaps a minor issue with newly developed products that enjoy patent protection, since the cost of product bears no correlation with cost of production. This is due to the significantly high markup in product price, which essentially serves to cover the substantial cost of product development. However, for generic biological products, the viability of a manufacturing process depends largely on the cost of production. Table 18.2 lists the bioseparation costs of certain biological products as percentage of total manufacturing cost. For high-value biological products such as generic therapeutic proteins, the purification cost can be very significant, mainly due to the following reasons:

1. Low product yield in bioreactors
2. Product complexity
3. Susceptibility of product degradation
4. Stringent quality requirements
5. Need for multistep separation
6. Need for specialized bioseparation techniques, e.g., affinity chromatography

Conventional bioseparation is based on an RIPP (recovery, isolation, purification, and polishing) scheme [1]. This involves using low-resolution, high-productivity techniques (e.g., precipitation, filtration, centrifugation, and crystallization) first, primarily to reduce the overall volume and concentration of the process stream (this being referred to as recovery and isolation). This is followed by high-resolution, low-productivity techniques (e.g., affinity separations, chromatography, and electrophoresis) for purification and polishing. With the advent of membrane separation processes and other new types of separations, it is now possible to combine high productivity with high resolution, and thus the opportunity exists to potentially

**TABLE 18.1**  
**Classification of Biological Products Based on Their Applications**

Categories	Biological Products
Industrial chemicals	Solvents, organic acids, industrial enzymes
Agrochemicals	Biofertilizers, biopesticides
Biopharmaceuticals	Antibiotics, hormones, monoclonal antibodies, plasma proteins, insulin, vaccines, alkaloids
Food and nutraceuticals	Whey proteins, milk proteins, egg proteins, soy proteins, vitamins, amino acids, protein hydrolysates, yeast cells, yeast extract
Diagnostic products	Glucose oxidase, peroxidase, hormones
Commodity chemicals	Detergent enzymes, insecticides
Laboratory reagents	Bovine serum albumin, ovalbumin, lysozyme
Cosmetic products	Plant extracts, animal tissue extracts

cut down the number of purification steps. Membrane processes such as ultrafiltration inherently give high productivity and can be fine-tuned or optimized to give high selectivity.

## 18.2 ULTRAFILTRATION

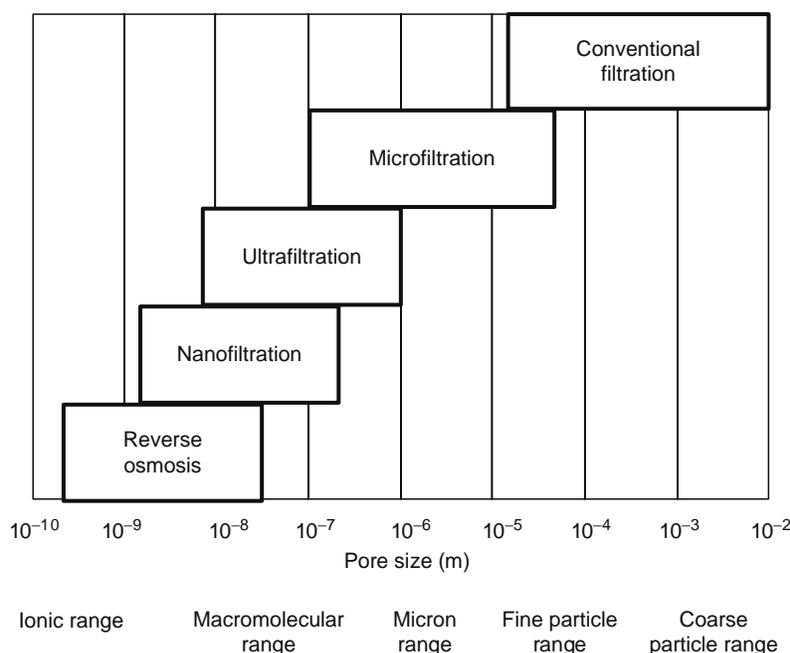

Ultrafiltration is a pressure-driven, selective permeability-based separation process in which membranes having pore sizes ranging from 1 to 100 nm are used for processing macromolecules such as proteins. Figure 18.1 shows ultrafiltration relative to other membrane-based separation processes. A common notion about ultrafiltration is that separation is solely based on solute size. However, solute size is only one of the many factors, which influence separation in ultrafiltration. Indeed, a membrane can be made to retain a smaller molecule while allowing a larger molecule to pass through; this phenomenon is referred to as reversed selectivity. One cannot overemphasize the fact that solute separation by ultrafiltration is highly complex in nature, and appreciating this complexity is absolutely essential if ultrafiltration is to be used efficiently. The complexity of ultrafiltration rather than being a weakness is its strength since it makes it possible to carry out separations that would not have been possible had ultrafiltration been a purely size-based separation process [2].

Ultrafiltration has a broad variety of applications ranging from the processing of biological macromolecules to wastewater treatment. Food and biotechnological applications account for nearly 40% of current total usage of ultrafiltration membranes [2]. Processing of biological macromolecules, such as proteins and nucleic acids, has assumed significant importance in the bioprocess industry, where the impact of downstream processing on the overall process economics is now better appreciated. From an operational point of view ultrafiltration is used for

1. Concentration (removal of solvent from protein solutions)
2. Desalting (removal of low-molecular weight compounds from protein solutions)
3. Clarification (i.e., removal of particles from protein solutions)
4. Fractionation (i.e., protein–protein separation)

**TABLE 18.2**  
**Cost of Bioseparation**

Product	Bioseparation Cost (%)
Solvents, e.g., ethanol, acetone	15–20
Cells, e.g., bakers yeast, brewers yeast	20–25
Crude cellular extracts, e.g., yeast extract	20–25
Organic acids, e.g., citric acid, lactic acid	30–40
Vitamins and amino acids, e.g., lysine, ascorbic acid	30–40
Gums and polymers, e.g., xanthan, gellan	40–50
Antibiotics, e.g., penicillins, rifampicin	20–60
Industrial enzymes, e.g., amyloglucosidase, glucose isomerase	40–65
Nonrecombinant therapeutic proteins, e.g., pancreatin, papain, diastase	50–70
r-DNA products, e.g., recombinant insulin, recombinant streptokinase	60–80
Monoclonal antibodies	50–70
Nucleic acid-based products	60–80
Plasma proteins, human albumin, human immunoglobulins	70–80

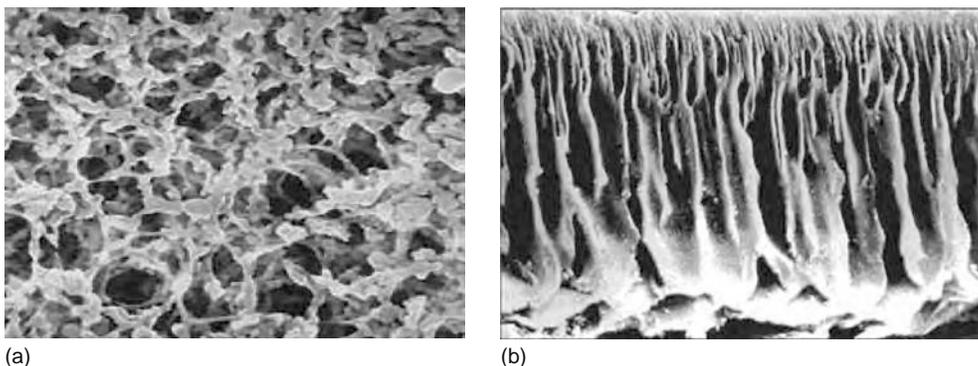

**FIGURE 18.1** Classification of membrane processes.

Concentration, desalting, and clarification processes are well-established operations in the industry for quite some time (since the 1970s). Macromolecular fractionation using ultrafiltration is significantly more challenging and is still a developing field. The major advantages of ultrafiltration over competing separation technologies are high throughput of product, relative ease of scale-up, and ease of equipment cleaning and sanitization.

### 18.3 MEMBRANES

A membrane is the key component of an ultrafiltration process and is defined as a thin barrier through which solutes are selectively transported. Ultrafiltration membranes are prepared from organic polymers, such as cellulose and cellulose derivatives like cellulose acetate (CA), polysulfone (PS), polyethersulfone (PES), polyvinylidene fluoride (PVDF), polyamide (PA), and polyacrylonitrile (PAN). Membranes made from ceramic material are widely used in the water industry but their use in protein processing has been very limited. From a structural point of view polymeric membranes can be broadly divided into two types: symmetric and asymmetric (or anisotropic). A symmetric membrane has similar structural morphology at all positions within it, while an anisotropic membrane is a composite of two or more structural planes of dissimilar morphologies (see Figure 18.2). Most ultrafiltration membranes are anisotropic. The selectivity and hydraulic permeability of an anisotropic membrane are usually due to an ultrathin skin layer, which can be 0.2–1  $\mu\text{m}$  thick. The skin layer is backed up by a microporous-supporting layer, which gives form and mechanical support.

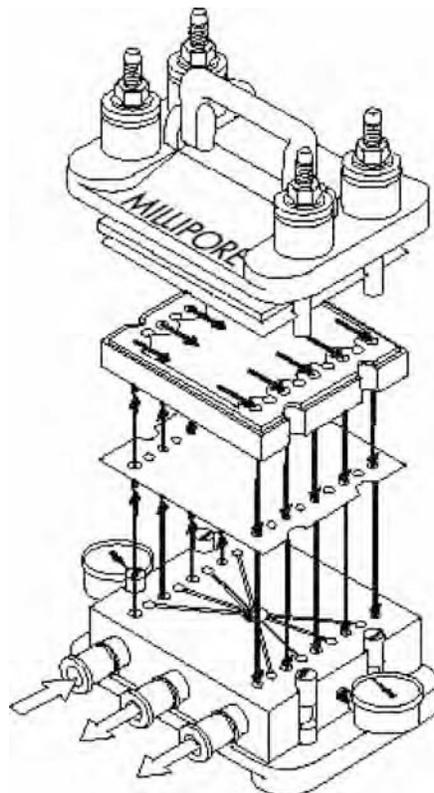

**FIGURE 18.2** (a) Symmetric and (b) asymmetric membranes. (Micrograph of symmetric membrane. Courtesy of Millipore Corporation. With permission.)

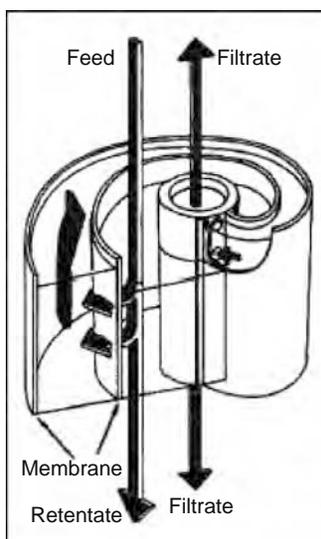

**FIGURE 18.3** Stirred cell. (Photo courtesy of Millipore Corporation. With permission.)

The term membrane element refers to the basic form in which a membrane is prepared. There are three types of membrane elements: flat sheets, hollow fibers, and tubular membranes. The device within which the membrane element is housed is referred to as the membrane module. The design of the membrane module largely depends on the type of membrane element, as well as on additional requirements such as the need for cleaning and disassembling, the required transmembrane pressure (TMP), and the required hydrodynamic conditions. Some of the different modules types are (see Figures 18.3 through 18.7):

**FIGURE 18.4** Flat sheet TF flow membrane module. (Figure courtesy of Millipore Corporation. With permission.)

**FIGURE 18.5** Spiral wound membrane module. (Figure courtesy of Millipore Corporation. With permission.)

**FIGURE 18.6** Tubular membrane module. (Photo courtesy of PCI Membranes. With permission.)

**FIGURE 18.7** Hollow fiber membrane module. (Photo courtesy of Millipore Corporation. With permission.)

**TABLE 18.3**  
**Characteristics of Membrane Modules**

Type	Applications	Feed Hold-up	Special Remarks
Stirred cell	Laboratory	High	Sometimes used for dead-end ultrafiltration
Flat sheet TF	Food, pharmaceuticals, biotechnology	Moderate	Easy dismantling and cleaning
Spiral wound	Food, pharmaceutical, water	Low	Uses flat sheet membrane element
Hollow fiber	Pharmaceuticals, water, bioreactors	Low	Susceptible to fiber blocking
Tubular	Water, wastewater, industrial chemicals	High	Easy cleaning

1. Stirred cells (only for laboratory-scale applications)
2. Flat sheet tangential (TF) flow module
3. Spiral wound module
4. Tubular module
5. Hollow fiber module

Table 18.3 lists the relative advantages and disadvantages of the different types of membrane modules.

Membrane modules can be operated in the dead-end or cross-flow modes (see Figure 18.8). Dead-end ultrafiltration is used mostly for laboratory-scale applications and industrial ultrafiltration processes are usually carried out in the cross-flow mode. The main advantage of cross-flow ultrafiltration is the lower extent of concentration polarization. The cross-flow mode also allows recirculation of the retentate stream to the feed tank followed by its mixing with fresh feed that leads to several operational advantages.

#### 18.4 THEORY OF ULTRAFILTRATION

Solvent transport through a membrane is driven by an applied TMP gradient. The TMP used in ultrafiltration ranges from 0 to 500 kPa, though most ultrafiltration processes are carried out at less than 100 kPa TMP. The transport of solvent through an ultrafiltration membrane is quantified in terms of the volumetric permeate flux ( $J_v$ ), which is obtained by dividing the volumetric filtration rate by the membrane area. Solute molecules may be either fully or partially transmitted or indeed totally retained (or rejected) by an ultrafiltration membrane. This depends on a number of factors that include steric, hydrodynamic, thermodynamic, and electrostatic effects. Solute retention leads to its build-up near the membrane surface this being referred to as concentration polarization. Concentration polarization results in generation of an osmotic back pressure, which acts against the TMP. The basic working equation for ultrafiltration processes is the osmotic pressure model [3]

$$J_v = \left( \frac{\Delta P - \Delta \pi}{\mu R_m} \right) \quad (18.1)$$

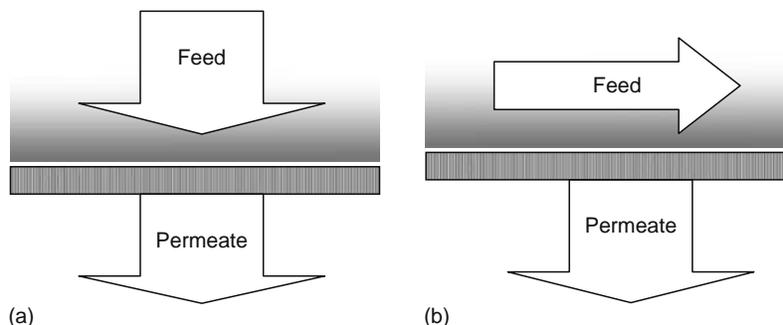

where

$\Delta P$  is the TMP

$\Delta \pi$  is the osmotic back pressure

$\mu$  is the permeate viscosity

$R_m$  is the resistance offered by the membrane

**FIGURE 18.8** Dead-end (a) and cross-flow (b) mode.

In certain cases the accumulated solute may form a gel layer on the membrane leading to an additional gel-layer resistance ( $R_g$ ):

$$J_v = \left( \frac{\Delta P - \Delta \pi}{\mu(R_m + R_g)} \right) \quad (18.2)$$

Concentration polarization is clearly a limiting factor in ultrafiltration. Several methods have been developed to reduce concentration polarization, which includes [4–10]:

1. Creation of pulsatile flow in membrane module
2. TMP pulsing
3. Creation of oscillatory flow
4. Flow obstruction using inserts
5. Generation of Dean vortices in membrane module
6. Generation of Taylor vortices in membrane module
7. Gas-sparging

Ultrafiltration relies on the ability of a membrane to act as a selective barrier. One of the major properties of an ultrafiltration membrane is its ability to act as a sieve for macromolecular substances. The transmission of a particular solute through an ultrafiltration membrane can be expressed in several ways, a commonly used way being in terms of sieving coefficients. The intrinsic or real sieving coefficient ( $S_i$ ) is defined as

$$S_i = \left( \frac{C_p}{C_w} \right) \quad (18.3)$$

where  $C_p$  is the solute concentration in the permeate, while  $C_w$  is that on the membrane surface.  $S_i$  depends on the solute-membrane system, the operating conditions such as pH, ionic strength, temperature, and presence of additives such as surfactants and organic solvents. The intrinsic sieving coefficient of a noninteracting solute can be predicted using the following equation that is based on the diffusive–convective membrane transport theory [11]:

$$S_i = \left( \frac{S_\infty \exp\left(\frac{S_\infty J_v \delta_m}{D_{\text{eff}}}\right)}{S_\infty + \exp\left(\frac{S_\infty J_v \delta_m}{D_{\text{eff}}}\right) - 1} \right) \quad (18.4)$$

where

$S_\infty$  is an asymptotic sieving coefficient

$\delta_m$  is the membrane thickness

$D_{\text{eff}}$  is the effective diffusivity of the solute within the pores

Most proteins would be expected to interact with the membrane to some extent. The intrinsic sieving coefficient of an interacting solute can be determined using Equation 18.5 [12]:

$$S_i^{\text{Interacting}} = S_i \exp\left(-\frac{E}{KT}\right) \quad (18.5)$$

where

$E$  is the activation energy

$K$  is the Boltzmann constant

$T$  is the absolute temperature

Due to concentration polarization, the solute concentration near the membrane surface tends to be higher than that in the bulk feed. Another sieving coefficient term that is commonly used is the apparent or observed sieving coefficient ( $S_a$ ) which is defined as

$$S_a = \left( \frac{C_p}{C_b} \right) \quad (18.6)$$

where  $C_b$  is the solute concentration in the bulk feed. The apparent sieving coefficient of a solute can be predicted using Equation 18.7 [13]:

$$S_a = \left( \frac{S_\infty \left( \frac{S_\infty J_v \delta_m}{D_{\text{eff}}} + \frac{J_v}{k} \right)}{(S_\infty - 1) \left( 1 - \exp\left( \frac{S_\infty J_v \delta_m}{D_{\text{eff}}} \right) \right) + S_\infty \exp\left( \frac{S_\infty J_v \delta_m}{D_{\text{eff}}} + \frac{J_v}{k} \right)} \right) \quad (18.7)$$

where  $k$  is the mass transfer coefficient of the solute and depends on the hydrodynamic conditions within the membrane module. For fully developed laminar flow on the feed side the following correlation could be used to calculate mass transfer coefficient [3].

$$k = 0.816\gamma^{0.33} D^{0.67} l^{-0.33} \quad (18.8)$$

where

$\gamma$  is the wall shear rate

$D$  is the solute diffusivity

$l$  is the length of the membrane module

The different solute concentrations on the feed and permeate sides are linked to the volumetric permeate flux in terms of the concentration polarization model, which is based on the stagnant film theory [14]:

$$J_v = k \ln \left( \frac{C_w - C_p}{C_b - C_p} \right) \quad (18.9)$$

Membrane manufacturers prefer to use a parameter called the nominal molecular weight cut-off (NMWCO) or simply the molecular weight cut-off (MWCO) to specify the sieving properties of their membranes. For a given membrane this is defined as the molecular weight of a solute that has an apparent sieving coefficient of 0.1. Polymers, such as dextran or polyethylene glycol, are usually used to determine MWCO.

Membrane fouling refers to the loss of membrane performance due to adsorption and deposition of material present in the feed on the membrane surface and within the pores. Membrane fouling primarily leads to reduction in volumetric permeate flux and alteration in solute transmission behavior. Membrane fouling usually leads to lowering of the sieving coefficients but in some cases, the sieving coefficients can be increased due to fouling. This is usually due to electrostatic shielding. Fouling can be reversible, i.e., its effects can be reversed by appropriate cleaning methods or irreversible, i.e., membrane properties are permanently altered. Proteins are major foulants and can cause both reversible and irreversible fouling. Fouling is a highly undesirable effect and efforts are necessary to keep it at an acceptably low level. Factors that affect membrane fouling are physicochemical properties of the membrane and the solutes, membrane morphology, operating parameters (TMP, system hydrodynamics), physicochemical properties of the feed solution (pH, salt concentration), and membrane operation history. With certain types of membranes, particularly when operated at high TMP, membrane compaction (i.e., resulting from deformation) may also result in flux decline.

## 18.5 CONCENTRATION

A concentration process involves removal of a solvent, typically water from a macromolecular solution. Ultrafiltration is the method of choice for large-scale concentration. The selectivity issue involving removal of water from a macromolecular solution using ultrafiltration is trivial. The main challenge in a concentration process is maintaining a high productivity on account of the increased macromolecular concentration in the feed solution. Some of the main applications of macromolecular concentration using ultrafiltration are listed below [2]:

1. Concentration of plasma proteins
2. Processing of milk products
3. Concentration of whey proteins
4. Concentration of soy proteins
5. Concentration of enzymes

The type of ultrafiltration membrane to be used for a particular concentration process would depend on the type of protein being concentrated. The membrane should typically give greater than 99% macromolecular retention. Membrane manufacturers frequently provide tabular information to aid membrane selection (see Figure 18.9). Membrane modules used in concentration processes should have low hold-up volume on the feed side, ability to handle viscous feed, and ability to give high mass transfer coefficient of the retained solute. Flag sheet TF flow membrane modules are widely used for concentration-type processes. Where the viscosity of the final concentrated product is low, hollow fiber membrane modules are used. Tubular membrane devices on account of their high hold-up volume are generally not used.

Concentration is commonly operated as a batch process (see Figure 18.10). The liquid to be concentrated is pumped from a feed tank through a cross-flow ultrafiltration membrane module and the retentate is returned to the tank. The ultrafiltration process is generally carried out at a constant TMP, which is generated by throttling the retentate line. The permeate that is free from protein is discarded and hence the feed concentration increases in the feed tank with time. The batch concentration system is conceptually simple and efficient due to the low possible material exposure to the membrane for a given degree of concentration. The main limitation of the batch concentration mode is the need for a large dedicated feed tank. This limitation can be overcome using a fed-batch process (see Figure 18.11) in which a small primary feed tank is fed from a larger secondary feed tank or where relevant, directly from a bioreactor. Batch process is preferred where dedicated equipment is used for a particular product-line. Where the same ultrafiltration equipment is used for multiple product-lines, fed-batch process is preferred since the membrane filtration setup can be mounted on a skid and can be moved around in the manufacturing plant. This provides operational flexibility and versatility. However, the efficiency of membrane usage is lower since the exposure of the membrane to material is greater when compared with the batch mode. Where continuous protein concentration is required, a continuous process can be carried out using the multistep setup shown in Figure 18.12. A single step setup would generally give very low degrees of continuous concentration. A partial recycle process (see Figure 18.13) could achieve reasonable good concentration factors since a certain proportion of the concentrated retentate is directly taken through a recycle line to the feed stream, thus effectively avoiding dilution in the feed tank.

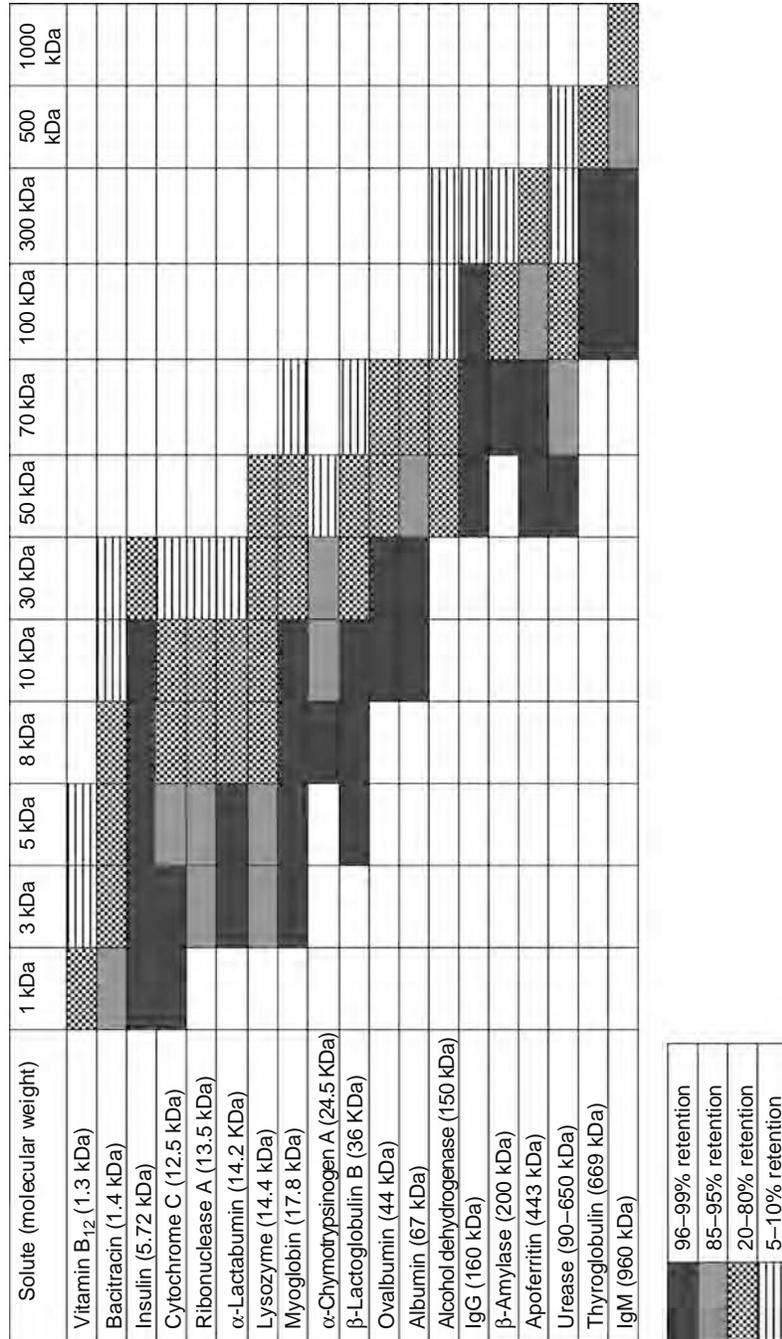

## 18.6 DESALTING

Desalting refers to the removal of low-molecular weight solutes (e.g., salts and peptide fragments) from protein solutions. This is an example of diafiltration and is achieved using an ultrafiltration membrane that retains the protein while allowing the low-molecular weight substance to pass. The macromolecular retention should be in excess of 98%. The principle of desalting is shown in Figure 18.14. Buffer exchange, which is operationally similar to desalting involves the gradual replacement of one buffer by another. Solute selectivity is mostly not a major issue in desalting on account of the significant differences in solute size. However, when low-molecular weight substances interact with proteins, obtaining good selectivity could be challenging. One of the main objectives in a desalting process is to achieve and sustain a high permeate flux. In a desalting process, it might sometimes be desirable to dilute the feed to enhance the permeate flux. Some of the major applications of desalting are listed below [2]:

1. Removal of salts used for precipitation from protein solutions
2. Removal of solvents used for precipitation from protein solutions
3. Removal of peptide fragments from protein solutions
4. Buffer exchange before and after chromatographic separation
5. Removal of toxic metabolites from blood
6. Formulation of therapeutic proteins in solutions
7. Removal of inhibitors from enzyme solutions
8. Protein refolding

Desalting is mostly carried out while keeping the feed volume constant, i.e., by replenishing the liquid lost in the filtrate. Therefore the protein concentration in the feed is also maintained constant. Exceptions are where simultaneous concentration and desalting are carried out.

Industrial-scale desalting processes are carried in the cross-flow mode at constant TMP. A wider variety of membrane modules than in concentration can be used for desalting. This includes flag sheet TF flow, hollow fiber, spiral wound, and tubular modules. A batch process (see Figure 18.15) is most commonly used for desalting. The feed solution is pumped into an ultrafiltration module and the retentate is sent back to the feed tank. The feed volume is usually maintained constant by continuous addition of fresh solvent. In a batch process the concentration of permeable species decreases with time while the concentration of the retained species remains unchanged. This is due to continuous replenishment of liquid by addition into the feed tank. In some separation processes, intermittent replenishment of solvent is preferred to continuous replenishment. Multiple stages are commonly used for continuous desalting (Figure 18.16).

## 18.7 CLARIFICATION

Clarification refers to the removal of particulate matter from protein solutions. In addition to efficient removal of particulate matter, high-protein transmission through the membrane is desirable. Microfiltration membranes are more widely used for clarification. However, in applications such as virus removal from biopharmaceutical solutions ultrafiltration is increasingly preferred on account of the higher efficiency and reliability of particulate retention. Some of the common applications of clarification are listed below [2]:

1. Sterile filtration of biopharmaceutical solutions
2. Sterile filtration of therapeutic products prior to injection
3. Removal of cell debris
4. Cell harvesting
5. Continuous recovery of products from bioreactor

High-macromolecular transmission through membrane is desirable in clarification. This depends on operating and physico-chemical parameters such as solution pH and ionic strength. These have to be taken into consideration when selecting a membrane and operating conditions for a particular application. Ultrafiltration is mainly used for virus removal from protein solutions. As long as satisfactory virus removal can be ensured, less than 100% protein transmission through the membrane is tolerated as an identified trade-off. Virus particles are removed by geometric exclusion, i.e., by sieving mechanism. The efficiency of virus removal is expressed in terms of the log removal value (LRV):

$$\text{LRV} = \log \left( \frac{N_F}{N_P} \right) \quad (18.10)$$

where

$N_F$  is the number of virus particles per unit volume of feed

$N_P$  is the number of virus particles per unit volume of permeate

Membrane modules suitable for clarification should have low feed hold-up. Stirred cell- and cartridge-type ultrafiltration modules are widely used. These are operated in a dead-end mode. Figure 18.17 shows the setup used for dead-end clarification. If protein is freely transmitted through the membrane, the dead-end mode gives high recovery and is hence preferred. However, if the protein is partially retained, the dead-end mode gives rise to severe concentration polarization and fouling. In such cases tubular and hollow fiber ultrafiltration modules, which are operated in the cross-flow mode are preferred. Figure 18.18 shows a setup used for a cross-flow clarification.

## 18.8 FRACTIONATION

Macromolecular fractionation, which involves high-resolution separation of solutes having comparable molecular weights using ultrafiltration, is challenging primarily due to the broad pore-size distribution of ultrafiltration membranes. This implies that purely size-based fractionation is not feasible using membranes currently available. The development of advanced membranes with narrow pore-size distributions could make fractionation more feasible. With currently available membranes

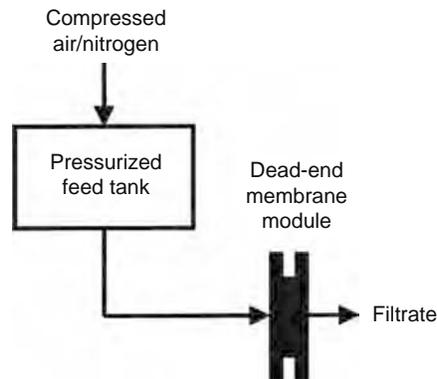

FIGURE 18.17 Dead-end clarification.

other factors such as membrane modification, solute–solute interactions, and solute-membrane interactions have to be utilized for macromolecular fractionation.

The use of ultrafiltration for macromolecular fractionation is not an established operation in the industry. This field is still a domain for fundamental and applied research [15–20]. Some of the projected applications are listed as follows:

1. Fractionation of plasma proteins
2. Purification of monoclonal antibodies
3. Fractionation of whey proteins
4. Fractionation of egg proteins
5. Separation of antivenins

The main challenges that need to be addressed for these applications are

1. Development of better membranes and membrane modification methods
2. Control of concentration polarization
3. Control of membrane fouling
4. Understanding the role of operating and physicochemical parameters on protein transport through ultrafiltration membranes
5. Understanding the role of protein–protein interactions in ultrafiltration
6. Development of processes specifically targeted at macromolecular fractionation

Development of new ultrafiltration membranes is focused on improving permeate, reducing membrane fouling, and increasing selectivity of separation. Increasing permeate flux can be achieved by developing hydrophilic membranes with higher porosities. Hydrophilic membranes inherently foul less. However, for a given membrane fouling increases with increase in permeate flux. Fouling affects both productivity and product quality. Even moderately high permeate fluxes in ultrafiltration give significantly higher productivities than competing separation techniques. Therefore where fouling can become a limiting

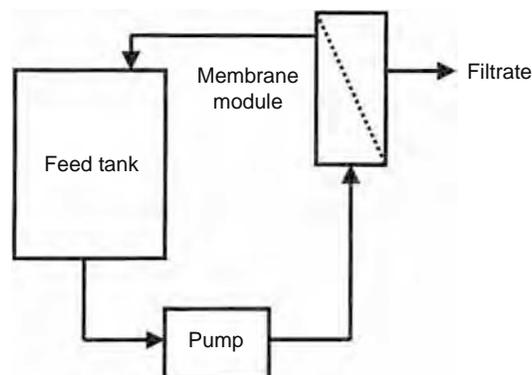

FIGURE 18.18 Cross-flow clarification.

factor a sensible approach is to lower the TMP and hence the flux, thereby reducing membrane fouling. In most ultrafiltration processes, an identifiable flux value exists, below which fouling is negligible, this being referred to as the critical flux [21]. Protein fractionation processes should ideally be carried out at subcritical fluxes. Concentration polarization is recognized as a limiting factor in fractionation processes. Fractionation processes should be carried out under conditions of low concentration polarization. Membrane fouling can also be minimized by reducing concentration polarization.

The transport of proteins is affected by a range of operating and physicochemical parameters such as TMP, feed flow rate, permeate flux, feed solution pH, and ionic strength. These parameters affect the way in which the proteins pass through the membrane, interact with the membrane, and interact among each other. Understanding these intricacies is the key to the development of efficient macromolecular fractionation processes. Development of processes specifically designed for fractionation processes is of equal importance. Currently used membrane processes are focused around concentration and desalting and hence are not suitable for macromolecular fractionation. Development of cascade-type separation processes would lead to more efficient membrane utilization [22].

## 18.9 CONCLUSIONS

The role of bioseparation in biological manufacturing is increasingly becoming important. Ultrafiltration offers an exciting prospect in the area of bioseparations engineering. The main advantages of using ultrafiltration are high productivity, ease of scale-up, and easy device sanitization and cleaning. The use of ultrafiltration in high-productivity, low-resolution operations such as concentration, desalting, and clarification is well established. However, its usage for high-resolution macromolecular fractionation can only be brought about by the development of better membranes, better understanding of membrane transport mechanisms, and better membrane processes.

## 19.1 INTRODUCTION

The origin of the term membrane distillation (MD) lies in the essential similarity between the conventional process of distillation and its membrane variant. Both processes depend upon the vapor–liquid equilibrium as a means of phase separation, where the latent heat of evaporation drives the change in phase from liquid to vapor.

Hitherto the commercial use of membranes in food processing was restricted to conventional processes such as micro-filtration, ultrafiltration, nanofiltration, reverse osmosis (RO), gas permeation, and electro dialysis. These unit operations include solid–liquid separation, concentration (dewatering), gassing/degassing, desalting, and deacidification. Membrane distillation (MD) as a concept was first described in a US patent in the early 1960s for making potable water [1]. However, its merits were progressively realized for wide range of application such as desalination of water [2,3]; treatment of oily feeds [4,5], humic acid [6], and solvents [7,8]; concentration of liquid foods [9], sugar solutions [10,11], and beverages [12,13]; and the recovery of products of fermentation [14], mineral acids [15,16], and aromas and fragrances [17].

The advantages of membrane distillation are associated with relatively lower energy costs as compared to competing processes such as distillation, reverse osmosis, and pervaporation (PV); much lower membrane fouling as compared with microfiltration (MF), ultrafiltration, and RO; a quantitative rejection of nonvolatile solutes from the feed stream; lower operating pressure and temperatures, without sacrificing flux as compared with competing processes.

Advances in preparation and modification of membranes used in membrane distillation and their configurations have been covered in a recent review by Curcio and Drioli [18] and it is evident that R&D efforts are largely concentrated on making improvements in these areas.

Concentration and dewatering of liquids are one of the key unit operations encountered in food processing, particularly in the processing of beverages, fruit juice, milk, whey, vegetable extracts, etc. In such unit operations, solid contents are generally increased from an initial value of 10%–12% to a final value of 65%–75% by weight [19]. This concentration step is aimed at lowering storage, packaging, and transport costs. It also helps, to a limited extent, in preventing microbial spoilage of these concentrates.

Today, multistage vacuum evaporation is the predominant method used for liquid food concentration. Its major drawback is that it causes heat-induced deterioration of sensory (color, taste, and aroma) and nutritional (vitamins, etc.) value of the finished product. The food industry has developed alternate methods, such as freeze concentration and thermally accelerated short time evaporation (TASTE) [20] for recovery and blending of such labile constituents for producing concentrates. Though they are currently practiced commercially, the final products in some cases do not satisfy the consumer requirement of their fresh or natural qualities. Some of these processes are energy intensive and therefore unattractive.

Membrane processes, in general, are very attractive for their simplicity and flexibility. They are capable of achieving separations at a molecular level. Membrane modules are often compact and easily scaleable. For clarification and concentration, microfiltration, ultrafiltration, and reverse osmosis are the current methods of choice. RO has been widely used in the food industries as an attractive alternative to classical evaporation; the only limitation being its dependence on osmotic pressure, which practically limits concentration of fluid streams to 25°Bx–30°Bx. Hence, currently it is used more as a preconcentration step. In recent years, membrane processes, notably pervaporation, membrane distillation and osmotic membrane distillation (OMD) [21], have been used either by themselves or in combination with other membrane processes to overcome the problems associated with thermal processes.

## 19.2 HISTORICAL BACKGROUND

Bodell [1] was the first to describe membrane distillation when he was granted a patent on an apparatus and methods for converting nonpotable aqueous fluids to potable water, where vapor and not liquid was permeable through a membrane. He also suggested the use of vacuum for recovery of permeate vapor. However, he did not describe the geometry, the structure of the membrane, and could not quantify his results. In 1967, Weyl [22] employed an air-filled porous hydrophobic membrane for improving the efficiency of desalination. Weyl also proposed a method for placing the hot feed and cold permeate solutions in direct contact with the membrane, thereby eliminating the macroscopic air gap found in other devices of that time. He reported fluxes up to  $1 \text{ kg m}^{-2} \text{ h}^{-1}$  using polytetrafluoroethylene (PTFE) membrane of 3.2 mm thickness with a pore size of 9  $\mu\text{m}$  and porosity of ~42%. In the late 1960s, Findley [23] was the first to publish the basic theory and results of direct contact membrane distillation (DCMD), which were performed using membranes of different materials treated either with silicone or PTFE to achieve the required hydrophobicity. Although, the equipment and experimental procedures used by Findley were rudimentary, he was able to quantify the effects of air trapped in the membrane pores, membrane thickness and porosity, and heat loss by conduction. After the work on desalination of seawater by Findley et al. [24–26] no further development took place till the 1980s. In 1982, Gore proposed a spiral-type module using a Gore-Tex membrane [27], which he called Gore-Tex Membrane Distillation. In 1983, the Swedish Development Co. (Svenska Utvecklings AB) reported similar test results using a plate and frame module. In 1984, Enka AG presented a transmembrane distillation module using hollow fibers, at the Europe–Japan Joint Congress on Membranes and Membrane Processes. At the second world congress on desalination and water reuse in 1985, papers presented on MD [28–31] led to a renewed interest in the subject and facilitated the development of various hydrophobic membranes (polypropylene, polytetrafluoroethylene) with porosities as high as 80% and membrane thickness as low as 50  $\mu\text{m}$ . Subsequently, work by Schofield et al. [32–35] contributed to a better understanding of temperature and concentration polarization, and their effect on membrane distillation.

In the late 1980s, it was observed that the same membranes that had been used in thermal membrane distillation could be used in a concentration-driven process called OMD [36]. Both these processes show great similarity in employing hydrophobic membranes, where a liquid–vapor interface is formed on both sides of the membrane pores. The source for the driving force (vapor pressure difference) is different in both cases. It is a temperature difference in the case of thermal membrane distillation, while it is a concentration difference in the case of OMD [37].

The OMD process can be included in the group of processes under membrane distillation [38], because it meets the terminology for membrane distillation that was decided by the expert committee at the workshop on “membrane distillation in Rome in 1986” [39]. Membranes used in MD need to satisfy certain conditions: For example, the membrane should be porous and should not be wetted by the process liquids; no capillary condensation should take place inside the pores of the membrane; the membrane must not alter the vapor–liquid equilibrium of the different components in the process liquids; at least one side of the membrane should be in direct contact with the process liquid; for each component the driving force of this membrane operation is partial pressure gradient in vapor phase.

Therefore, in this chapter OMD will be considered as a part of membrane distillation. The composition of the gas phase above the liquid surface is often expressed by partial pressure and the difference in partial pressure is therefore accepted as a driving force for the MD process [38–43]. The magnitude of this driving force depends on the solution temperature and composition of the layers adjacent to the membrane surface.

The main advantages of the membrane distillation process over conventional distillation are the configuration of the evaporation surface can be made into various membrane modules with a compact area density, mist can be eliminated, and highly pure water can be obtained as product; corrosion may be less than that with metal surfaces.

Considering these merits, the fundamental characteristics of the membrane distillation process have been studied, and progressively, articles by various researchers [32,33,36–39,41,43,44] have provided insights into various process aspects.

### 19.3 MEMBRANE DISTILLATION

Membrane distillation is a relatively new process in which a microporous hydrophobic membrane separates two aqueous solutions or a solution and gas, either at different temperatures or at different compositions. Because of the vapor pressure difference, water evaporates on one surface of the membrane and passes through the membrane in the form of vapor and gets condensed on the other side of membrane, resulting in the concentration of feed and dilution of permeate solutions. In membrane distillation one side (usually the feed side) of the membrane is always in contact with an aqueous solution. The other side (i.e., the permeate side) may be brought into contact with different phases: For example (1) with an aqueous solution, giving rise to the configuration called DCMD; (2) with a sweeping gas, in which case the process is termed sweeping gas membrane distillation (SGMD); (3) with a stagnant air gap plus a cold plate called air gap membrane distillation (AGMD); (4) with a vacuum and the process is called vacuum membrane distillation (VMD); and (5) with an osmotic solution where the process is termed OMD. While the first four processes are non-isothermal, the last process is isothermal. More details of these processes are discussed in the following sections.

#### 19.3.1 DIRECT CONTACT MEMBRANE DISTILLATION

Direct contact membrane distillation is a form of membrane distillation in which both the heated feed (liquid) and cold permeate (liquid) are kept in contact with porous hydrophobic membrane (Figure 19.1). In the absence of hydrostatic pressure difference, liquid–vapor interfaces are formed at the entrance of each membrane pore, and a vapor pressure difference is maintained on both sides of the membrane by applying a temperature difference. Water molecules evaporate from the hot liquid–vapor interface, diffuses through the membrane in the form of vapor, and get condensed on the permeate liquid–vapor interface kept at

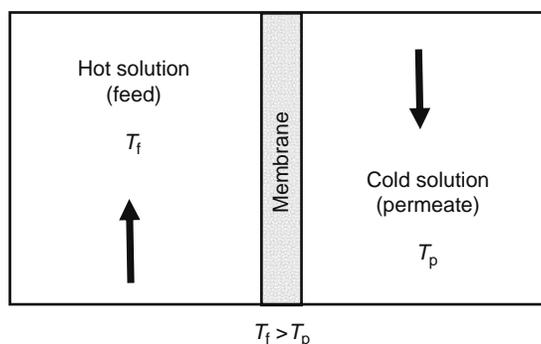

FIGURE 19.1 Schematic representation of DCMD.

lower temperature. Hence the DCMD process takes place at atmospheric pressure and at temperatures much lower than the normal boiling point of the feed solution, thus it can be used for concentration of temperature insensitive liquids, such as liquid foods. Most MD processes are carried out in the form of DCMD, which is easy to operate, consumes relatively low energy, and gives high water permeate flux. It is commonly applied for situations where water is the major fluxing component [39,45,46], such as desalination or the concentration of aqueous solutions. Desalination by DCMD has exhibited fluxes as high as  $75 \text{ kg m}^{-2} \text{ h}^{-1}$  [22], which are comparable with the fluxes typically observed in RO. Additionally, salt rejections of nearly 100% have been observed in DCMD desalination, which cannot be accomplished with RO (at high fluxes) [47].

### 19.3.1.1 Heat and Mass Transfer

Heat and mass transfer takes place simultaneously in DCMD. The mass and heat transport can be described by three steps, namely transport through boundary layer on the feed side, transport through membrane, and transport through boundary layer on the permeate side.

The mass transfer in the boundary layers can be described by a mass transfer coefficient. In the membrane phase, the diffusion of water vapor can be described by either of the four mechanisms, namely molecular/Knudsen diffusion model, or Poiseuille flow, or by the dusty gas model (DGM). Heat transfer coefficients are used to describe the heat transfer in the boundary layer on either side of the membrane. In the membrane heat transfer occurs through the vapor and by conduction. These aspects have been explained in detail in the following sections.

#### 19.3.1.1.1 Heat Transfer

The modes of heat transfer and the possible heat transfer resistances in membrane and the corresponding boundary layers of DCMD are shown in Figure 19.2. The basic equation for the total heat transferred due to the difference in temperatures of the feed ( $T_f$ ) and permeates ( $T_p$ ) is given by

$$Q = H(T_f - T_p) = H\Delta T_f \quad (19.1)$$

where  $H$  is the overall heat transfer coefficient that accounts for all the three resistances for water transport and is given by

$$H = \left[ \frac{1}{h_f} + \frac{1}{\frac{k_m}{\delta} + h_v} + \frac{1}{h_p} \right]^{-1} \quad (19.2)$$

where

$h_f$  and  $h_p$  are the heat transfer coefficients in feed and permeate layers, respectively

$k_m$  is the membrane conductivity

$\delta$  is the membrane thickness

$h_v$  is the vapor heat transfer coefficient

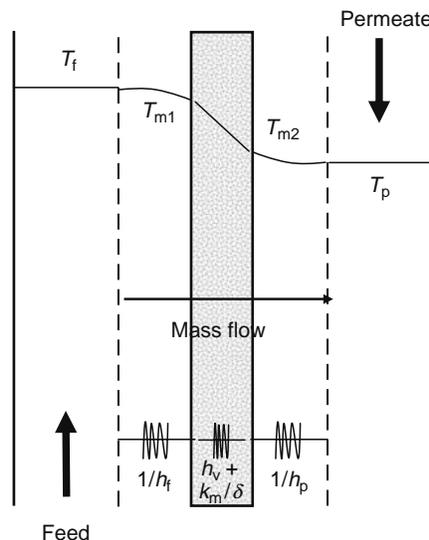

FIGURE 19.2 Heat transfer resistances in DCMD.

### 19.3.1.1.1.1 Heat Transfer through the Membrane

Heat transfer through the membrane occurs by two mechanisms, first, by latent heat through the vapor, and second, by sensible heat conduction across the membrane material.

The latent heat flux for dilute solutions is given by [34]

$$Q_v = J\Delta H_v = h_v\Delta T_m \quad (19.3)$$

The conductive heat flux is given by [32]

$$Q_c = \left(\frac{k_m}{\delta}\right)(T_{m1} - T_{m2}) \quad (19.4)$$

The membrane conductivity  $k_m$  in Equation 19.4 can be estimated using the following three models [48]:

*isostrain or parallel model*

$$k_m = (1 - \varepsilon)k_s + k_g \varepsilon \quad (19.5)$$

*isostress or series model*

$$k_m = \left[\frac{\varepsilon}{k_g} + \frac{(1 - \varepsilon)}{k_s}\right]^{-1} \quad (19.6)$$

and *flux law model*

$$k_m = k_g \left[\frac{1 + (1 - \varepsilon)\beta_{s-g}}{1 - (1 - \varepsilon)\beta_{s-g}}\right] \quad (19.7)$$

where

$$\beta_{s-g} = \frac{\frac{k_s}{k_g} - 1}{\frac{k_s}{k_g} + 2} \quad (19.8)$$

Equation 19.5 is often utilized in MD, while Equations 19.6 and 19.7 are the alternate expressions to calculate the membrane thermal conductivity, where  $\varepsilon$  is the porosity,  $k_s$  and  $k_g$  are thermal conductivities for solid (polymer) and gases in the pores (air and water vapor), respectively. The values of thermal conductivity of polyvinylidenedifluoride (PVDF), Polytetrafluoroethylene (PTFE), and Polypropylene (PP) have been reported in a narrow range 0.17–0.29 W m<sup>-1</sup> K<sup>-1</sup> [48]. The thermal conductivities of air are in the range of 0.026–0.03 W m<sup>-1</sup> K<sup>-1</sup> and that of water vapor in the range 0.020–0.022 W m<sup>-1</sup> K<sup>-1</sup>. Since there is a very small difference between the thermal conductivities of vapor and air, it is possible to assume that the gases in the pores behave as one component.

From Equations 19.3 and 19.4, the total heat transfer across the membrane ( $Q_m$ ) can be written as

$$\begin{aligned} Q_m &= Q_v + Q_c \\ &= \left(h_v + \frac{k_m}{\delta}\right)\Delta T_m \end{aligned} \quad (19.9)$$

Heat transfer through the membrane pores by convection can also be considered. It is the ratio of convective to conductive heat transfer rates within the membrane pores and is given by the Peclet number,  $Pe$  [39]

$$\begin{aligned} Pe &= Re \cdot Pr \\ &= \frac{NC_p}{h_m} \end{aligned} \quad (19.10)$$

where

$N$  is the molar flux

$C_p$  is the molar heat capacity of the vapor

Studies of Schofield [49] and Gostoli [50] showed that, the heat transfer by convection accounts for only 0.6% of the total heat transferred across the membrane and at most 6% of the total heat lost by dissipation in the membrane. So heat transfer by convection is very small as compared to that of conduction and could be neglected.

#### 19.3.1.1.1.2 Heat Transfer through Boundary Layers

Heat transfer across the boundary layers is often the rate-limiting step for mass transfer, because a large quantity of heat must be supplied to the surface of the membrane to vaporize the liquid.

The rate of heat transfer through the feed boundary layer can be given as

$$Q_f = h_f(T_f - T_{m1}) \quad (19.11)$$

The rate of heat transfer through the permeate boundary layer can be calculated using

$$Q_p = h_p(T_{m2} - T_p) \quad (19.12)$$

where  $h_f$  and  $h_p$  are the heat transfer coefficients through the feed and permeate boundary layers, respectively, and can be estimated using empirical equations. Empirical correlations are readily available to estimate the heat transfer coefficients for different geometries and heat transfer mechanisms, and some of these correlations used in the literature are discussed here [51–53].

#### 19.3.1.1.1.3 Heat Transfer Correlations for Turbulent Flow

For fully developed turbulent flow in smooth tubes, Dittus and Boelter have recommended the following relation:

$$\frac{hd}{k_1} = 0.023 \left( \frac{dG}{\mu} \right)^{0.8} \left( \frac{C_p \mu}{k_1} \right)^n \quad (19.13)$$

where

$d$  is the tube diameter

$k_1$  is the thermal conductivity of the liquid

$G$  is the mass velocity

$\mu$  is the bulk liquid viscosity

$C_p$  is the liquid heat capacity

$n$  takes the values of 0.4 and 0.3, for heating and cooling of the fluid

Equation 19.13 is valid for the boundary conditions of  $10^4 < Re < 12 \times 10^4$ ,  $0.7 < Pr < 120$  and  $L/d > 60$  ( $L$  is the tube length). The use of this equation is limited to cases where the difference in tube surface temperature and the bulk fluid temperature is more than 5.5°C for liquids and 55°C for gases. Equations listed in Table 19.1 can be used as an alternative to the Equation 19.13 depending upon hydrodynamic conditions.

**TABLE 19.1**  
**List of Equations Used in MD at Different Hydrodynamic Conditions**

Sl. No	Flow Regime	Equations	Reference
1	Turbulent	$\frac{hd}{k_1} = 0.023 \left( \frac{dG}{\mu} \right)^{0.8} \left( \frac{C_p \mu}{k_1} \right)^n \left( \frac{\mu}{\mu_w} \right)^{0.14}$ (19.14) <sup>a</sup>	[51]
2	Turbulent	$\frac{h}{h_\infty} = 1 + \left( \frac{d}{L} \right)^{0.7}$ or $\frac{h}{h_\infty} = 1.33 \left( \frac{d}{L} \right)^{0.055}$ (19.15) <sup>b</sup>	[51]
3	Laminar	$\left( \frac{hd}{k} \right) = 3.66 + \frac{0.067 G_z}{1 + 0.04 G_z^{2/3}}$ , $G_z = \frac{mC_p}{k_1 L}$ (19.16)	[55,56]
4	Laminar	$h_f = 1.86 K \left( \frac{RePr}{d_h^2 L} \right)^{0.33}$ (19.17)	[58]
5	Transition	$h_f = 0.116 k (Re^{0.66} - 125) Pr^{0.33} \left[ \frac{1 + (d_h/L)^{0.66}}{d_h} \right]$ (19.18)	[58]
6	—	$h_a = 0.206 \left( \frac{k}{d_h} \right) (Re \cos \alpha)^{0.63} Pr^{0.36}$ (19.19) <sup>c</sup>	[58]

<sup>a</sup> Valid at higher Prandtl numbers ( $0.7 < Pr < 16,700$ ) and  $L/d > 60$ .

<sup>b</sup> For short tube  $L/d < 50$ .

<sup>c</sup> To determine the heat transfer coefficient in the permeate side  $h_a$  in Equation 19.58.

These correlations can also be used for noncircular geometry by substituting the equivalent diameter of the flow channel, for example,

$$d_e = 4r_H = 4 \frac{S}{L_p} \quad (19.20)$$

where

$r_H$  is the hydraulic radius

$S$  is the cross-sectional area of the flow channel

$L_p$  is the length of the wetted perimeter of the flow channel

$d_e = d$ , for circular flow channels,  $d_e = 2l$ , for parallel plates separated by a distance  $l$ , and  $d_e = l$ , for a square channel of side  $l$

#### 19.3.1.1.1.4 Heat Transfer Correlations for Laminar Flow

For laminar liquid flow in circular tubes with constant wall temperature, Sieder and Tate have recommended Equation 19.21 [51,53]

$$\frac{hd}{k_1} = 1.86 \left( Re \cdot Pr \cdot \frac{d}{L} \right)^{\frac{1}{3}} \left( \frac{\mu}{\mu_w} \right)^{0.14} \quad (19.21)$$

Knudsen and Katz [54] have shown that it is valid for  $Re \cdot Pr \cdot d/2 > 10$ . Equation 19.21 cannot be used for long tubes, since it would yield zero heat transfer coefficient. Sarti et al. have employed a different Equation 19.16 to estimate the heat transfer coefficient for laminar flow in circular tubes (shown in Table 19.1).

Recently, Phattaranawik et al. [48] have used several equations to estimate the heat transfer coefficient in laminar and turbulent flow regimes. They found that Equation 19.22 is the most suitable for laminar flow, while the Dittus–Boelter equation was most suitable for turbulent conditions.

$$Nu = 4.36 + \frac{0.036 Re Pr \left(\frac{d}{L}\right)}{1 + 0.0011 \left(Re Pr \left(\frac{d}{L}\right)\right)^{0.8}} \quad (19.22)$$

#### 19.3.1.1.2 Mass Transfer

##### 19.3.1.1.2.1 Mass Transfer through the Membrane

Resistance to mass transfer comes both from the membrane structure and the air present within the membrane pores. The resistance by the membrane structure (in the absence of air) can be described by Poiseuille flow. In presence of air within the membrane pores either Knudsen diffusion or molecular diffusion, or a combined Knudsen–molecular diffusion flow model can be used.

The correct choice of model requires some knowledge of the membrane morphology, which is scant in the literature. This problem has been extensively discussed in the literature [32–34,39,57]. A few of these models, which were originally developed for mass transfer through the porous media, have been adopted for MD.

The mass flux may be written as a linear function of the vapor pressure difference across the membrane (Figure 19.3) and is given by

$$J_m = K_m(p_{m1} - p_{m2}) \quad (19.23)$$

where

$J_m$  is the mass flux

$p_{m1}, p_{m2}$  are the partial pressures of vapor (water) at the membrane surfaces on the feed and permeate sides, respectively

$K_m$  is the membrane coefficient that is a function of membrane properties (pore size, thickness, porosity, and tortuosity), properties of the vapor transported across the membrane (molecular weight and diffusivity) and temperature gradient

Any study that relates to the transport of vapor or gas through microporous structure begins with a comparison of the mean free path of the gas ( $\lambda$ ) and the mean pore size of the structure ( $d_p$ ) (shown in Figure 19.4). In general, the Knudsen number ( $Kn$ ) is used to determine the diffusion mechanisms across the pores of the membrane [41], which is defined as

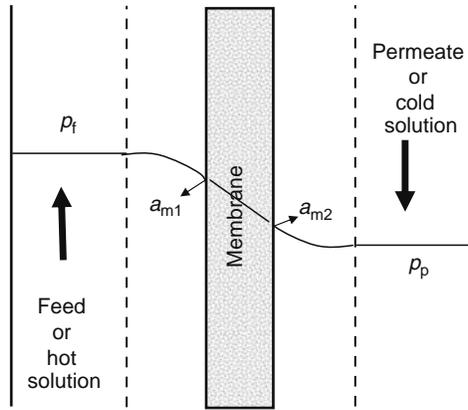

FIGURE 19.3 Water activity profile in MD.

$$Kn = \frac{\lambda}{2r} \tag{19.24}$$

where

$r$  is the pore radius

$\lambda$  is the mean molecular free path defined as the average distance the molecule travels between successive collisions

The value of  $\lambda$  can be calculated using Equation 19.25:

$$\lambda = \frac{k_B T}{P \sqrt{2} \pi \sigma^2} \tag{19.25}$$

where

$k_B$  is the Boltzmann constant

$\sigma$  is the collision diameter of the molecule, for saturated water ( $\sigma = 2.7 \text{ \AA}$ ) at  $60^\circ\text{C}$  and  $20 \text{ kPa}$ , the mean free path is  $0.7 \text{ }\mu\text{m}$  [39] and is a function of temperature ( $T$ ), pressure ( $P$ ), and mean collision diameter of the molecule.

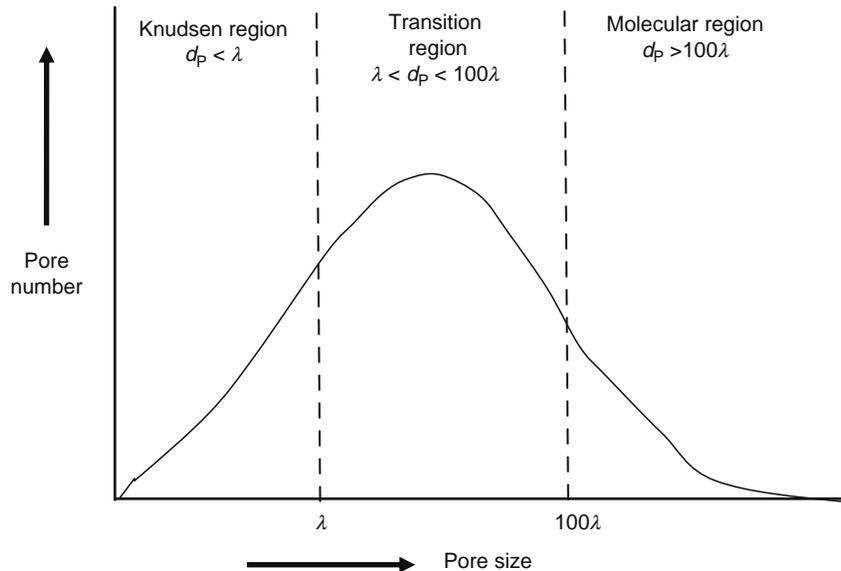

FIGURE 19.4 Regions of gas diffusion.

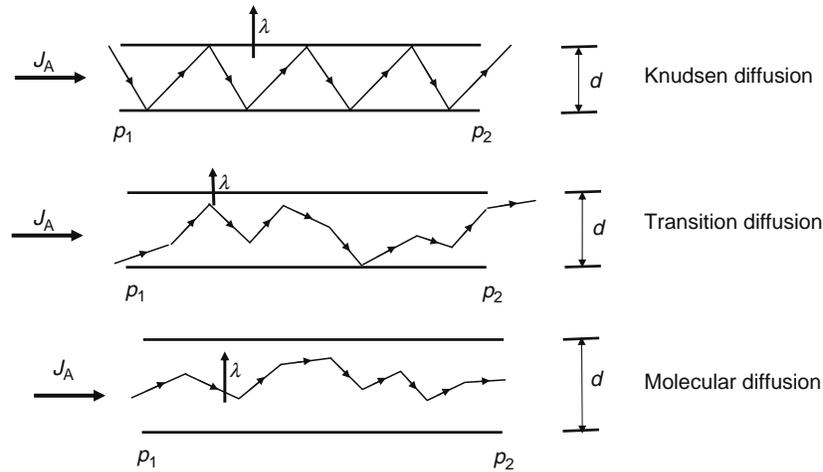

FIGURE 19.5 Types of diffusions of water vapor in a membrane pore.

If the mean free path of the water molecules is much greater than the pore size of the membrane ( $\lambda \gg d_p$ ,  $Kn \geq 10$ ), then the molecules will collide with pore walls and the transport mechanism follows Knudsen diffusion as shown in Figure 19.5. In this case, the membrane coefficient is calculated using Equation 19.26 [32]

$$K_m = 1.064 \frac{r\varepsilon}{\tau\delta} \left( \frac{M}{RT} \right)^{0.5} \quad (19.26)$$

where

- $\varepsilon$  is the fractional void volume
- $\delta$  is the membrane thickness
- $\tau$  is the tortuosity
- $R$  is the gas constant
- $M$  is the molecular mass of water
- $T$  is the absolute temperature

If the resistance caused by the stagnant air is trapped within the membrane pores, for flow of water vapor, the mechanism is called molecular diffusion and the membrane coefficient is expressed as [34]

$$K_m = \frac{1}{Y_{ln}} \frac{D\varepsilon}{\tau\delta} \frac{M}{RT} \quad (19.27)$$

where

- $D$  is the diffusion coefficient
- $Y_{ln}$  is the mole fraction of air (log mean)

It may be noted that in this model the air entrapped in the pore is regarded simply as a motionless medium in which the vapor molecules diffuse. Furthermore, the interaction between the vapor molecules and the membrane pores is not taken into account [57]. However, it is clear that the vapor transport will also be limited by the membrane structure itself that has been indicated in Equation 19.26. If  $Kn$  is between the two limits  $\lambda \ll d_p \ll 100\lambda$ ,  $0.01 \leq Kn \leq 10$ , then both the mechanisms will coexist whereby both molecule–molecule collisions as well as molecule–wall collisions take place. Such a mechanism in this transition region is called the Knudsen molecular diffusion and the following relationship (Equation 19.28) could be used for estimating the membrane coefficient [58].

$$K_m = \frac{M}{RT\delta} \left[ \frac{3\tau}{4\varepsilon r} \left( \frac{\pi M}{2RT} \right)^{0.5} + \frac{\tau PD}{\varepsilon p_a} \right]^{-1} \quad (19.28)$$

If the mean free path of the gas (vapor) is much lower than the pore size ( $\lambda \ll d_p$ ,  $Kn \leq 0.01$ ) then molecules will collide with one another, while permeating through the pore (Figure 19.5), and the mechanism is called viscous or Poiseuille flow. Equation 19.29, which is used for estimating the membrane coefficient is given by

$$K_m = 0.125 \frac{r^2 \varepsilon}{\delta \tau} \frac{MP_{\text{avg}}}{\mu RT} \quad (19.29)$$

where

$\mu$  is the water viscosity

$P_{\text{avg}}$  is the average gas pressure inside the membrane

Similarly, the membrane coefficient to describe the transition region between molecular/Knudsen diffusion and Poiseuille flow can be written as [33]

$$K_m = a\delta[1 + b(P_r - 1)] \quad (19.30)$$

and

$$a = mv(A + BP_{\text{ref}}/L) \frac{1}{\delta} \quad (19.31)$$

$$b = \frac{(BP_{\text{ref}}/L)}{(A + BP_{\text{ref}}/L)} \quad (19.32)$$

where

$a$  is the membrane permeation constant

$b$  is 0 for Knudsen diffusion and 1 for Poiseuille flow

$A = 2r\varepsilon/3\tau RT$ ,  $B = \pi r^2 \varepsilon/32\tau RT$ , and  $v = (8RT/\pi M)^{0.5}$  are the gas mean molecular speed

$L$  is the mean free path at unit pressure

The membrane constant  $a$  is the permeability divided by the membrane thickness evaluated at the reference pressure. The physical significance of  $a$  is that it represents the proportionality constant between flux and pressure drop at the reference pressure. The parameter  $b$  indicates the extent to which Poiseuille flow contributes to the permeability and lies between 0 and 1. Equation 19.30 is known as Knudsen–Poiseuille model, where  $P_r$  is the dimensionless pressure defined as  $P_{\text{avg}}/P_{\text{ref}}$ , the  $P_{\text{ref}}$  is chosen in such a way that  $P_r$  becomes close to unity for the range of application of the equation. If a different pressure is assumed, Equation 19.30 may be modified retaining its original form, but having different values for the parameters  $a^*$  and  $b^*$  with the reference pressure as a new  $P_r^*$  close to unity. In such a case the new parameters  $a^*$  and  $b^*$  can be written as [59]

$$a^* = a \left[ (1 - b) + b \frac{P_{\text{ref}}^*}{P_{\text{ref}}} \right] \quad (19.33)$$

$$b^* = \frac{b(P_{\text{ref}}^*/P_{\text{ref}})}{1 - b + b(P_{\text{ref}}^*/P_{\text{ref}})} \quad (19.34)$$

Equations 19.33 and 19.34 can be employed over a range of pressure using gas permeation data obtained in a different reference pressure.

The mass transport through the membrane can also be described by assuming that the overall membrane resistance is equal to the membrane resistance plus the molecular resistance, where the Knudsen–Poiseuille transition model (Equation 19.30) is coupled with an expression for the resistance due to entrapped air (Equation 19.27), in such case the membrane coefficient can be written as [34,59]

$$K_m = \left[ \frac{1}{a(1 - b) + ab \left( \frac{P_{\text{avg}}}{P_{\text{ref}}} \right)} + \frac{P_{\text{am}} \tau \delta RT}{\varepsilon DPM} \right] \quad (19.35)$$

Equation 19.35 can also be used as general equation for membrane coefficient. When the feed solution is distilled water, Equation 19.35 provides a model that asymptotes to the Knudsen–Poiseuille transition flow Equation 19.30, When the

membrane is deaerated, it asymptotes to molecular diffusion through a stagnant air film Equation 19.27, where the partial pressure of air is high.

The other mechanism that rarely occurs in gas permeation is surface diffusion, where the vapor molecules (solutes) adsorb on to the surface of the pores and diffuse under a pressure gradient. This mechanism is neither likely to be dominant for noncondensable gases at low pressures and ambient temperatures, nor is it expected for water vapor permeation through hydrophobic materials [33].

The models above may be useful for predicting mass fluxes in MD; however, each of these models has its limitations. The Knudsen and Poiseuille model require knowledge of  $r$ ,  $\delta$ , and  $\varepsilon$ , which in general can be estimated by applying the models to experimental gas fluxes through the given membrane. The molecular diffusion model is inadequate at low-partial pressures of air, as it predicts infinite flux since, in totally deaerated membrane  $Y_{in}$  tends to zero.

Most of the general models for describing flux through porous media is given by the DGM. The term DGM, which was first described by Maxwell in 1860 [39], is relatively unfamiliar in the membrane separation field and has only recently been appearing in the membrane literature [33,39,41,60,61]. In this model, the porous medium is visualized as a collection of uniformly distributed dust particles, which are construed to be stationary.

The most general form of DGM applicable to MD is given by Equations 19.36 and 19.37 [39]

$$\frac{N_i^D}{D_{ie}^k} + \sum_{j=1 \neq i}^n \frac{p_j N_i^D - p_i N_j^D}{D_{ije}^o} = \frac{-1}{RT} \nabla p_i \quad (19.36)$$

$$N_i^V = \frac{-p_i B_0}{RT \mu} \nabla P \quad (19.37)$$

where

$N_i$  (total flux) =  $N_i^D + N_i^V$  (diffusive flux + viscous flux)

$P$  is the total pressure

$p_i$  is partial pressure of component  $i$

$\mu$  is the fluid viscosity

Effective diffusivities can be written as

$$D_{ie}^k = K_0 \left( \frac{8RT}{\pi M_i} \right)^{\frac{1}{2}}, \quad D_{ije}^o = K_1 P D_{ij} \quad (19.38)$$

where

$(8RT/\pi M_i)^{0.5} = v_i$  is the mean molecular speed

$D_{ij}$  is the ordinary diffusion coefficient

$M_i$  is the molecular weight of component  $i$

$K_0$ ,  $K_1$ , and  $B_0$  are the constants that are strongly dependent on membrane geometry and the interactions between membrane and molecule

These constants are best determined experimentally as the membrane structure is very complex and difficult to characterize, which makes the direct calculation impossible. However, estimates of the constants can be obtained from the membrane pore radius  $r$ , tortuosity  $\tau$ , and porosity  $\varepsilon$  by assuming that the membrane contains uniform cylindrical pores and can be given as [39,43,59]

$$K_0 = \frac{2\varepsilon r}{3\tau}, \quad K_1 = \frac{\varepsilon}{\tau}, \quad \text{and} \quad B_0 = \frac{\varepsilon r^2}{8\tau} \quad (19.39)$$

Based on the gas permeation experiments, Fernandez et al. [59] concluded that parameters  $K_0$  and  $B_0$  are independent of the gas used, and an average value of the parameters for water vapor:  $K_0 = 3.5 \times 10^{-8}$  m and  $B_0 = 2.1 \times 10^{-15}$  m<sup>2</sup> are used.

When  $\lambda < d_{\text{pore}}$ , the transport mechanism is Poiseuille (viscous) flow and the molar flux  $N_i^V$  from Equations 19.37 and 19.39 can be written as [61]

$$N_i^V = \frac{p_i r^2 \varepsilon}{8RT \mu \tau} \frac{\Delta p_i}{\delta} \quad (19.40)$$

where  $\lambda > d_{\text{pore}}$ , the transport mechanism is Knudsen flow and the molar flux  $N_i^k$  from Equation 19.37 can be given as [39,61]

$$N_i^k = \frac{D_i^k}{RT} \frac{\Delta P_i}{\delta} \quad (19.41)$$

where  $D_i^k$  is the Knudsen diffusion coefficient, which is given by

$$D_i^k = \frac{2r\varepsilon}{3\tau} \left( \frac{8RT}{\pi M_i} \right)^{0.5} \quad (19.42)$$

when  $d_{\text{pore}}$  is much larger than  $\lambda$ , and the stagnant air is trapped within the membrane pores, then the transport of vapor through the membrane is by molecular diffusion. The DGM then gives the well-known diffusion through a stagnant film equation.

$$N_i = \frac{K_1 P D_{w\text{-air}} T^{b-1}}{T^b} \frac{\Delta P_i}{R \delta} \frac{1}{P_{\text{am}}} \quad (19.43)$$

where  $P_{\text{am}}$  is the log mean of air pressures at the feed and permeate vapor–liquid interfaces. The temperature has been separated into two terms  $T^{b-1}$  and  $T^b$  and  $b = 2.334$ .

When the average membrane pore size is comparable to the molecular mean free path length ( $\lambda$ ), that is  $d_p \approx \lambda$ , the surface and molecular diffusion can be neglected and in such case the general form of DGM falls into Knudsen–Poiseuille transition region and can be written as [61]

$$N_i = \frac{1}{RT_{\text{avg}}} \left[ K_0 v \frac{\Delta p_i}{\delta} + B_0 \frac{P_{i\text{avg}}}{\mu} \frac{\Delta P}{\delta} \right] \quad (19.44)$$

where

$P$  is the total pressure

$\Delta p_i$  is the gradient in the partial pressure of  $i$ th species

$T_{\text{avg}}$  is the average temperature

Schofield [49] has shown that in DCMD applications, the net flux of air across the membrane is extremely small relative to the flux of water, and viscous flux can be neglected (unless the process solutions have been degassed). With these assumptions Equations 19.36 and 19.37 reduce to the Knudsen–molecular diffusion transition form and can be written as [43]

$$N_w = \frac{\Delta p_w}{RT\delta} \left( \frac{1}{K_0 v} + \frac{p_a}{K_1 P D_{w\text{-air}}} \right)^{-1} \quad (19.45)$$

where  $D_{w\text{-air}}$  is the ordinary water diffusion coefficient and can be calculated from Equation 19.46 [43,52]

$$P D_{w\text{-air}} = 4.46 \times 10^{-6} T^{2.334} \quad (19.46)$$

From Equations 19.37 and 19.38 another flux Equation 19.47 can be written for water vapor, where the Knudsen and molecular diffusion, and viscous flow are considered, while surface flow was neglected.

$$N = -\frac{M}{\delta} \left[ \frac{K_0 K_1 D_{wa} v}{K_1 D_{wa} + x_a K_0 v} \Delta n_w + \frac{B_0 n_w}{\mu} \left( \frac{\Delta P_T}{1 + (x_a K_0 v / K_1 D_{wa})} \right) \right] \quad (19.47)$$

where

$n_w$  is the mole concentration of water vapor

$\Delta n_w$  is the water vapor mole concentration difference across the membrane

$x_a$  is the mean mole fraction of air, and other parameters as defined earlier

Mass transfer through boundary layer is explained in Section 19.3.5.

### 19.3.1.2 Comparison of the Models

Schofield showed in his model Equation 19.30 (or Equation 19.23) that  $T \propto P\Delta P$  for viscous flux and  $J \propto \Delta P$  for Knudsen flux, and obtained a correlation  $J_m = aP_r^b \Delta P$  that approximates the Knudsen–Poiseuille transition of DGM. However, the Schofield model has the advantage that the exponent  $b$  indicates the extent of Knudsen diffusion and Poiseuille flow contributes to the permeability, while such approximations are not possible from  $K_0$  and  $B_0$  used in the DGM. Schofield tested his model on membranes having different pore sizes ranging from 0.10 to 0.45  $\mu\text{m}$  and estimated the values of  $b$  in a range of 0.1–0.6, which suggest that both the mechanisms (Knudsen and viscous) play an important role in MD flux. On the other hand, Schofield's model has two main disadvantages compared to the DGM model. One is, the components  $a$  and  $b$  are dependent upon the gas used. The other is, reference pressure  $P_{\text{ref}}$  is chosen in such a way that the dimensionless pressure becomes close to unity ( $P_r \approx 1$ ), and  $a$  is evaluated at  $P_{\text{ref}}$ , hence the parameters  $a$  and  $b$  also depend on the reference pressure chosen.

Further, Imdakm and Matsuura [61] have developed a Monte Carlo simulation model to study vapor permeation through membrane pores in association with DCMD, where a three-dimensional network of interconnected cylindrical pores with a pore size distribution represents the porous membrane. The network has 12 nodes (sites) in every direction plus boundary condition sites (feed and permeate). The pore length  $l$  is assumed to be of constant length (1.0  $\mu\text{m}$ ), however, it could have any value evaluated experimentally or theoretically [62].

The mass balance for each node of the entire network, assuming the transport of pure substance (water vapor only) can be written as [61]

$$\sum_j C_{ij} \Delta P_{ij} = 0 \quad (19.48)$$

where  $C_{ij}$  is the mass conductance coefficient in the  $ij$ th pore, for viscous flow transport  $C_{ij}$  is defined as  $C_{ijv}$

$$C_{ijv} = \frac{P_{\text{pavg}} \pi r^4}{8RT_{\text{pavg}} \mu l} \quad (19.49)$$

Similarly for Knudsen transport mechanism  $C_{ijk}$

$$C_{ijk} = \frac{-2r^3}{3l} \left( \frac{8\pi}{RT_{\text{pavg}} M_i} \right)^{0.5} \quad (19.50)$$

where

$\mu$  is the fluid viscosity

$\Delta P_{ij}$  is the pressure drop across the pore

$P_{\text{pavg}}$  and  $T_{\text{pavg}}$  are the average pore pressure and temperature, respectively

Once the pore size and length  $l$  are given to the pore network, one can calculate the effective pressure field (by using iteration method), the temperature field through the network, and its effect on the vapor flux through the membrane. This model takes into account all molecular transport mechanisms based on the kinetic gas theory for a single cylindrical tube and could be applied to all forms of membrane distillation process [61].

### 19.3.1.3 Process Parameters

The effect of parameters such as concentration, operating temperature, and flow rate on permeate flux are generally considered for the optimization of DCMD.

Permeate flux decreases with an increase in feed concentration. This phenomenon can be attributed to the reduction of the driving force due to decrease of the vapor pressure of the feed solution and exponential increase of viscosity of the feed with increasing concentration. The DCMD flux gradually increases with an increase in temperature difference between feed and cooling water. Lagana et al. [63] reported that the viscosity of apple juice at high concentration induces severe temperature polarization. It may be noted that temperature polarization is more important than concentration polarization, which is located mainly on the feed side.

In DCMD, increase in flow rate increases the permeate flux. The shear force generated at high-flow rate reduces concentration polarization. Banat [64] found that the flow rate of cooling water had minimal effect on the permeate flux. Ohta [65] has shown that an increase in coolant velocity from 0.02 to 0.08  $\text{m s}^{-1}$  resulted in 1.5-fold increase in the permeate flux. In the same study, it was found that an increase in velocity of hot feed increased the flux by twofold.

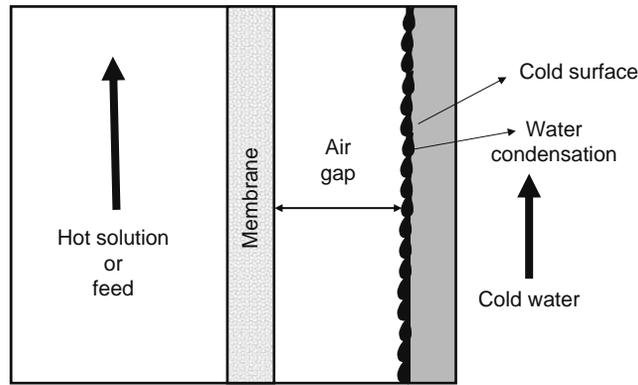

FIGURE 19.6 Schematic representation of AGMD.

### 19.3.2 AIR GAP MEMBRANE DISTILLATION

In air gap membrane distillation (AGMD), an air gap is interposed between the membrane and the condensation surface (Figure 19.6). In this configuration, water evaporates on the feed surface of the membrane, transports through the membrane pores, and condenses on a cold surface, which is separated from the membrane by an air gap. Carlsson [66] was the first to describe the AGMD in 1983, subsequently; more studies were carried out on AGMD and its applications [26,33,67–71]. In AGMD, the presence of air gap acts as a thermal insulation between membrane and condenser wall, and reduces considerably the heat loss caused by conduction and temperature polarization, improving the separation efficiency.

The main advantage of AGMD over DCMD arises from the possibility of condensing the permeate vapors directly in a cold surface rather than in a cold liquid. Additionally, in AGMD the permeate boundary layer is absent thus reducing the overall mass transfer resistance.

#### 19.3.2.1 Heat and Mass Transfer

The stages of heat transfer in AGMD (Figure 19.7) include heat flux from the feed boundary layer to the membrane surface, vapor permeation through the membrane, and the diffusion in air gap, then condensation at the cold surface and finally heat transfer to the cooling water.

Heat flux from the feed boundary layer to the membrane surface can be written similar to Equation 19.11:

$$Q_f = h_1(T_f - T_{s1}) \quad (19.51)$$

where  $h_1$  is the liquid film heat transfer coefficient that can be calculated from Equation 19.21 for laminar flow and Equation 19.13 for turbulent flow.

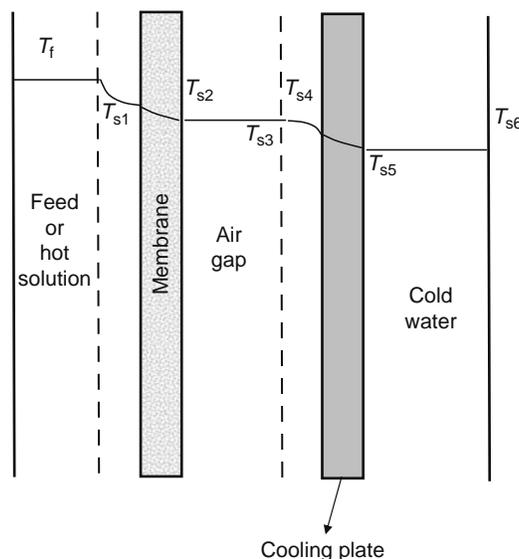

FIGURE 19.7 Temperature profile in AGMD.

The heat transfer through membrane material takes place by conduction and the latent heat transferred by vapor flow through the membrane, which is small and could be neglected. The equation for heat transfer through the membrane can be written as

$$Q_m = \frac{k_m}{\delta} (T_{s1} - T_{s2}) \quad (19.52)$$

The vapors flow from the cold surface of the membrane to the condensation surface through the air gap. Natural convection is very small and could be neglected [72], and only heat transfer ( $Q_a$ ) by conduction across the air gap is considered, which is given by

$$Q_a = \frac{k_g}{(\delta_g - \delta_c)} (T_{s2} - T_{s3}) \quad (19.53)$$

where

$k_g$  is the thermal conductivity of the air

$\delta_g$  and  $\delta_c$  are the air gap and condensate film thickness, respectively

The condensate film thickness can be calculated by [51]

$$\delta_c = \left( \frac{3m\mu_c}{\pi D_t \rho_f^2 g} \right)^{0.33} \quad (19.54)$$

where

$m$  is the flow rate of condensate

$\mu_c$  is the viscosity of condensate film

$D_t$  is the plate thickness

$\rho_f$  is the density of condensate film

The heat transfer by condensation of a pure vapor on a solid surface at constant temperature is given by

$$Q_4 = h_1 (T_{s3} - T_{s4}) \quad (19.55)$$

where  $T_{s3}$  is the dew point temperature of the vapor and  $h_1$  is the film heat transfer coefficient, which can be obtained from Equation 19.56 (for vertical walls) [52]

$$h_1 = 1.333 \left( \frac{k^3 \rho^2 d \pi g}{3 \mu m} \right)^{0.33} \quad (19.56)$$

Heat transferred by conduction through the cooling plate and further by convection to the cooling fluid can be calculated from equations similar to Equations 19.52 and 19.51, respectively.

The mass transfer studies in AGMD suggest that, the transport of vapor through the membrane can be modeled by molecular diffusion mechanism [57], since the pore size of the membrane used is much bigger than the molecular mean free path of water vapor. Equations 19.23 and 19.27 can be used to calculate the mass transfer through the membrane.

### 19.3.2.2 Process Parameters

The process parameters influencing the water vapor flux and energy efficiency are the temperature difference between hot and cold solutions, flow velocities of feed and permeate, air gap pressure, air gap width, and membrane type.

The permeate flux is strongly dependent on the temperature. An increase in inlet temperature of the hot solution from 40°C to 80°C increases the flux by nearly an order of magnitude and the thermal efficiency by 12%, while decreasing the coolant temperature has a lesser effect on the flux increase and even slightly reduces the efficiency [72]. The hot solution temperature has a greater influence because of the exponential increase of the partial pressure of the vapor with the temperature, so the driving force is greater at higher temperature.

The permeate flux increases with increasing feed velocity due to the reduction of the boundary layer thickness. Therefore, the temperature and concentration at the liquid–vapor interface are approaching values close to those in the bulk solution. Garcia et al. [71] have observed that the feed pressure measured at the inlet of the feed cell frame increased with an increase in the feed flow rate consequently increasing the risk of membrane wetting.

The air/vapor gap width is one of the important parameter that plays a major role in AGMD. The major drawback of the air gap is that it creates an extra resistance to mass transfer, which can lower the flux about eight times (for a 5 mm air gap) compared to DCMD under similar conditions [73]. The literature overview of flux obtained so far in flat sheet AGMD [10,50,70,71,73,74] demonstrates that the flux increases considerably by decreasing the air gap width. Alklaibi and Lior [72] and Jönsson et al. [28] observed 2.6-fold increase in the permeate flux as the thickness of the gap is reduced. The increase in permeate flux can be explained by the fact that the air gap conductivity is very low relative to the other regions between the hot and cold solutions. The resultant high temperature and consequent vapor pressure drop across membrane increase flux. Jönsson et al. [28] estimated the optimal air gap width to be 0.2 mm, resulting in large water vapor flux and low-energy loss. However, the practical value of this air gap width has never been tested (because the available space 0.2 mm air gap is quite small for condensed water vapor). Alternative methods to increase the vapor flux, other than reduction of air gap width are reduction in air gap pressure and use of ultrasound technique. Gostoli et al. [50] have showed that decreasing the air gap pressure from 1000 to 400 mbar has increased the flux by 2.4-fold. Reduction of the air gap total pressure from atmospheric to the saturated water vapor pressure of the hot water flow raises the flux by a factor of 2.5–3 in hollow fiber module [75]. Zhu [70] has shown that the permeate flow rate could be increased up to 25% by ultrasonic stimulation.

In practical applications of the membrane distillation processes the most important and crucial issue is heat economy, which is determined by cell design and eventually, the operating parameters. Calculations from the literature [28,69,74] claim theoretical energy efficiencies in the range of 70%–99% for AGMD. In other words 70%–99% of energy drop of the hot water flow is used for evaporation of water and that 1%–30% is lost by heat conduction across the membrane and the air gap. Compared to DCMD, AGMD is expected to be more energy efficient especially at lower feed temperatures. Alklaibi and Lior [72] speculate that air gap width exceeding 2 mm does not raise process efficiency; however, Guijt [75] has shown that the theoretical energy efficiencies of 95%–98% can be achieved in a hollow fiber module of air gap width 3 mm, which could be explained by a small heat loss to the surroundings.

### 19.3.3 VACUUM MEMBRANE DISTILLATION

Vacuum membrane distillation, such as any membrane distillation process, is a thermally driven process in which a feed solution is brought into contact with one side of a microporous membrane and a vacuum is created on the opposite side to create a driving force for transmembrane flux (Figure 19.8). The microporous membrane only acts as a support for a vapor–liquid interface, and does not affect the selectivity associated with the vapor–liquid equilibrium [76].

The experimental procedures are quite similar to and often confused with pervaporation. The main difference between VMD and pervaporation is the nature of the membrane used, which plays an important role in the separations. While VMD uses a porous hydrophobic membrane and the degree of separation is determined by vapor–liquid equilibrium conditions at the membrane–solution interface, pervaporation uses a dense membrane and the separation is based on the relative perm-selectivity and the diffusivity of each component in the membrane material.

#### 19.3.3.1 Heat and Mass Transfer

In VMD, the conductive heat transfer across the membrane is very low, mainly due to the low pressure on the permeate side of the membrane and could be neglected. Thus latent heat of vaporization is the only mode for heat transfer to be considered through the membrane [17,47,77]. Equation 19.3 can be used for calculating the rate of heat transfer across the membrane.

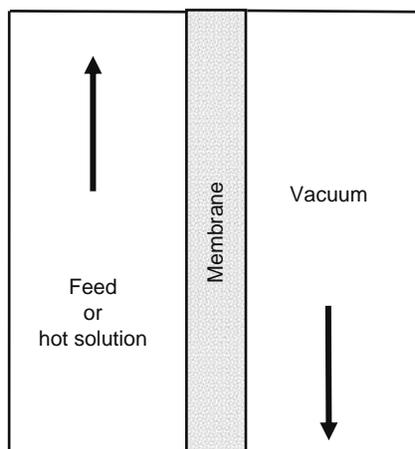

FIGURE 19.8 Schematic representation of VMD.

The heat transfer across the boundary layer present only on feed side (turbulent flow) can be calculated using Equations 19.13 through 19.21, based on the hydrodynamic conditions.

In VMD, the pore size of the membrane falls in the range of 0.1–0.2  $\mu\text{m}$  [17,78]. The mean free path of the diffusing species is usually larger than the pore size of the membrane and under such conditions; Knudsen diffusion is the only mechanism for mass transfer through the membrane and the molecular diffusion resistance can be neglected because the molecular diffusion resistance is proportional to the partial pressure of air in the membrane pores. Since VMD generally operates at total pressures in the order of 10–50 kPa, which is below the vapor pressure of the diffusing species, only trace amounts of air can exist within the membrane pores [77]. Thus, VMD is Knudsen diffusion controlled for the membrane with relatively small pores ( $r \ll \lambda$ ). In this case, the expression is derived based on the kinetic theory of gases or more precisely the DGM Equations 19.26 and 19.23 can be used to estimate the mass transfer across the membrane. However, VMD membranes typically have pores that are comparable to mean free path ( $\lambda$ ), consequently the more complete Knudsen–Poiseuille transition Equation 19.44 is more applicable [77].

### 19.3.3.2 Process Parameters

Feed temperature, flow rate, and solute (nonvolatile) concentrations are some of the parameters commonly studied in VMD.

Mengual et al. have observed an Arrhenius type of dependence of the permeate flux on the feed temperature. An increase in the feed circulation velocity increases the heat transfer coefficient in the liquid boundary layer, which in turn increases the VMD flux due to the reduction in the temperature polarization. Concentration factors increased with a decrease in feed temperature during VMD, and for a decrease of 30°C to 10°C, increase in concentration factors from 7–15.5 to 21–31 were obtained for a highly volatile black currant aroma ester [17].

One of the benefits of VMD relative to the other MD configurations is that conductive heat loss through the membrane is negligible. This enables estimation of the boundary layer heat transfer coefficient. Care must be taken in VMD to prevent membrane wetting, because  $\Delta P_{\text{interface}}$  is typically higher in VMD than in other MD configurations.

### 19.3.4 SWEEPING GAS MEMBRANE DISTILLATION

In this case when the water molecules are collected with the help of a sweeping gas, the process is named SGMD (Figure 19.9). The survey of literature [24,79–82] suggests that very little work has been done with regard to SGMD, although this configuration has the advantages of a relatively low conductive heat loss with a reduced mass transfer resistance. This is probably due to the fact that a very small volume of permeate is vaporized into a large volume of sweep gas and has to be collected in an external condenser, which is not an easy task. Basini et al. [80] were the first to study this configuration for the desalination of water. Later it was employed for the concentration of sucrose solutions and the separation of ethanol–water mixtures [83].

In SGMD, a hot feed solution is circulated on one side of a microporous membrane and cold sweep gas on the other side of the membrane. The temperature difference gives rise to a water vapor pressure difference, and consequently, to a water flux through the membrane.

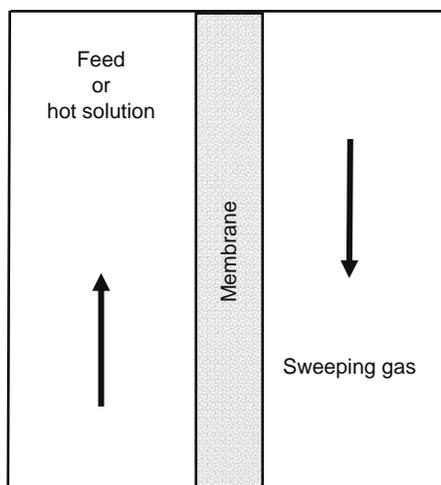

FIGURE 19.9 SGMD configuration of MD.

The SGMD configuration has a great scope for the future due to the advantages mentioned above. SGMD provides much higher permeate fluxes than AGMD while maintaining high temperature polarization coefficient and evaporation efficiency [80–84]. The apparent advantages of SGMD over DCMD are better selectivity, smaller temperature polarization, and higher evaporation efficiency, albeit a low permeate flux [84].

#### 19.3.4.1 Heat and Mass Transfer

The SGMD is a temperature driven process, and it involves: (a) evaporation of water at the hot feed side, (b) transport of water vapor through the pores of hydrophobic membrane, (c) collection of the permeating water vapor into an inert cold sweeping gas, and (d) condensation outside the membrane module. A decrease in driving force has been observed due to polarization effects of both temperature and concentration [80,82]. To calculate both heat and mass transfer through microporous hydrophobic membrane as well as the temperature and concentration polarization layer, the theoretical model suggested by Khayet et al. [58] can be written as

$$N^2 + \left[ (w_{in} + 0.622) \frac{m_a}{A} + B(P - p_v(C_f, T_f)) \right] N + B \frac{m_a}{A} [P w_{in} - p_v(T_a)(w_{in} + 0.622)] = 0 \quad (19.57)$$

where

- $N$  is the mass flux
- $w_{in}$  is the inlet humidity ratio
- $m_a$  is mass flow rate of air
- $A$  is the membrane area
- $P$  is the total pressure
- $p_v$  is the vapor pressure
- $C_f$  is the solute concentration in feed
- $B$  is the net membrane coefficient
- $T_f$  and  $T_a$  are the feed and air temperatures, respectively

In Equation 19.57, the net membrane coefficient  $B$  can be calculated by using Equation 19.45, because the combined Knudsen molecular diffusive flux is responsible for the transport in SGMD [58,81,82], while the temperature of the feed  $T_f$  at the membrane surface can be obtained from

$$T_f = \frac{\frac{\varepsilon k_g + (1-\varepsilon)k_m}{\delta} \left( T_{ba} + \frac{h_f}{h_a} T_{bf} \right) + h_f T_{bf} - N \lambda_L}{\frac{\varepsilon k_f + (1-\varepsilon)k_m}{\delta} + h_f \left[ 1 + \frac{\varepsilon k_g + (1-\varepsilon)k_m}{\delta h_a} \right]} \quad (19.58)$$

where

- $T_{bf}$  is the temperature in the feed (bulk) solution
- $T_f$  is the temperature at the feed membrane surface
- $T_{ba}$  is the temperature in the permeate bulk solutions, respectively
- $\lambda_L$  is the latent heat of vaporization
- $k_g$  and  $k_m$  are the thermal conductivities of the gas in the membrane pores and membrane matrix, respectively

In Equation 19.58, the heat transfer coefficients  $h_f$  and  $h_a$  can be determined using Equations 19.17 and 19.19 (Table 19.1).

#### 19.3.4.2 Process Parameters

In SGMD, the temperature of the liquid feed and the circulation velocity of the sweeping gas are very important parameters. To avoid membrane wetting, it is important that the circulation velocity of the air needs to be varied with caution such that pressure difference between both fluids needs to be lower than the liquid entry pressure of water ( $LEP_w$ ) and the air pressure must be lower than the liquid pressure. The increase in temperature of the feed and the circulation velocity of the sweep gas increases the flux; mainly due to the increase in vapor pressure difference (the driving force). In general, SGMD is the most difficult to describe, since in the downstream compartment, unlike in other MD configurations, none of the variables remain constant along the module. All temperatures, concentrations, as well as heat and mass transfer rates change during passage of gas within the module. Gas entering the cold chamber contains low permeate vapor, with a temperature of cooling water. As it

sweeps the membrane, condensable vapors and heat are accumulated in the gas phase changing its temperature, concentration, and flux. Khayet et al. [79] have observed an increase in the sweep air temperature by 20°C for a module length of 6.5 cm. The heat transferred through the membrane increases the sweep gas temperature along the module length, which results in a progressive increase in partial pressures of the gas. Consequently the driving force decreases rapidly, making the process impracticable at an industrial scale. In order to overcome these problems, Rivier et al. [84] have developed a modified SGMD configuration called thermostatic sweeping gas membrane distillation (TSGMD), in which, a cold wall is added in a downstream compartment to attenuate the increase in sweep gas temperature. Hence the driving force along the module could be enhanced. In TSGMD, an inert gas circulates at more or less constant temperature in the cold chamber and collects the vapors that permeate through the membrane. Part of these permeating vapors condenses inside the module depending on the operating conditions, and the rest in an external condenser.

### 19.3.5 OSMOTIC MEMBRANE DISTILLATION

Osmotic membrane distillation is one of the membrane distillation variants that operate at ambient temperature and atmospheric pressure. In OMD, a microporous hydrophobic membrane separates the two aqueous solutions, namely, feed and osmotic agent (OA) having different solute concentrations (osmotic pressure). The driving force in OMD is vapor pressure difference across the membrane. Water evaporates from the surface of the feed solution having higher vapor pressure, diffuses through the membrane in the form of vapor, and condenses on the surface of a solution with a lower vapor pressure. This results in the concentration of feed and dilution of osmotic agent solution.

Like any other membrane distillation, in OMD the membrane material is also hydrophobic, so that water in liquid form cannot enter the pores unless a hydrostatic pressure exceeds the  $LEP_w$  [37]. In the absence of such pressure difference, a liquid–vapor interface is formed on either side of the membrane pores. In some aspects membrane distillation and OMD can be considered as closely related, although there are some remarkable differences between them. In both cases, it is necessary to maintain a vapor pressure difference across the membrane pores to get a difference in water chemical potential. However, the means of obtaining this vapor pressure difference is different in both the cases. Whereas it is a temperature difference in the case of membrane distillation, it is a concentration difference in the case of OMD.

OMD offers major advantages in comparison with the conventional thermal concentration techniques. The low temperature employed can help avoid chemical or enzymatic reactions associated with heat treatment [85] and prevent degradation of flavor, color, and loss of volatile aroma [38]. The low-operating pressure (atmospheric pressure) results in low investment costs, low risks of fouling, and low limits on compactive strength of the membrane. Since the separation is based on vapor–liquid equilibrium, only volatile compounds which can permeate the membrane and the nonvolatile solutes such as ions, sugars, macromolecules, cells, and colloids are totally retained in the feed. These factors make OMD an attractive alternative to traditional thermal routes currently used for concentration of liquid foods or aqueous solutions of thermally labile pharmaceutical products and biologicals [86].

#### 19.3.5.1 Heat and Mass Transfer

The water transport in OMD is a simultaneous heat and mass transfer process. Evaporation cools the feed and condensation warms the brine solution. This results in a temperature gradient across the membrane, which adversely affects the driving force and in turn the mass flux.

The heat transfer through the membrane can be explained by the convective and the conductive component related to the temperature difference. Thus the expression for rate of heat transfer through the system can be calculated using Equation 19.9. Further, Gostoli [87] attempted to integrate the thermal effect in the mass transfer by introducing an efficiency coefficient,  $\eta$ , which represents the fraction of the driving force really effective for mass transfer through the membrane. This is analogous to MD temperature polarization. The value of  $\eta$  was reported to be 0.85 and the permeability was observed to be 15% lower than the experimental values for NaCl and water system with stirred membrane cell where concentration polarization was neglected. The heat transfer coefficients of the two compartments of the OMD system could be estimated using a friction factor, by combining the experimental pressure loss to the theoretical value that would be obtained in the module having straight shaped circulation channels.

The basic model used to describe the water transport in the system that relates the mass flux ( $J$ ) to the driving force is given by

$$J = K(p_1 - p_2) \quad (19.59)$$

where  $K$  is the overall mass transfer coefficient that accounts for all three resistances (feed, membrane, and OA side) for water transport.

### 19.3.5.2 Mass Transfer through the Membrane

Diffusion is the main mechanism involved in the mass transfer during osmotic distillation and the resistance to mass transfer comes from both membrane structure and presence of air trapped within the membrane pores. While the former resistance can be described by Knudsen diffusion Equation 19.26, the latter is described by molecular diffusion Equation 19.27.

The DGM equations can also be used to find out the mass transfer across the membrane. Since the DGM was derived for isothermal conditions, it would be appropriate to use it for an isothermal membrane process such as OMD. It has been shown that the DGM could be applied to a non-isothermal system also by the inclusion terms for thermal diffusion and thermal transpiration [39,88]. In DCMD, AGMD, VMD, and SGMD these terms are negligible, hence  $T_{\text{avg}}$  has to be used in place of  $T$  in the DGM equations. Since OMD is generally carried out at ambient temperature and atmospheric pressure, using membranes with pore size ranging from 0.1 to 1  $\mu\text{m}$ , so it can be assumed that, the main transport mechanisms present in this case is Knudsen and molecular diffusion, and the Equation 19.45 can be used to calculate the mass transfer through the membrane.

### 19.3.5.3 Mass Transfer through Boundary Layers

Boundary layers of concentrated feed and brine solution are present on either side of the membrane. This results in significant resistance to mass transfer that cannot be neglected.

In order to characterize mass transfer in the boundary layers, it is necessary to determine the respective mass transfer coefficients. These coefficients depend on the properties of the solutions and on the hydrodynamic conditions of the system. Such coefficient can either be obtained by experiments or be estimated with the help of empirical correlations of dimensionless numbers. The majority of the correlations referred to in the literature for various hydrodynamic conditions have the same general form. These include Sherwood number ( $Sh$ ), which contains the mass transfer coefficient, as a function of the Reynolds number ( $Re$ ) and Schmidt number ( $Sc$ ) [89–91]. General mass transfer correlation can be written as

$$Sh = \alpha Re^{\beta} Sc^{\gamma} \quad (19.60)$$

$$Sh = \frac{kb}{D_w}, \quad Re = \frac{\rho Nd^2}{\mu}, \quad Sc = \frac{\mu}{\rho D_w} \quad (19.61)$$

where

$D_w$  is the water diffusion coefficient

$\alpha$ ,  $\beta$ , and  $\gamma$  are constants and are to be selected appropriately for the given hydrodynamic conditions [43,92]

In the case of a noncircular flow channel, for instance a square channel, an equivalent diameter is given by  $d_e = 4S/L_p$  where  $S$  is the cross-sectional area and  $L_p$  the wetted perimeter length of the flow channel [41].

### 19.3.5.4 Process Parameters

Osmotic agent, flow rate, membrane pore size, and feed concentration are some of the key parameters associated with OMD.

The salt chosen as osmotic agent is, in general, NaCl because of its low cost and nontoxicity [57]. Different salts can lead to remarkably different fluxes mainly due to the different osmotic activity of the salts. In general osmotic pressure difference up to 700 bar can be achieved, however, some authors have reported data for pressures as high as 1500 bar [57]. The commonly used OA in OMD other than NaCl are  $\text{CaCl}_2$ ,  $\text{MgCl}_2$ ,  $\text{MgSO}_4$ ,  $\text{K}_2\text{HPO}_4$ , and  $\text{KH}_2\text{PO}_4$ . Potassium salts of ortho- and pyrophosphoric acid offer several advantages, including low-equivalent weight, high water solubility, steep positive temperature coefficients of solubility and safety in foods and pharmaceuticals [93,94].

It has been observed from the literature that transmembrane flux increases with an increase in flow rate. This could be attributed to reduction in the concentration polarization layer. The work carried out by Sheng et al. [95] showed that the transmembrane flux decreased with increase in juice concentration and exhibited a strong dependence on the osmotic pressure difference between the two aqueous solutions. When the difference in osmotic pressure decreased by 33% (from 416 to 280) atmospheric pressure, a fivefold decline in transmembrane flux was observed. As discussed earlier, the pore size plays an important role in influencing the type of diffusion for water transport through membrane. The effect of membrane pore size on transmembrane flux was studied [37,92] and no significant change in flux was observed in the range 0.05–0.2  $\mu\text{m}$  studied. However, from theoretical calculations it was observed that the mode of diffusion (and in turn transmembrane flux) depends on the membrane pore size employed. Naveen et al. [92] have shown the mode of diffusion to be Knudsen when membrane pore size is 0.05  $\mu\text{m}$  and molecular when pore size is 0.2  $\mu\text{m}$ . Brodard et al. [96] who employed ceramic membranes made of alumina having pore sizes of 0.2 and 0.8  $\mu\text{m}$  observed practically no effect of pore size on water flux.

## 19.4 MEMBRANES

Membrane characteristics such as porosity, pore size, tortuosity, and membrane thickness dictate the resistance to mass transfer through microporous membranes used in MD [35,97–99]. Furthermore, studies [100,101] have shown that the relationship between intrinsic membrane properties and operating conditions, e.g., swelling, compaction, and wetting, are important in deciding efficient operations. Therefore, selection of an appropriate membrane that poses the least resistance to mass transfer is crucial. Lefebvre [36] has given some criteria for the choice of membranes.

Both the Poiseuille and Knudsen models show a large dependence of membrane flux on pore radius. Therefore, it is inimical that membranes used in MD should have a high porosity (60%–80%). Since flux is inversely proportional to the membrane thickness, in OMD it needs to be as thin as possible (0.1–1.0  $\mu\text{m}$ ) and should have high heat conductivity to achieve rapid temperature equilibrium near the boundary, while in other variants of MD, such as DCMD, AGMD, SGMD, VMD where temperature gradient is the driving force, membranes should be thicker and should have low thermal conductivity [57]. However, one should not conclude that thick membranes alone are recommended for MD. In fact, with an increase in membrane thickness, the heat resistance increases so also temperature and vapor pressure differences. Similar to OMD, the permeate flux in the DCMD increases with decreasing membrane thickness [102]. The hydrophobic nature of the membrane plays an important role in the performance of MD; a variety of membranes having these characteristics are available. Table 19.2 lists the membranes used by the various researchers till date. This list includes mainly hydrophobic polymers with low surface

free energies, i.e., polytetrafluoroethylene (PTFE,  $9.1 \text{ kN m}^{-1}$ ), polyvinylidene fluoride (PVDF,  $30.3 \text{ kN m}^{-1}$ ), polyethylene (PE,  $33.2 \text{ kN m}^{-1}$ ), and polypropylene (PP,  $30.0 \text{ kN m}^{-1}$  surface energy). The survey of literature suggests that the pore size, porosity, and thickness of most of the membranes used in MD fall in the range of  $0.2\text{--}1.0 \text{ }\mu\text{m}$ ,  $65\%\text{--}85\%$ , and  $0.06\text{--}0.25 \text{ mm}$ , respectively. The thermal conductivities of polymers are mainly dependent on temperature and the degree of crystallinity of the polymer, which varies in the range of  $0.15\text{--}0.45 \text{ W m}^{-1} \text{ K}^{-1}$  [123]. Hydrophilic membranes that have been treated to make their surfaces hydrophobic have also been applied successfully to MD [124,125].

The pressure variable can be used in defining wettability in terms of LEP, as represented by the Laplace (Cantor) equation

$$\Delta P_{\text{entry}} = \frac{-2B\gamma_l}{r_{p,\text{max}}} \cos \theta \quad (19.62)$$

where

$\Delta P_{\text{entry}}$  is the entry pressure difference

$\gamma_l$  is the surface tension of the solution

$\theta$  is the angle of contact between the solution and the membrane surface

$B$  is a geometric factor

$r_{p,\text{max}}$  is the largest pore size

Once the pressure drop across the vapor–liquid interface  $\Delta P_{\text{interface}}$  exceeds penetration pressure  $\Delta P_{\text{entry}}$ , the liquid can penetrate the membrane pores and the membrane is termed as wetted. Contact angle measurement and surface tension are the traditional methods to describe the wettability of the membranes. The contact angle comprised of a liquid droplet deposited onto the surface of a smooth solid will have a value higher than  $90^\circ$  if there is low affinity between liquid and solid, and will be less than  $90^\circ$  in the case of high affinity. Wetting occurs at  $0^\circ$ , when the liquid spreads onto the surface. In general the solid–liquid angle of contact for the membrane should be at least  $90^\circ$ , while a value of  $130^\circ$  being the optimal for use in MD [39]. Recently, the use of some copolymers of tetrafluoroethylene (TFE) and 2,2,4-trifluoro-5-trifluoromethoxy-1,3-dioxole (TTD), commercially known as HYFLON AD, for fabricating polymeric membranes have provided an increased reliability to the MD process. They have been used for preparing asymmetric and composite membranes that show a high contact angle ( $120^\circ$ ) for water, demonstrating a highly hydrophobic character [126]. Brodard et al. [96] successfully employed hydrophobic ceramic tubular membranes in the osmotic evaporation process. These ceramic membranes have been obtained by grafting siloxane compounds on alumina porous supports. Ceramic membranes have the advantage of higher physical and chemical stability as compared with polymeric membranes. Barbe et al. [117] have studied nine types of hydrophobic microporous membranes for their influence on the retention of range of volatile organic species. The results of this investigation suggest that membranes having relatively large surface pores have been shown to retain higher organic volatiles per unit water removed than those with smaller surface porosity. However, pores with larger diameters at the membrane surface allow greater intrusion of the feed and OA solutions, leading to an extended boundary layer. This extended layer offers extra resistance for diffusion of volatile components. Further Barbe et al. [127] have studied changes in the surface morphology in hydrophobic membranes. A change in morphology was observed when the membranes were in contact with water as against no change observed when in contact with 30% w/w  $\text{CaCl}_2$ . This was attributed to a lower degree of intrusion of the  $\text{CaCl}_2$  solution, relative to that of water because of the higher surface tension of the former. Their results also suggested that the larger pores become larger while smaller pores showed shrinkage.

Although fouling seems to be of minor importance for MD compared to other membrane techniques, periodic membrane cleaning is necessary. Durham and Nguyen [128] evaluated the effectiveness of several cleaning agents for microporous PTFE and cross-linked acrylic-fluoroethane copolymer membranes. The membranes were cleaned after 2 h of processing of a 21.5% solution of tomato puree, and the change in flux and membrane hydrophobicity measured before and after cleaning. The authors showed that repetitive cleaning and fouling can rapidly destroy certain membranes, an important result in regard to industrial applications.

## 19.5 MEMBRANE MODULES

The choice of membrane module for MD is mainly determined by functional and economic considerations. A large variety of membrane modules, such as plate and frame, spiral wound, tubular, capillary, and hollow fiber have been designed and tested for MD.

In plate and frame modules, the membranes are placed (with or without spacers) between two plates. The packing density of this configuration varies between  $100$  and  $400 \text{ m}^2 \text{ m}^{-3}$ , depending on the number of membranes or cassettes used. Andersson et al. [31] have used a plate and frame configuration for desalination purposes, where various cassettes were stacked together, each consisting of injection molded plastic frames of two membranes. Naveen et al. [92] used a plate and frame membrane

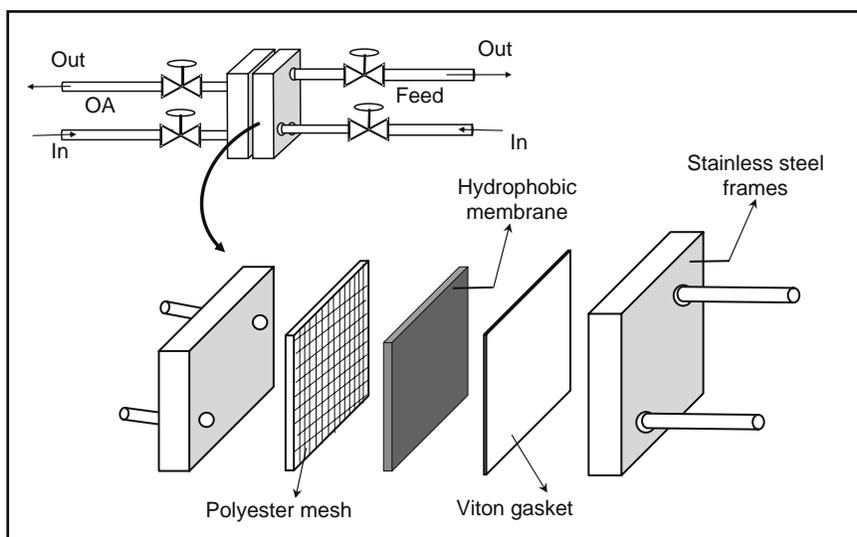

FIGURE 19.10 Plate and frame membrane module.

module having a membrane area of  $0.016 \text{ m}^2$  for the concentration of pineapple and sweet limejuice. The module (Figure 19.10) consists of a polyester mesh, a Viton gasket, and a hydrophobic microporous membrane of pore size ( $0.05\text{--}0.2 \mu\text{m}$ ) supported in between two stainless steel frames. Feed solution and osmotic agent solution were circulated on either side of the membrane in cocurrent mode using peristaltic pumps.

Spiral-wound modules have a packing density of  $300\text{--}1000 \text{ m}^2 \text{ m}^{-3}$ , which is greater than that of the plate and frame module. This packing density depends upon height of the channel spacers. Koschikowski et al. [129] have used a spiral-wound MD module for desalination experiments, which is assembled by spiral winding of PTFE membrane and condenser foils. It has been reported to have a specific thermal energy consumption of  $140\text{--}200 \text{ kW h m}^{-3}$  of distillate and gained output ratio of 4–6. The use of spiral-wound modules has been proposed by Gore [27] for industrial scale desalination units.

Tubular membranes unlike capillaries and hollow fibers are not self-supporting. Hence, such membranes tubes are placed into porous stainless steel, ceramic, or plastic tubes. The diameter of tubular membranes usually varies from 1 to 2.5 cm, with a packing density of about  $300 \text{ m}^2 \text{ m}^{-3}$ . In MD operations, the tubular modules are used either for highly viscous fluids or while operating under high-flow rates. In some cases, tubular modules are used to reduce fouling and concentration polarization phenomena. In order to make SGMD practicable at industrial scale Rivier et al. [84] have used a tubular membrane module (TSGMD) as shown in Figure 19.11. The module is made of glass and has six tubular membranes, each one surrounded by a glass tube of  $13 \times 10^{-3} \text{ m}$  i.d. (inner diameter). The effective membrane surface of the module is  $0.019 \text{ m}^2$ . The feed and sweeping gas are circulated inside and outside the tubular membrane, respectively. Capillary membrane modules consist of a

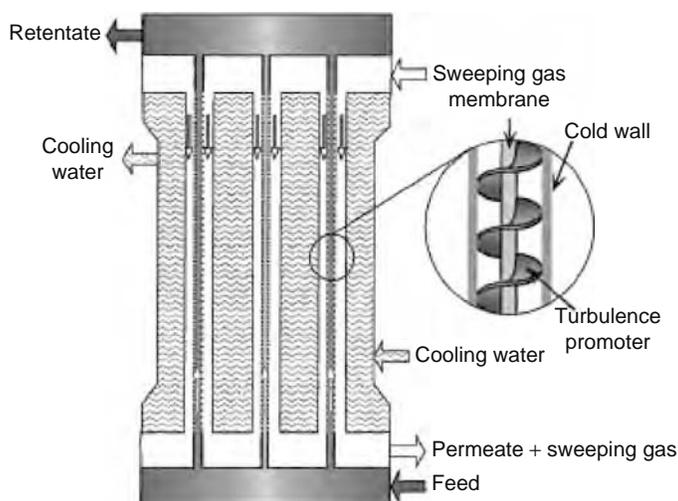

FIGURE 19.11 Schematic representation of TSGMD module.

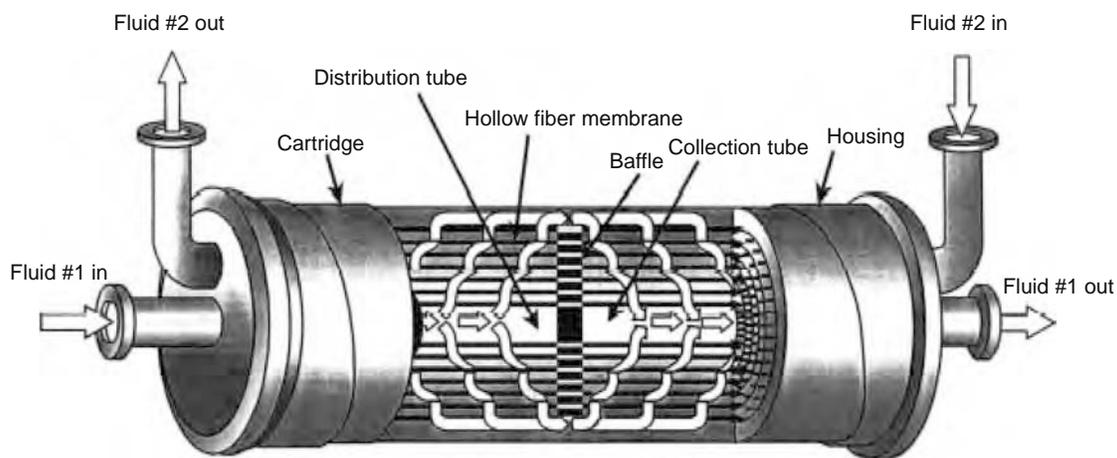

FIGURE 19.12 Liqui-Cel Extra-Flow membrane contractor from CELGARD LLC.

large number of capillaries, which are arranged in parallel as a bundle in a shell and tube configuration. The capillary membranes are self-supporting, and two kinds of module arrangement are possible based on flow of feed or permeate (through the capillary or outside of the capillaries). The packing density is in the order of  $600\text{--}1200\text{ m}^2\text{ m}^{-3}$ , which is between the tubular and hollow fiber modules.

A hollow fiber module is conceptually similar to the capillary module, but differs in dimensions. In this case the diameter of the tubular membrane varies between  $50\text{ and }100\text{ }\mu\text{m}$  and several thousand of fibers can be placed in the vessel. The hollow fiber module is the configuration with the highest packing density (with values up to  $30,000\text{ m}^2\text{ m}^{-3}$ ).

Liqui-Cel Extra-Flow (Figure 19.12) is one of the well studied hollow fiber modules for concentration-driven mass transfer. This module consists of several microporous polypropylene fibers, which are woven into a fabric and wrapped around a central tube feeder that supplies the shell side fluid. The woven fabric allows more uniform fiber spacing, which in turn leads to higher mass transfer coefficients than those obtained with individual fibers. The fiber lumen diameter and wall thickness are  $240\text{ and }30\text{ }\mu\text{m}$ , respectively [93,130]. The smallest Liqui-Cel modules are 2.5 in. in diameter and contain  $1.4\text{ m}^2$  of contact area, while the largest are 10 in. in diameter and offer  $130\text{ m}^2$  of contact area by virtue of 225,000 fibers. The large modules can handle liquid flow rates of several 1000 L/min.

Some more module configurations are reported for use in MD. Lawson and Lloyd [77] have designed a laboratory-scale MD module as shown in Figure 19.13, where the membrane was sandwiched between the two half-cells, and several hose clamps held the module together. The total area available is  $9.7\text{ cm}^2$  and the smooth transitions at the module entrance as well as exit allow achievement of relatively high Reynolds numbers, whereby conventional boundary layer equations are applicable. The module does not require a support in low pressure-drop applications such as DCMD. Wider permeate channels would require a support for VMD experiments. A porous sintered stainless steel material has been used for the gas permeation experiments.

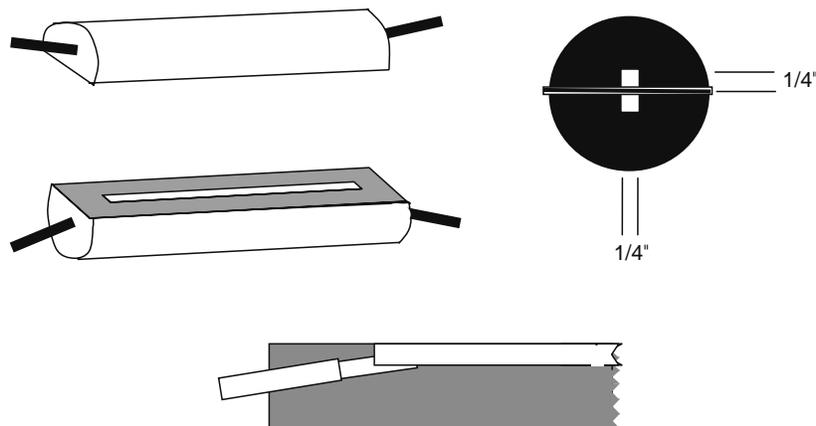

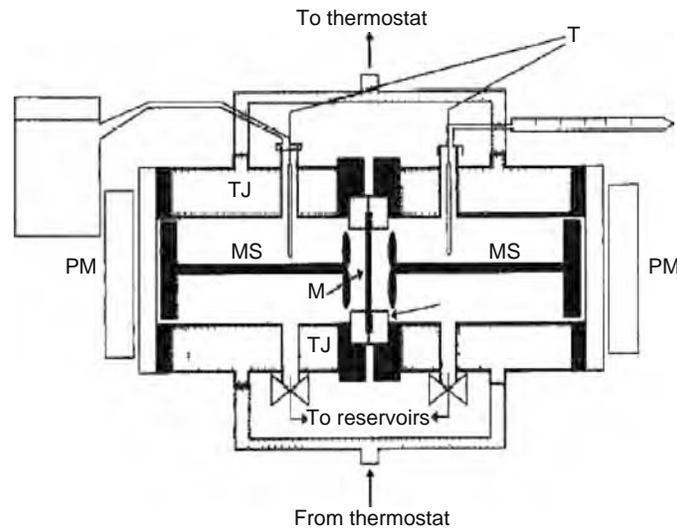

FIGURE 19.13 Schematic diagram of the MD module.

**FIGURE 19.14** Stirred cell. M: membrane, H: membrane holder, MS: magnetic stirrer, PM: propelling magnet, T: thermometer, TJ: thermostated jacket.

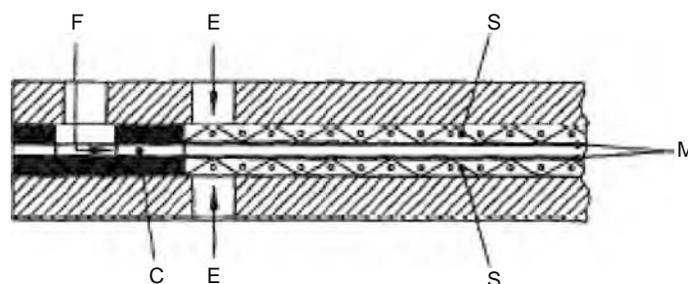

Mengual et al. [37] have used Lewis cell (stirred cell) for their experiments on MD (Figure 19.14). This mainly consists of two equal cylindrical chambers made of stainless steel having a length of 20.5 cm. The membrane was fixed between the chambers by means of a PVC holder. Three viton O-rings were employed to eliminate leaks in the assembly. The membrane surface area exposed to the flow was 27.5 cm<sup>2</sup>.

To investigate the role of heat transfer in OMD and measure the asymptotic temperature difference, Celere and Gostoli [86] used the flat sheet membrane module shown in Figure 19.15. This contains a few flat sheet membranes placed 1 mm apart and supported by mesh-type spacers of 2 mm thickness, leaning against polypropylene walls. One stream (feed) flows between the membranes and other (extractant) flows cocurrently through the spacers. The mass transfer zone of each membrane is 80 mm in breadth and 200 mm in length.

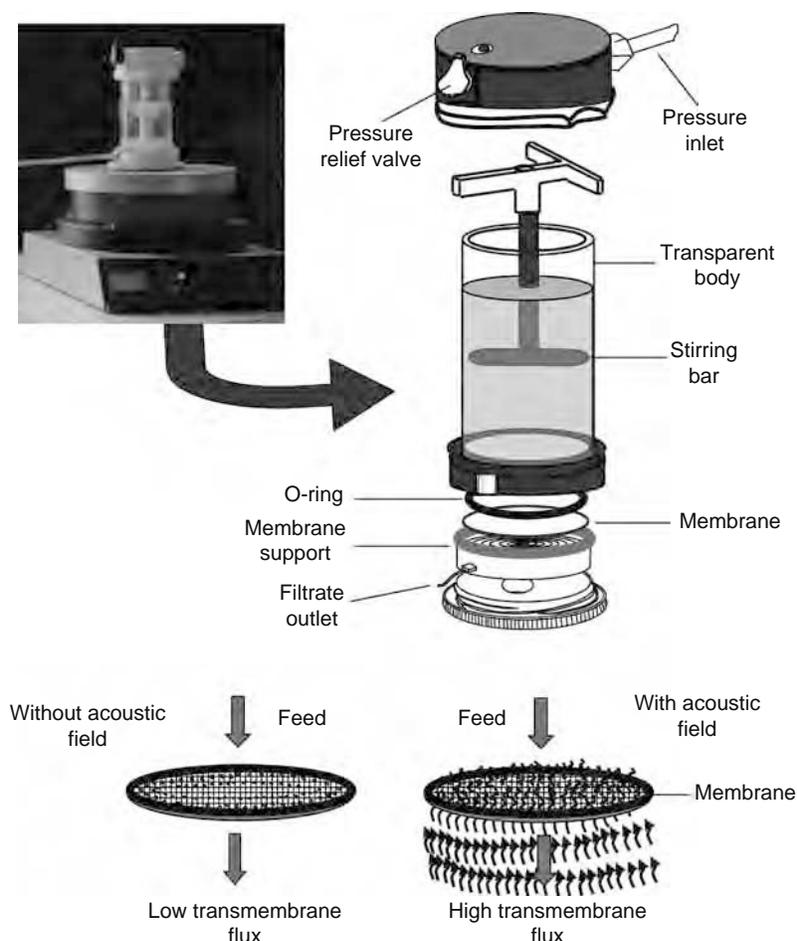

## 19.6 ENHANCEMENT OF FLUX IN MEMBRANE DISTILLATION

In spite of their advantage and potential over conventional processes, membrane distillation suffers from the drawback of low transmembrane flux when compared to RO. In the past few years, additional innovations in module design and new strategies have been explored to reduce concentration polarization and to enhance mass transfer. Some of these attempts are discussed here.

Enhancement of transmembrane flux has been shown in OMD of grape juice pretreated by UF [131]. The increase in flux has been attributed to a reduction in the viscosity of the concentrated juice–membrane boundary layer as the result of removal of high-molecular weight biopolymers present in juice. UF is a powerful method for removing natural polymers (polysaccharides, proteins) from fruit and vegetable juices. Lukanin et al. [12] have improved the concept of (UF + OMD), by enzymatic pretreatment of the apple juice prior to the UF step. Introduction of an additional enzymatic deproteinization step with the pectinase/amylase treatment of apple juice followed by UF has yielded minimal biopolymer content. Such a treatment is found to enhance transmembrane flux during concentration of clarified juice by MD. As in the case of grape juice this has been

**FIGURE 19.15** Cross section of the MD module. F: feed inlet, C: feed manifold, E: extractant inlet, S: spacers, M: membranes.

**FIGURE 19.16** Stirred membrane cell with acoustic field.

attributed to reduction in juice viscosity. Lower viscosity improved hydrodynamic conditions in membrane channel thereby decreasing concentration and temperature polarization.

An ultrasonic technique was applied to AGMD to enhance the permeability for the concentration of various aqueous solutions. In this study, an ultrasonic stimulation of resonance frequency of 20 kHz and power up to 90 W was applied to a flat-plate AGMD system of 1  $\mu\text{m}$  PTFE membrane with a temperature difference of 55°C. A 200% improvement in the transmembrane flux was observed with an ultrasonic intensity of 5  $\text{W cm}^{-2}$ . Experimental investigation of the basic mechanism of ultrasonic enhancement of AGMD suggests that, for a continuous ultrasonic stimulation the dominating mechanisms are microstreaming and cavitation [70,130].

Narayan et al. [111] have tried to enhance the transmembrane flux by using an acoustic field (1.2 MHz), by placing the membrane cell over an ultrasonic transducer (Figure 19.16). Their results show an increase in flux by approximately 35% to 98% when compared with control runs (without acoustic field). The increase in flux is due to the fact that acoustic field induces mild circulation currents, which disturbs the hydrodynamic boundary layers of feed and OA solutions, thereby reducing the effect of concentration polarization.

On examining the effect of membrane compaction on the membrane permeability, Lawson et al. [100] concluded that the transmembrane flux in MD could be increased significantly up to 11% with relatively small pressure drops <70 kPa.

Concentration and temperature polarization can be reduced by the presence of spacers that are turbulence promoters, which enhance the mass flux by increasing the film heat transfer coefficient. Spacers also change the flow characteristics and promote regions of turbulence thus improving boundary layer transfer [106]. DCMD in spacer-filled channels have been shown to improve flux by 31%–41% than that without spacers. The temperature polarization coefficients are substantially increased and approach unity when the spacers are used in the channels.

Cath et al. [97] have demonstrated that, careful design of membrane module and configuration of MD processes could simultaneously reduce temperature polarization and permeability obstructions in the DCMD of salt solutions. Results have shown that fluxes almost double those that are observed in the traditional mode of DCMD, can be achieved at relatively low temperatures.

**TABLE 19.3**  
**Comparative Performance of RO and VMD for a Commercial Membrane**

Membrane Process	Energy Consumption (kWh m <sup>-3</sup> )	Flux (L m <sup>-2</sup> h)
RO with energy recovery	4.0	5–10
VMD single pass	3.2	0.7
VMD discontinuous	1.2	0.5–0.7

## 19.7 APPLICATIONS IN FOOD PROCESSING

Most of the applications reported for MD have been carried out at a laboratory scale. Data on pilot scale studies are available for demineralization of water and to a limited extent on beverages and fruit juice, that too for OMD.

### 19.7.1 DEMINERALIZED WATER

This is by far the most promising food-related application of MD. The advantages of MD over traditional methods, such as RO and multiple stage evaporation lie in the quantitative solute rejection achieved and the comparatively low-energy inputs required for MD when feed water has a high salt concentration, as in seawater.

The work carried out by Lawson and Lloyd [47] suggests that, the DCMD is a viable process for seawater desalination, with fluxes of 2 mol m<sup>-2</sup> s<sup>-1</sup>, which is twice that reported for RO. Banat and Simandl [74] have used an AGMD module with PVDF membrane for their desalination experiments. Pure water with less than 5 ppm total dissolved solid was obtained with a reproducibility of ±20%.

Energy consumption for manufacture of demineralized water from seawater is an issue, which has received much attention. Criscuoli and Drioli [132] found the energy costs for RO to be between 4 and 12 kW h m<sup>-3</sup> depending on whether or not an efficient energy recovery system was in place. Cabassud and Wirth [133] have estimated costs for VMD using PVDF hollow fiber membranes for salt concentrations varying between 15 and 300 g L<sup>-1</sup> (Table 19.3).

They proposed that VMD could compete with RO on energy consumption for membranes 100 times more permeable than those used in their experiment at 25°C at the same permeate flux (5–15 L m<sup>-2</sup> h<sup>-1</sup>). However, if coupled to a solar energy-based system, the flux could be enhanced to 40–85 L m<sup>-2</sup> h<sup>-1</sup> and would make it competitive with RO. Reports on using solar energy coupled to MD [134–137] appear to reinforce this belief.

The energy ( $Q_{req}$ ) required increasing inlet feed solution temperature to the hot channel ( $T_{hi}$ ) was expressed by Alklaibi and Lior [123] as follows:

$$Q_{req} = m_h C_{ps} (T_{hi} - T_{sr}) \quad (19.63)$$

where

$T_{sr}$  is the temperature of the feed solution at source

$m_h$  is the mass flow

Drioli et al. [138] suggested an integrated desalination process of MD and RO for decreasing the cost of production. They arrived at the following cost for MD and RO using a fixed membrane area of 116 m<sup>2</sup> (Table 19.4).

**TABLE 19.4**  
**Cost Comparison of Different Processes for Desalination of Seawater**

Process	Cost of Water Produced \$ m <sup>-3</sup>	Production	Recovery Factor (%)
Only RO	1.25	0.391; $F_1$	40.0
Only MD	1.32	0.856; $F_2$	87.6
RO + MD	1.25	0.856; $F_2$	87.6

Source: From Drioli, E., et al., *Desalination*, 122, 141, 1999. With permission.

Note: Fixed cost of \$116 m<sup>-2</sup> membrane area; feed containing  $F_1 = 60.6\%$ ,  $F_2 = 14\%$  salt.

A novel idea for the production of water is by the combination of MD and membrane crystallization [139], where the salt is concentrated on the feed side to a point close to super-saturation, thereby inducing nucleation of crystals. Recently Gryta and Morawski [140] performed experiments using polypropylene capillary membranes with pore diameters ranging between 0.2 and 0.6  $\mu\text{m}$ , and 70% porosity. They found crystallization to occur at the membrane surface, but by increasing the distillate temperature to 328 K, the problem was eliminated and stable flux restored.

A new development reported by Li and Sirkar [141] for MD-based desalination makes use of polypropylene hollow fibers coated with a plasma polymerized silicone-fluoropolymer. This ultrathin coating on the outside of the fiber was water vapor permeable and was instrumental in decreasing the susceptibility of the composite membrane to wetting and fouling. They reported stable water vapor fluxes between 41 and 79  $\text{kg m}^{-2} \text{h}^{-1}$  for runs lasting up to 400 h.

MD holds great promise as a unit operation for water desalination, by itself and in conjunction with other processes such as RO and traditional distillation. Advances in membrane chemistry and module design are expected to close the gap between these processes in the near future.

### 19.7.2 BEVERAGES AND FRUIT JUICE

The concentration of fruit juice and allied beverages is very challenging from the view of retention of natural aroma and flavor, which decides its acceptance by the consumer. The literature indicates membrane processes currently in use, RO for concentration and pervaporation for aroma capture are mature technologies [21,142]. OMD in combination with RO for concentration of juice beyond 25°Bx (when osmotic pressure imposes limits on RO) has greater prospects than as a stand-alone OMD operation [21].

Direct contact membrane distillation was shown by Drioli et al. [143] and Calabro et al. [13] to be very effective in the concentration of orange juice. Drioli et al. report showed that most of the soluble solids in orange juice were rejected by a microporous PVDF membrane, with the exception of vitamin C, which showed passage and oxidation because of the high temperatures employed. While the report of Calabro et al. from the same group using the same membrane indicated that an early UF pretreatment gave steady flux compared with untreated juice. The decay in flux of untreated juice was attributed to pectin fouling of membrane. Bailey et al. [144] observed similar effects for single strength grape juice. This was attributed to increase in viscosity in the juice-membrane boundary layer where the solute concentration is highest. Lukanin et al. [12] in a study carried on apple juice showed that the stability of productivity in MD concentration improved with decreasing viscosity. Lagana et al. [63] were able to concentrate apple juice up to 64°Bx with transmembrane fluxes of 1  $\text{kg m}^{-2} \text{h}^{-1}$ . They too observed that the viscosity of juice at high concentrations induced concentration polarization, thereby causing decline in flux. DCMD offers advantages for processing high-osmotic pressure feeds, extremes of pH solutions, and application in remote systems using solar or waste heat.

Bagger-Jorgensen et al. [17] found VMD to be a promising technique for retaining the aroma compounds in black currant juice. Their observations on the improved retention of aroma compound *cis*-3-hexen-1-ol as a function of increased cross-flow was attributed to reduced temperature and concentration polarization, which in turn increases the aroma concentration at the vapor-liquid interface. The accumulation of aroma compounds at the boundary layer was eventually found to control flux in spite of increase in cross-flow rate.

Sheng et al. [95] reported the concentration of orange, apple, and grape juices using OMD with a plate and frame module having a membrane surface area of 1  $\text{m}^2$ . They quoted typical flux values of 5–10  $\text{L h}^{-1} \text{m}^{-2}$  for a plant installation with spiral-wound membranes and a juice concentration of at least 75% of solid content. In their installation the diluted salt solution is separately concentrated by pervaporation through a hollow fiber membrane at 50°C. Thompson [145] reported a novel application of OMD, for the concentration of grape juice to make wine from reconstituted concentrate. The author mentioned that wine obtained in this way was difficult to be distinguished from wine produced in the conventional way from simple strength grape juice. This was done at a pilot plant scale having a feed rate of approximately 80–100  $\text{L h}^{-1}$ . He mentioned that an OMD plant for processing between 10,000 and 23,000 L of feed grape juice was in operation.

Barbe et al. [117] studied nine different membranes for their retention of aromatic components commonly found in grape and orange. Using GC-MS analysis of the head space of the simulated feed and elaborate scanning electron microscopy, they showed conclusively that membranes with large pore sizes at the surface show higher retention of volatile components than those, which have narrow surface pores. They have proposed a model to explain this phenomenon.

Ali et al. [146] investigated the passage of aroma constituents of fruit juice during OMD on a pilot plant scale. Using headspace analysis of feed and permeate, they concluded that the loss in aroma could be minimized by operating at low temperature and low feed velocity.

In feeds containing oily constituents (limonene in orange juice), there is often the problem of wetting of the pores of hydrophobic membranes. For OMD applications, Mansouri and Fane [4] used polyvinyl alcohol (PVA) and polyhydroxy 2-ethyl methacrylate (PHEMA) hydrogels to coat membranes such that a hydrophilic gel layer was formed near the mouth of pores. This laminate effectively controlled the ingress of oily constituents into the membrane, at the same time the permeability of water vapor through the pore remained unaffected. Recently Xu [147] has reported alginate hydrogel coatings on PTFE

**TABLE 19.5**  
**Comparison of OMD and MD with respect to Aroma**

Process	Feed	$N_{eb}/N_w$ ( $10^{-6}$ )	$N_c/N_w$ ( $10^{-6}$ )
OMD	Only volatiles	2.8	2.3
MD	Only volatiles	7.2	4.5
OMD	Sucrose (45%) + volatiles	2.6	2.4
MD	Sucrose (45%) + volatiles	5.9	5.4

*Note:*  $N_{eb}$ ,  $N_c$ , and  $N_w$  are the molar fluxes for ethyl butyrate, citral, and water, respectively.

membrane. They reported a 10-fold increase in the adhesion strength between the hydrophilic alginate and the hydrophobic PTFE, by adjusting the surface tension of the coating material. Resistance to wetting of the composite membrane was tested with feed containing 0.2%–0.8% orange oil over a period of 300 min.

Recently Alves and Coelho [148] have compared the concentration of a simulated orange juice (glucose, citral, and ethyl butyrate) using MD and OMD. Using Accurel PP2E HF (Membrana, GmbH, Waltham, Massachusetts) polypropylene membrane, they concluded that as long as viscosity was low the contribution of the sucrose solution boundary layer (shell side) in OMD was not significant. However, toward the end of the experiment, when kinematic viscosity of sucrose solution increases, this resistance becomes considerable. For MD, using the same feed and similar driving force, the flux was found to be less than half of that for OMD [148]. Transport of aroma compounds (citral and ethyl butyrate) for MD showed greater permeation than in OMD for a normalized water removal rate (Table 19.5).

The results suggest that OMD has a distinct advantage over MD, both in terms of flux and aroma retention.

To summarize some of these observations: The viscosity and colloidal content of juice strongly influenced flux because of concentration polarization; due to passage of vapor through pores, there is a fall in temperature at the vapor–liquid interface causing temperature polarization. An increase in feed velocity would increase this temperature at the interface, thereby maintaining flux; at lower solute concentrations, the water vapor flux is high and therefore aroma compositions at the vapor–liquid interface are high; pores with a wider surface diameter allow greater retention of aroma compounds.

Jiao et al. [21] have compared the overall performance of membrane concentration techniques vis-à-vis conventional evaporation (Table 19.6).

Though MD has provoked intense research activity that has led to numerous publications and patents, it finds relatively fewer commercial applications as a stand-alone process, as compared with other membrane processes.

This could be attributed to some of the disadvantages that continue to plague membrane distillation, namely the lack of selectivity of the pores for permeation of vapor through the membrane; significant energy loss due to conduction across the boundary layers close to the membrane; leakage through the membrane caused by trace constituents of the feed stream that lowers the surface tension at the liquid–membrane interface causing intrusion of liquid into the pores.

### 19.7.3 INTEGRATED MEMBRANE PROCESS

On the one hand, MD and OMD suffer from low flux (compared to RO) and temperature concentration polarization that limits their full commercial application. On the other hand, RO process has the problem of maximum achievable concentration (can

**TABLE 19.6**  
**Salient Features of Evaporation and Membrane Concentration Processes**

Process	Maximum Achievable Concentration (°Bx)	Product Quality	Evaporation Rate (L h <sup>-1</sup> ) or Flux (L m <sup>-2</sup> h <sup>-1</sup> )	Product Flexibility	Operating Costs	Capital Investment	Energy Consumption	Status of Technology
Evaporation	80	Very poor	200–300	No	Moderate	Moderate	Very high	Developed
Reverse osmosis	25–35	Very good	5–10	No	High	High	High	Developed
Direct osmosis	50	Good	1–5	Yes	High	High	Low	Under development

reach only up to 25°Bx–30°Bx). To overcome these drawbacks and to improve the product quality and process economics integrated process are gaining popularity. They provide an efficient scalable alternative to thermal processes for the concentration of liquid foods, pharmaceuticals, and biologicals.

Johnson et al. [149] have studied the three-stage hybrid membrane process for the concentration of ethanol–water extracts of the *Echinacea* plant, wherein ethanol removal from the extract was achieved by pervaporation in stage 1. This gave an ethanol-free aqueous product containing suspended alkyl amides that were suitable for marketing in tincture form. In stage 2, the precipitated alkyl amides were removed from the product of stage 1 by microfiltration. In stage 3, the MF permeate was concentrated several fold by OMD. This gave a highly concentrated product suitable for marketing in capsule form.

Gryta [150] conducted integration of fermentation process with membrane distillation for the production of ethanol. The removal of by products, which tends to inhibit the yeast productivity, from the fermenting broth by MD process increased the efficiency and productivity of the membrane bioreactor. The ethanol concentration in permeate was 2–6 times higher than that in the fermenting broth. The enrichment coefficient was found to increase with decrease of ethanol concentration in the broth.

The use of an integrated membrane process for the clarification and the concentration of citrus and carrot juices was proposed as an alternative to the traditional techniques of the agro–food industry [151]. The ultrafiltration process was studied on a pilot plant unit to clarify the raw juice. A clear phase was produced in this step and it was used for concentration by successive membrane treatments. The RO process, performed on a laboratory plant unit, was used to preconcentrate the permeate from UF up to 15–20 g TSS/100 g. A final OMD step yielded a concentration of the retentate from the RO up to 60–63 g TSS/100 g.

Shaw [152] has carried out pilot scale experiments for the concentration of orange and passion fruit juices involving microfiltration followed by osmotic evaporation. Both juices were concentrated threefold to 33.5°Bx and 43.5°Bx, respectively.

Cassano et al. [153] proposed an integrated membrane process involving OMD for concentration of kiwifruit juice (Figure 19.17). They passed 10°Bx–11°Bx juice through a UF membrane to separate solids (pulp) from the serum. Solids were passed through a pasteurizer, while serum was preconcentrated using RO to 25°Bx–26°Bx. This was fed to an OMD device, which further concentrated the juice to 63°Bx–65°Bx. The diluted OA (brine) was recycled after concentration using a conventional evaporator. This concentrated juice was reconstituted with the pasteurized pulp. Alvarez et al. [154] conducted an in-depth study on integrated membrane processing of fruit juice, which they found to be comparable if not better than the conventional process. Using an integrated process for treatment of apple juice, they used an enzyme–membrane reactor to clarify the raw juice, reverse osmosis to preconcentrate the juice up to 25°Bx and pervaporation to recover and concentrate aroma compounds. An evaporation step to concentrate apple juice to 72°Bx was followed by an aroma reconstitution step.

These operations were tested in both laboratory and pilot plant units. The product was far superior to apple juice produced by conventional methods. Details on investment cost of conventional and integrated membrane processes are

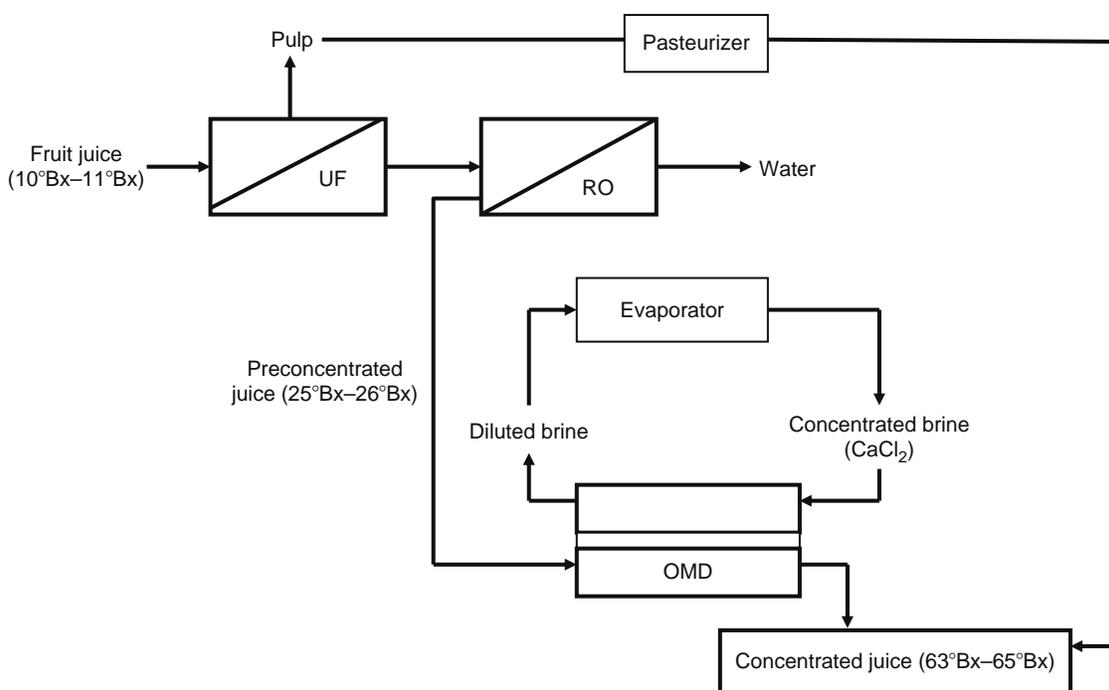

FIGURE 19.17 Integrated membrane process for production of fruit juice concentrates.

shown in Table 19.7. The analysis of profitability indicated that return on investment in conventional process and membrane process is 24.6% and 30%, respectively, with corresponding pay back period of 4.1 and 3 years.

## 19.8 FUTURE DIRECTIONS

The MD process has several technical advantages and scope for promoting its industrial application. However, implementation of MD on process scale would require long-term validation on a pilot scale. For achieving these goals more intensive and focused research effort is needed in this field. Research on new membrane materials and composite membranes that enhance transmembrane flux and selectivity is required. Modeling and scale-up studies will form an integral part of this activity.

Studies also need to be undertaken for the enhancement of transmembrane flux in the presence of the acoustic field for applications on a large scale.

Integrated processes encompassing MD and its variants (OMD) are likely to provide solutions to challenging problems like aroma and fragrance retention in food products.

The literature suggests that most of the studies on the application of MD in juice processing have focused on producing highly concentrated juices. However, little attention has been paid to influence juice composition on the mass transfer, membrane properties, and quality of resulting concentrated juices.

In view of the possible industrial applications of MD for concentration of juice, beverages, and aroma compounds, sufficient quantifiable data need to be generated within installations working in continuous mode rather than batch mode.

## GLOSSARY

**Asymmetric membrane**—A composite membrane, consisting of two or more structural planes of nonidentical morphologies.

**Boundary layer**—Fluid layer in contact with membrane surface in which velocity gradient exists unlike the bulk fluid.

**Concentration**—Increasing solute percentage in solution by the removal of solvent.

**Concentration Polarization**—Accumulation of solute rejected by membrane in the vicinity of the membrane surface resulting a gradient in concentration of the solute (higher than the well mixed bulk solution).

**Diffusion**—Process of movement of dissolved solute from higher to lower concentration.

**Fouling**—Deposition or adsorption of particulate or dissolved substances in the openings of the pores.

**Flux**—Amount of fluid passing through the membrane per unit area per unit time.

**Membrane**—A thin barrier or film through which solvents and solutes are selectively transported.

**Membrane Module**—The unit in which the membrane area is packed.

**Osmotic Pressure**—The pressure exerted due to difference in solute concentration between two distinct zones and can be calculated using Vant Hoff equation ( $\pi = CRT/M$ ,  $C$  = concentration of the solution,  $R$  = gas constant,  $T$  = temperature,  $M$  = molecular weight).

**Porosity**—Ratio of void space to total membrane volume (in porous membrane).

**Pore tortuosity**—Ratio of actual pore length to membrane thickness.

**Permeate**—The portion of the feed solution that passes through the membrane.

**Retentate**—The portion of the feed solution that is retained by the membrane.

**Spacers**—A mesh-like material used to separate successive layers of membrane and/or support backing.

**Transmembrane Pressure ( $\Delta P$ )**—Average pressure difference between the upstream and downstream sides of the membrane, which is the driving force.

**Temperature Polarization**—The difference in temperature of the bulk liquid and the membrane surface is called temperature polarization.

**Vapor and Gas**—Any vapor above its critical temperature is called gas.

**Volatile**—A compound is said to be more volatile if it gives more vapor on heating.

**Vapor pressure**—The pressure exerted by the vapor at equilibrium condition where the rate of condensation is equal to the rate of vaporization (all liquids and solids exhibit definite vapor pressure at all temperature).

## NOMENCLATURE

$a$	water activity (–)
$B$	net membrane coefficient ( $s\ m^{-1}$ )
$B_0$	viscous flux coefficient ( $m^2$ )
$b$	stirred cell diameter (m)
$C_p$	molar heat capacity ( $J\ mol^{-1}\ K^{-1}$ )
$C_{ij}$	mass conductance of pore $ij$ (–)
$C_f$	solute concentration in feed ( $mol\ l^{-1}$ )
$D$	diffusion coefficient ( $m^2\ s^{-1}$ )
$D_w$ or $D_{w-air}$	water diffusion coefficient ( $m^2\ s^{-1}$ )
$D_t$	plate thickness (m)
$D^k$	Knudsen diffusion coefficient ( $m^2\ s^{-1}$ )
$D^o$	pressure independent $D$ ( $pa\ m^2\ s^{-1}$ )
$d$	tube diameter (m)
$d_e$ or $d_h$	equivalent diameter (m)
$d_p$	pore diameter (m)
$G$	mass velocity ( $kg\ s^{-1}$ )
$H$	overall heat transfer coefficient ( $W\ m^{-2}\ K^{-1}$ )
$h$	individual heat transfer coefficient ( $W\ m^{-2}\ K^{-1}$ )
$h_1$	film heat transfer coefficient ( $W\ m^{-2}\ K^{-1}$ )
$h_f$	heat transfer coefficient for feed ( $W\ m^{-2}\ K^{-1}$ )
$h_p$	heat transfer coefficient for permeate ( $W\ m^{-2}\ K^{-1}$ )
$h_v$	vapor heat transfer coefficient ( $W\ m^{-2}\ K^{-1}$ )
$h_m$	heat transfer coefficient of the membranes ( $W\ m^{-2}\ K^{-1}$ )
$h_\infty$	heat transfer coefficient for fully developed flow in long pipes ( $W\ m^{-2}\ K^{-1}$ )
$J$	flux ( $l\ m^{-2}\ h^{-1}$ )
$J_m$	mass flux through membrane ( $l\ m^{-2}\ h^{-1}$ )
$K$	overall mass transfer coefficient ( $kg\ m^{-2}\ h^{-1}\ Pa^{-1}$ )
$K_m$	membrane coefficient ( $kg\ m^{-2}\ h^{-1}\ Pa^{-1}$ )
$K_B$	Boltzmann constant ( $J\ K^{-1}$ )
$K_0$	Knudsen diffusion constant (m)
$K_1$	molecular diffusion constant
$k_m$	membrane conductivity ( $W\ m^{-1}\ K^{-1}$ )
$k_s$	thermal conductivity of solid (polymer) ( $W\ m^{-1}\ K^{-1}$ )
$k_g$	thermal conductivity of gases (air and water vapor) ( $W\ m^{-1}\ K^{-1}$ )
$k_l$	thermal conductivity of liquid ( $W\ m^{-1}\ K^{-1}$ )

$k$	mass transfer coefficient through boundary layer ( $\text{m s}^{-1}$ )
$L$	tube length (m)
$L_p$	length of the wetted perimeter (m)
$l$	pore length (m)
$LEP_w$	liquid entry pressure of water (Pa)
$M$	molecular mass ( $\text{kg mol}^{-1}$ )
$m$	mass flow rate ( $\text{kg s}^{-1}$ )
$N$	molar flux ( $\text{mol m}^{-2} \text{sec}^{-1}$ )
$N_i$	total flux ( $\text{mol m}^{-2} \text{sec}^{-1}$ )
$N_i^D$	diffusive flux ( $\text{mol m}^{-2} \text{sec}^{-1}$ )
$N^V$	viscous flux ( $\text{mol m}^{-2} \text{sec}^{-1}$ )
$n_w$	mole concentration of water ( $\text{mol m}^{-3}$ )
$\Delta_{nw}$	water vapor mole concentration difference ( $\text{mol m}^{-3}$ )
$P$	pressure (pa)
$P_{m1}$	partial pressure of vapor at membrane surface on feed side (pa)
$P_{m2}$	partial pressure of vapor at membrane surface on permeate side (pa)
$P_a$	partial pressure of air (pa)
$P_{avg}$	average gas (air) pressure inside the membrane (pa)
$P_{ref}$	reference pressure (pa)
$P_r$	dimensionless pressure ( $P_{avg}/P_{ref}$ )
$P_{am}$	logarithmic mean pressure of air (pa)
$P_w$	partial vapor pressure of water (pa)
$P_{pavg}$	average pore pressure (pa)
$\Delta P$	vapor pressure difference (Pa)
$Q$	heat flux ( $\text{w m}^{-2}$ )
$Q_v$	latent heat flux ( $\text{w m}^{-2}$ )
$Q_c$	conductive heat flux ( $\text{w m}^{-2}$ )
$Q_f$	rate of heat transfer through feed boundary layer ( $\text{w m}^{-2}$ )
$AQ_p$	rate of heat transfer through permeate boundary layer ( $\text{w m}^{-2}$ )
$Q_m$	heat transfer across the membrane ( $\text{w m}^{-2}$ )
$Q_a$	heat transfer across the air gap ( $\text{w m}^{-2}$ )
$R$	gas constant ( $\text{J mol}^{-1} \text{K}^{-1}$ )
$r_H$	hydraulic radius of channel (m)
$r$	pore radius (m)
$S$	cross-sectional area ( $\text{m}^2$ )
$T$	temperature (K)
$T_f$	feed temperature (K)
$T_p$	permeate temperature (K)
$T_{s1}$	hot membrane surface temperature (K)
$T_{s2}$	cold membrane surface temperature (K)
$T_{s3}$	dew point temperature of the vapor (K)
$T_{s4}$	solid surface temperature (K)
$T_{m1}$	feed side membrane temperature (K)
$T_{m2}$	permeate side membrane temperature (K)
$T_a$	air temperature (K)
$T_{avg}$	average temperature (K)
$T_{pavg}$	average pore temperature (K)
$T_{sr}$	temperature of the feed solution at source (K)
$\Delta T_f$	temperature difference (between feed and permeate fluids) (K)
$\Delta T_m$	temperature difference (between membrane surfaces) (K)
$v$	mean molecular speed ( $\text{m s}^{-1}$ )
$w_{in}$	inlet humidity ratio
$x$	liquid mole fraction
$x_a$	mean mole fraction of air
$y$	vapor mole fraction
$Y_{ln}$	mole fraction of air (log mean)
$\mu$	viscosity (Pa s)

$\mu_c$	viscosity of condensate film (Pa s)
$\mu_w$	viscosity at wall temperature (Pa s)
$\lambda$	mean free path (m)
$\lambda_L$	latent heat of vaporization (J kg <sup>-1</sup> )
$\sigma$	collision diameter of the molecule (saturated water $\sigma = 2.7 \text{ \AA}$ )
$\varepsilon$	fractional void volume or porosity (-)
$\tau$	tortuosity factor (-)
$\gamma_l$	liquid surface tension (N m <sup>-1</sup> )
$\delta$ or $\delta_m$	membrane thickness (m)
$\delta_g$	air gap thickness (m)
$\delta_c$	condensate film thickness (m)
$\rho$	density (kg m <sup>-3</sup> )
$\rho_f$	density of condensate film (kg m <sup>-3</sup> )
$\alpha$	yaw angle <sup>o</sup>
$\theta$	contact angle <sup>o</sup>

### DIMENSIONLESS NUMBERS

$Nu$	Nusselt number
$Kn$	Knudsen number
$Pe$	Pecklet number
$Re$	Reynolds number
$Pr$	Prandtl number
$Gz$	Greatz number
$Sh$	Sherwood number
$Sc$	Schmidt number

## 20.1 PLACE AND ROLE OF MEMBRANE SEPARATION IN THE BEER INDUSTRY

Beer is the second most consumed beverage in the world after tea [1]. Beer production reached approximately 1.48 billion hL/year\* in 2003 and keeps increasing every year. The world per capita consumption in the same year was 23.6 L, the highest consumption being recorded in the European Union (70 L) and on the American continent (66 L) [2]. The beer industry is continuously challenged to meet the high standards required for producing beer of consistent quality, with unique taste and flavor, while maintaining relatively low production costs and minimizing waste disposal. For the modern, highly demanding consumer, purity and freshness are extremely important characteristics of a good beer, and this is why the beer industry is permanently seeking new technical solutions that will enable it to deliver a product matching its customers' expectation.

Membrane separation is increasingly emerging as an attractive alternative processing method for the brewing industry, with applications ranging from beer clarification and cold sterilization to tank bottoms recovery, alcohol removal, as well as water and effluent treatment. Other applications of membrane separation include the filtration of utilities, such as air filtration for tank venting in yeast storage tanks or the filtration of air used for wort aeration. Another utility that could be filtered is the steam used in the yeast storage and propagation area. Part of this steam or its condensate might come in contact with the yeast, and therefore the steam needs to be filtered to separate any contaminating particles. Figure 20.1 shows an overview of the chemical and biological species that can be found in beer, as well as the membrane processes that can be used to separate these molecules or particles based on their size, from reverse osmosis (RO) to microfiltration (MF). Figure 20.2 provides a simplified process flow diagram of a brewery, indicating the products and processes involving membrane separation reviewed here.

**FIGURE 20.2** Simplified process flow diagram of a brewery. The shaded blocks indicate the products and processes that may use membrane separation.

Laboratory applications for microbiological analyses are another area where membrane separation is used in the brewing industry. Such applications are not described in detail in this chapter, as they are not necessarily specific to brewing.

## 20.2 FACTORS THAT INFLUENCE THE MEMBRANE SEPARATION OF BEER

The main factors that affect the separation efficiency and yield in the membrane separation of beer are beer composition, membrane characteristics, process parameters, and membrane fouling.

### 20.2.1 BEER COMPOSITION

Filtration and storage behavior of beer depend strongly on its chemical composition (Table 20.1). Beer production is based on natural ingredients and therefore beer contains a wide variety of chemical compounds. Most chemical components of beer have an influence on beer filtration in general and membrane filtration in particular. Carbohydrates, such as pentosans and  $\beta$ -glucans, proteins and protein–polyphenol complexes, are of particular importance in membrane filtration of beer, as they are responsible for membrane fouling [3], which has negative consequences on both the flux and quality of the filtered beer, as it will be discussed in detail later on in this chapter.

Among carbohydrates, it is the high mass molecular weight compounds that, under certain conditions, can impede the efficiency of beer filtration. About 80% of these carbohydrates are represented by molecules that contain 4–20 glucose residues, and only about 20% have more than 20 glucose residues. Dextrins ( $\alpha$ -glucans) do not affect beer viscosity and have solely a caloric contribution [4,5].

$\beta$ -glucans are polymers of glucose that are found in the endosperm of barley, primarily in the cell walls. Some  $\beta$ -glucans can have a molecular weight of above  $10^6$  Da. Their presence represents one of the major factors that lead to low filterability of beer, as well as haze formation during storage. Based on their molecular size,  $\beta$ -glucans can be divided into the following categories [6]:

1.  $\beta$ -glucans of molecular size  $>0.2 \mu\text{m}$
2.  $\beta$ -glucans of molecular weight  $>300,000$  Da (which, together with those from the first category, represent about 57% of the total  $\beta$ -glucan amount)
3.  $\beta$ -glucans of molecular weight between 30,000 and 300,000 Da (about 10% of the total)
4.  $\beta$ -glucans of small and medium molecular weight—below 30,000 Da (about 30% of the total)

Despite the fact that the data available in literature is somewhat controversial, the amount of  $\beta$ -glucans in beer is generally considered to range between 300 and 700 mg/L, from which about 10% can be found in gel form [8]. An extensive review and

characterization of barley  $\beta$ -glucans' structure and properties has been published recently by Vaikousia et al. [8]. The flow behavior and gelling properties of barley  $\beta$ -glucans are of special interest in brewing, since an excess of  $\beta$ -glucans can cause problems such as slow filtration of wort and beer, as well as contribute to haze formation during storage [3,9].

The majority of the nitrogen compounds in beer have molecular weights between 5 and 70 kDa. The protein components of this fraction are of particular importance in brewing, as some of them contribute to foam formation (positive effect) while others, in association with polyphenols, lead to haze formation (undesirable effect) [10].

Beer contains a mixture of phenolic compounds, averaging about 150–350 mg/L, out of which about two thirds originate in barley and the remaining in hops [11]. Of these, polyphenols present the greatest interest for beer processing and storage, since they tend to associate with proteins into insoluble complexes, leading to the formation of cold haze in beer.

### 20.2.1.1 Haze Formation and Its Impact on Beer Filtration and Stability

Beer stability, defined as the ability of beer to maintain its properties unchanged from bottling to the end of the estimated shelf life, has three distinct aspects: biological stability, colloidal stability, and sensory stability. The sensory stability of beer is closely related to its biological and colloidal stability, and additionally can be affected by the presence of oxygen, which leads to oxidative processes that can alter the taste of beer.

Biological stability is related to the yeasts and spoilage bacteria, which are possibly present in beer and could trigger undesirable sensory and aspect changes during beer shelf life. In order to ensure its biological stability, microorganisms have to be removed from beer, which for yeast cells is achieved by filtration. The maximum limit allowed for the number of yeast cells accepted for filtered beer is generally 5 cells per 100 mL, but the modern filtration techniques can yield less than 2 cells per 100 mL beer [12].

In colloidal stability the presence of visible haze can significantly limit the shelf life of beer. Haze compounds can also contribute to the fouling of equipment surfaces, forming deposits that are difficult to remove by in-place cleaning [13]. A generic composition of beer haze is given in Table 20.2. Based on their size, the haze-forming particles can be classified into the following categories [14]:

- Coarse dispersions (sizes  $>0.1 \mu\text{m}$ ) represent the macroscopic haze and is formed out of coagulated proteins, yeasts, and bacteria.
- Colloids (size between  $0.01$  and  $0.1 \mu\text{m}$ ), which can be visualized under refracted light, are represented by proteins, gums, and resins from hops.
- Molecular dispersions ( $<0.01 \mu\text{m}$ ) cannot be visualized.

Haze formation is mostly attributed to proteins, polyphenols, and their interactions. It is also possible that there are also other factors that influence haze formation in beer, but their effect has not been yet clearly defined [15]. The amount of haze formed depends both on the concentration of proteins and polyphenols, and on their ratio. Polyphenols can combine with proteins to form colloidal suspensions that scatter light, which creates the cloudy appearance of beer. Beer polyphenols originate partly from barley and partly from hops. The beer polyphenols most closely associated with haze formation are the proanthocyanidins, which are dimers and trimers of catechin, epicatechin, and gallic acid. These have been shown to interact strongly with haze-active proteins [13,15–17] and their concentration in beer was directly related to the rate of haze formation [18]. Ahrenst-Larsen and Erdal [19] have demonstrated that anthocyanogen-free barley produces beer that is extremely resistant to haze formation, without any stabilizing treatment, provided that hops do not contribute polyphenols either. Not all proteins are equally involved in haze formation. It has been shown that haze-active proteins contain significant amounts of proline and that proteins that lack proline form little or no haze in the presence of polyphenols [13,15–17]. In beer, the source of the haze-active protein has been shown to be the barley hordein, an alcohol-soluble protein rich in proline [16].

At least initially, the protein–polyphenol complexes are held together by weak associations and haze can be dispersed by warming, which in brewing is commonly referred to as reversible haze or chill haze. The practical consequence of this phenomenon is that beer should be filtered at the lowest possible temperature. The mechanism of haze formation appears to be

**TABLE 20.2**  
**Main Components of Beer Haze**

Compounds	Concentration (mg/L)
Total nitrogenous substances ( $N \times 6.25$ )	450–650
Polyphenols	200–600
Dextrins plus $\beta$ -glucans	150–200
Glucose	20–40
Minerals	7–35

a non-covalent interaction—a combination of hydrogen and hydrophobic bonding—in which protein molecules are held together by polyphenolic compounds acting as bridges [16]. According to Siebert and Lynn [20], polyphenols bind only to specific sites in haze-active proteins, and the largest amount of haze forms in situations when there are comparable numbers of polyphenol-binding sites in the proteins and binding ends of the polyphenol molecules. Since beer contains a large excess of haze-active proteins as compared to haze-active polyphenols, most of the polyphenols are able to bridge two proteins together, but there are not enough polyphenols to link these protein–polyphenol–protein aggregates, which results in relatively small particles [20].

### 20.2.2 MEMBRANE CHARACTERISTICS

Generally, the operating conditions in a brewing operation involve high flow rates, high pressures, and high production capacity, which is challenging for any type of filtration operation. The filtration media must also withstand the high temperatures, extreme pH conditions, and large temperature differences used during cleaning (i.e., from 0°C during filtration to about 80°C in the cleaning stage). The membranes used in beer processing have to comply with all these conditions. The membrane types typically used in beer filtration applications are flat sheets, hollow fibers, or ceramic. It should be noted that ceramic membranes have better chemical and temperature resistance as compared to polymeric membranes, but typically require higher investment and membrane replacement costs.

Recent research efforts brought about new and exciting developments in membrane technology, some with direct implications for the membrane filtration of beer. For example, Stopka et al. [21] reported flux enhancement in the microfiltration of a beer yeast suspension when using a ceramic membrane with a helically stamped surface. A relatively simple modification of the ceramic membrane surface resulted in modified hydrodynamic conditions and disturbance of the fouling layer. As compared with a regular, smooth ceramic membrane of the same nominal pore size, the stamped membrane leads to higher flux and lower power consumption per unit volume of permeate at the same velocity of the feed.

Kuiper et al., in The Netherlands, developed and fabricated ceramic microsieves with a very small flow resistance and used them for beer clarification [22,23]. They reported fluxes about two orders of magnitude larger than fluxes typically obtained membrane in separation of beer ( $\sim 10^4$  L/(m<sup>2</sup> h)), and a good quality of the filtered beer—a haze value of 0.46 EBC after 9 h of filtration was reported. These membranes allowed for much less fouling as compared to the traditional membranes. Although very promising, the manufacturing of these membranes is still in the experimental stage and scaling up is required.

The development of high-selectivity nanotube membranes might also have some potential for beer membrane filtration. Carbon nanotube membranes can be functionalized and tailored to efficiently separate molecules both on the basis of their molecular size and shape, and on chemical affinity [24]. Newly developed nanotechniques can be used to functionalize supported microfiltration or ultrafiltration polymeric membranes by filling their pores with polymeric or oligomeric liquids that have an affinity for the compound of interest [25]. An Australian–American team of researchers has developed a nanoparticle-enhanced membrane that combines organic polymers with inorganic silica nanoparticles, which enable large molecules to pass through more readily than small molecules [26]. The addition of the silica resulted in over 200% improvement in the flux and increased the permeability of the membrane. The reported use of these membranes is to purify fuel (ethanol and methanol) inexpensively, but food-related applications, including beer filtration, could also become possible. While still too expensive for regular food applications, such technologies might become a feasible technical solution in the future.

### 20.2.3 MEMBRANE FOULING IN MEMBRANE SEPARATION OF BEER

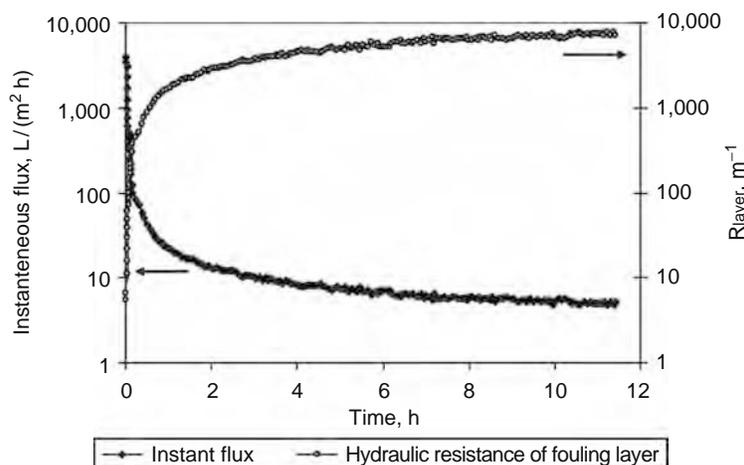

Crossflow microfiltration (CMF) using semipermeable membranes has been evaluated as a potential alternative to conventional processing in the brewing industry since the early 1980s. Yet, the extensive adoption of this technology by the beer industry was hindered by the protein and aroma retention, and the severe flux decline (Figure 20.3) that takes place during this process.

The drastic reduction of the permeate flux to only a fraction of the theoretical capacity of the membrane is rather common in pressure-driven membrane processes, but it is more pronounced for beer as compared to other fluid foods such as milk, wine, or fruit juices. This explains the earlier introduction of membrane technology at a commercial scale in those industries as compared to the beer industry.

Eagles and Wakeman [27] noted that when filtering beer through membranes with pore sizes less than 0.5  $\mu\text{m}$  the filtered beer (permeate) lacks some components that are important for bitterness, fullness, and foam retention characteristic to beer. When filtering beer through a 0.22  $\mu\text{m}$  polysulfone membrane, Ryder and coworkers [28] found decreases in original gravity (12.30–11.73°P)\* alcohol (3.94–3.78 wt%), protein (0.72–0.59 wt%), and bitterness (15.1–13.5 EBU). Both flux reduction and quality effects have been attributed to membrane fouling and concentration polarization.

It is important to distinguish the effects of membrane fouling from those of concentration polarization. At the initial stage of a filtration run, the solids concentration at the membrane level is relatively small, but it builds up progressively as permeate is removed from the system. If a substantial flux decline is observed at low solids concentration, membrane fouling aspects are believed to be important. A flux decrease with an increase in solids concentration is largely due to concentration polarization.

\* °P = Degree Plateau; represent total amount of soluble solids in beer, in kg/100 kg.

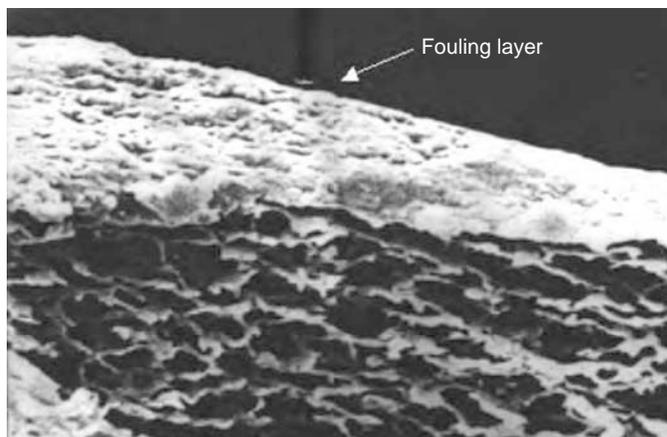

**FIGURE 20.3** Evolution of flux with time in the CMF of rough beer with a cellulose acetate membrane of  $0.45 \mu\text{m}$  pore size. (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University “Dunarea de Jos” Galati, Romania, 1999.)

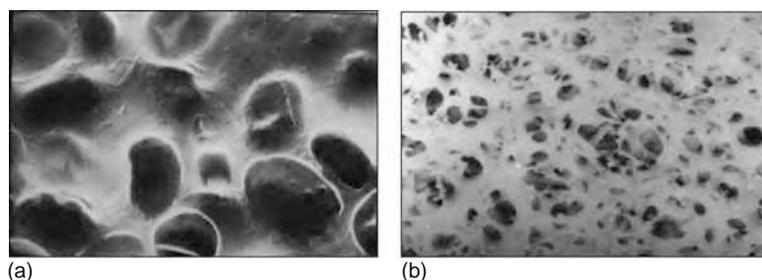

During membrane filtration, some components (dissolved molecular species or particulates) of the feed are rejected by the membrane and are transported back into the bulk by diffusion. If the concentration of the solute(s) at the surface is above the solubility limit, a gel layer is formed.

The occurrence of fouling affects the performance of a membrane either by deposition of a layer onto the membrane surface or by total or partial blockage of the pores, which changes the effective pore size distribution. Blanpain-Avet et al. [29] investigated the fouling mechanisms and protein rejection for the microfiltration of a beer previously clarified by kieselguhr filtration through a  $0.2 \mu\text{m}$  polycarbonate membrane, and concluded that the permeate flux decay was governed by two successive fouling mechanisms. An internal pore fouling took place during the initial stages of filtration, followed by external surface fouling. The change of protein retention level throughout the duration of filtration was found to be closely related to the nature of fouling, with an initial high-protein transmission rate being followed by a sharp decrease. Protein retention remained constant and low ( $<20\%$ ) during the internal pore fouling stage, then increased abruptly (up to  $60\%$ ) and stabilized when a steady fouling gel layer formed over the membrane surface. Figures 20.4 and 20.5 represent a visualization of the fouling layer characteristic for membrane filtration of beer [30].

The analysis of the fouling layer performed by Gans [12] and then by Taylor and coworkers [31] showed that it contains carbohydrates, proteins, and polyphenols, and that the composition is dominated by proteins associated with polyphenols and  $\beta$ -glucans. Gans reported that in the CMF of rough beer with hollow fiber polysulphonic membranes of  $0.45 \mu\text{m}$  pore size the total amount of the fouling layer per unit of membrane area was  $8.6 \text{ g/m}^2$ , and consisted of  $5.5 \text{ g/m}^2$  total nitrogen compounds,  $1.3 \text{ g/m}^2$  polyphenols, and  $1.8 \text{ g/m}^2$   $\beta$ -glucans [12]. Gan noted that, besides the chemical species mentioned in the above

**FIGURE 20.4** Scanning electron micrographs (SEM) micrographs of the cross section of a cellulose acetate membrane of  $0.45 \mu\text{m}$  pore size after being used for beer CMF experiments. A dense fouling layer is observed on the membrane surface. (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University “Dunarea de Jos” Galati, Romania, 1999.)

**FIGURE 20.5** SEM micrographs of a cellulose acetate membrane of  $0.45\ \mu\text{m}$  pore size used in beer CMF experiments. (a) New, clean membrane surface; (b) membrane surface after beer CMF. (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University “Dunarea de Jos” Galati, Romania, 1999.)

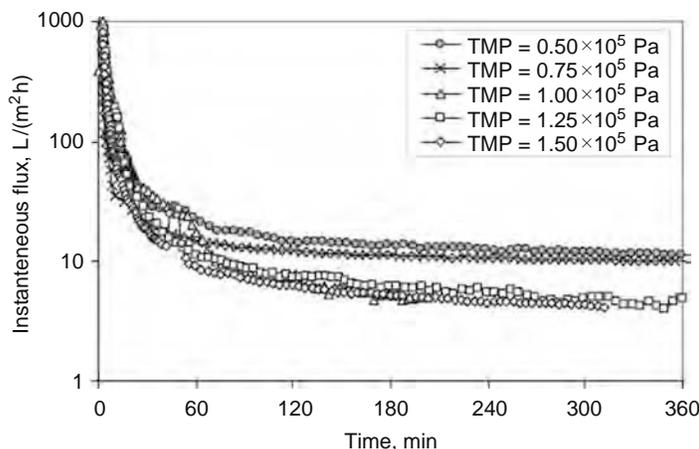

studies, trace minerals such as  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$  also play an important role in the surface complexation of the key membrane foulants [32]. The author hypothesized that these ions act as sequestering or chelating agents in the formation of macromolecular complexes, which results in stronger fouling and a tighter structure of the fouling layer. This supports the earlier conclusions of Güell and Davis, who reported that protein fouling of membranes does not depend on the size of individual proteins, but rather on their ability to form aggregates [33].

The presence of  $\beta$ -glucans, and particularly the deposition of a dense  $\beta$ -glucan gel layer at the membrane surface, is considered to be another critical factor in fouling during membrane filtration of beer. The mechanisms of  $\beta$ -glucan gel formation are described in detail by Vaikousia et al. [8]. The  $\beta$ -glucan gel has a thixotropic character [8,34,35], which means that its viscosity becomes smaller at high shear rates. It is also worth mentioning that beer itself has as a Newtonian behavior, and therefore its viscosity is not affected by shear. The enzymatic solubilization of  $\beta$ -glucans could potentially diminish the filtration problems created by the  $\beta$ -glucan gel, but labeling requirements limit this practice in many countries, as the addition of enzymes needs to be specified on the label, which might have a negative impact on traditionalist consumers.

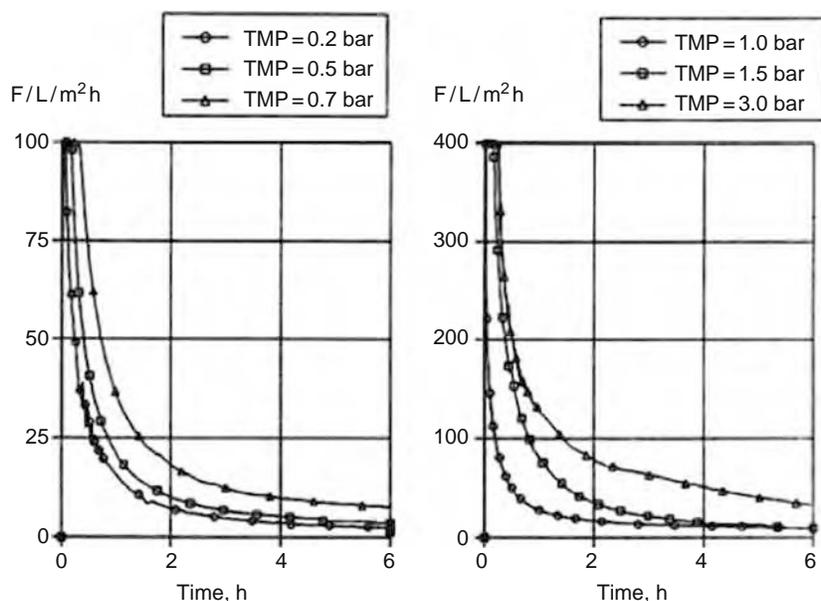

It is generally agreed that yeast cells do not really play a role in membrane fouling [12,30,32]. Gan proved that increasing yeast cell concentration had almost no appreciable effect when the fractional mass concentration of large particles increased from 0.015% to 0.059% [32].

#### 20.2.4 INFLUENCE OF PROCESS PARAMETERS ON MEMBRANE SEPARATION OF BEER

The driving force in CMF is transmembrane pressure (TMP), defined as the pressure differential between the feed side and the permeate side. Given the fact that CMF is a pressure-driven process, it would be expected that the higher the TMP, the larger the permeate flux. Yet, the results of beer CMF studies published in literature demonstrate that the TMP–flux relationship is not necessarily straightforward. Gan reported that changing TMP between 0.3 and 1.15 bar (30–115 kPa) did not produce any significant effect on the 10 h average flux in the CMF of beer with ceramic membranes (Ceramem Corporation, Waltham, Massachusetts) of  $0.5\ \mu\text{m}$  nominal pore diameter [32]. He did, however, observe the beneficial effect of increased TMP when

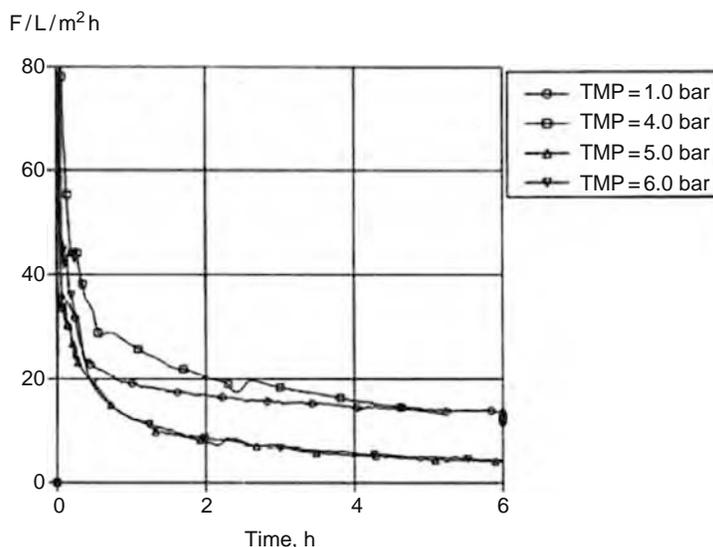

**FIGURE 20.6** Effect of TMP on the permeate flux in beer CMF through a  $0.45\ \mu\text{m}$  cellulose acetate membrane, at  $T = 0^\circ\text{C}$  and  $w = 2\ \text{m/s}$ . (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University “Dunarea de Jos” Galati, Romania, 1999.)

**FIGURE 20.7** Effect of low TMP values on the permeate flux in beer CMF through a  $0.45\ \mu\text{m}$  polysulphonic membrane. (From Gans, U., *Die wirtschaftliche Crossflow-Mikrofiltration von Bier*. Fortschritts-Berichte VDI Reihe 3 Nr. 385. Düsseldorf, Germany: VDI-Verlag, 1995. With permission.)

using a reversed morphology membrane. Details about this technique will be discussed later on in this chapter. On the other hand Moraru [30], who performed beer CMF experiments using single sheet cellulose acetate membranes with  $0.45\ \mu\text{m}$  nominal pore size, observed that generally higher TMP values resulted in higher values of the initial permeate flux, but lower values of the flux after 6 h of microfiltration (Figure 20.6). This is explained by the fast build-up of a fouling layer at high TMP values, which counteracts the faster transport of the filtered beer through the membrane.

These conclusions are similar to those of Gans, who performed beer CMF experiments with a polyethersulphone hollow fiber membrane of  $0.45\ \mu\text{m}$  nominal pore size [12]. He did observe a slight increase of the permeate flux when increasing TMP up to  $\sim 4$  bar (400 kPa) (Figure 20.7), but increasing the TMP to 5–6 bar (500–600 kPa) resulted in a negative effect on the permeate flux (Figure 20.8). The same effect is observed in industrial scale installations.

**FIGURE 20.8** Effect of  $\text{TMP} > 1$  bar on the permeate flux in beer CMF through a  $0.45\ \mu\text{m}$  polysulphonic membrane. (From Gans, U., *Die wirtschaftliche Crossflow-Mikrofiltration von Bier*. Fortschritts-Berichte VDI Reihe 3 Nr. 385. Düsseldorf, Germany: VDI-Verlag, 1995. With permission.)

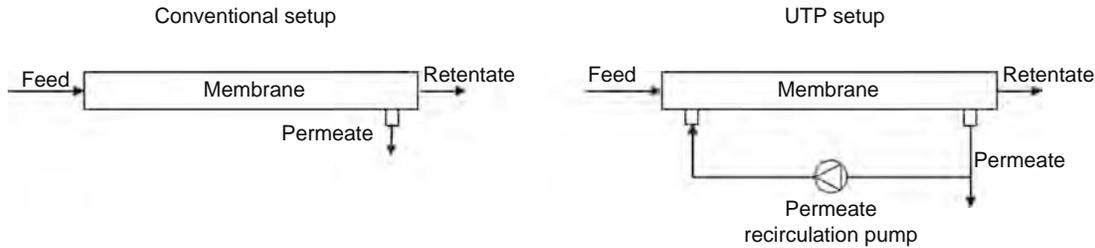

FIGURE 20.9 Conventional vs. UTP configurations in membrane separation.

A direct consequence of the effect of TMP in microfiltration is the unequal distribution of the fouling layer along the membrane. The TMP is the highest next to the feed inlet and decreases toward the end of the flow channel due to the drop in pressure along the membrane, caused by frictional forces. This happens especially when the process is conducted at high crossflow velocities, in which cases it is possible to experience TMP values at the module inlet up to 50% higher than the TMP values at the outlet [36]. The distribution of the fouling layer will closely follow the TMP distribution, with a more pronounced build-up near the entrance in the flow channel, which promotes unequal separation efficiency and yield. A solution that is sometimes used to alleviate this problem is the reversal of flow direction at certain time intervals, which allows the leveling of the fouling layer.

A recent approach to improving the CMF performance involves the concept of uniform transmembrane pressure (UTP). This is achieved by varying the pressure on the permeate side with a recirculation pump, which maintains the TMP at a constant value along the membrane. The schematics of the conventional crossflow and the UTP configurations are shown in Figure 20.9 and the TMP profiles for the two operational modes are shown in Figure 20.10. According to Bhave, flux improvements of up to 500% have been achieved when using UTP systems as compared with the conventional crossflow mode in many practical applications [36]. The membranes used in UTP systems must be able to structurally withstand significant backpressures on the permeate side, and therefore this concept cannot be used with all membrane types.

In beer microfiltration, besides the TMP level—which is chosen to achieve the best possible separation yield and efficiency—there are certain requirements for the value of the absolute pressure. The absolute pressure during this processing step needs to be higher than the saturation pressure of  $\text{CO}_2$  at the process temperature, to ensure that  $\text{CO}_2$  remains solubilized in beer.

It is generally accepted that crossflow velocity has a positive effect on yield in beer CMF, with higher fluxes being recorded at higher flow rates across the membrane surface (Figure 20.11).

In practical applications, one has to keep in mind that the permeate flux will be determined by the combination of crossflow velocity and TMP. As seen in Figure 20.12, the CMF experiments performed by Moraru indicated that the flux enhancement caused by increasing crossflow velocity was particularly pronounced at low values of the TMP ( $<1$  bar), due to the TMP effects discussed above [30]. Thomassen and coworkers studied the effect of varying TMP and crossflow velocity on the microfiltration fouling of a model beer using Carbosep filters of nominal pore size  $0.45 \mu\text{m}$  [37]. Fouling occurred over a range of TMPs and crossflow velocities at a constant temperature of  $20^\circ\text{C}$ . The permeate flux decreased with time during the development of the fouling layer, but once the fouling layer was established, the permeate flux became constant for a given set of experimental conditions. The steady-state flux increased with increasing TMP and with increasing crossflow velocity. For a given crossflow velocity, an increase in TMP resulted in an increase in the fouling layer thickness and density due to higher permeate fluxes. For a given TMP, an increase in crossflow velocity led to increased transmission, due to the inhibition of fouling layer development through the larger wall shear stress and thinner laminar sub-layer. Overall, it is therefore safe to say that moderate TMPs and high flow rates at the membrane surface are conducive of high permeate fluxes in the microfiltration of beer.

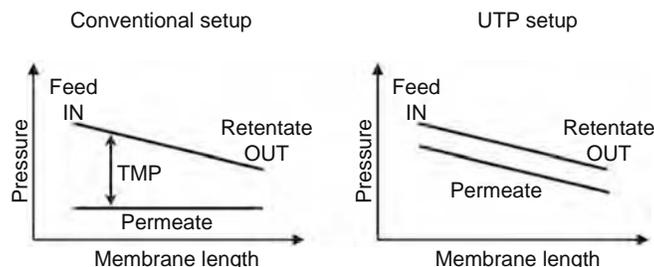

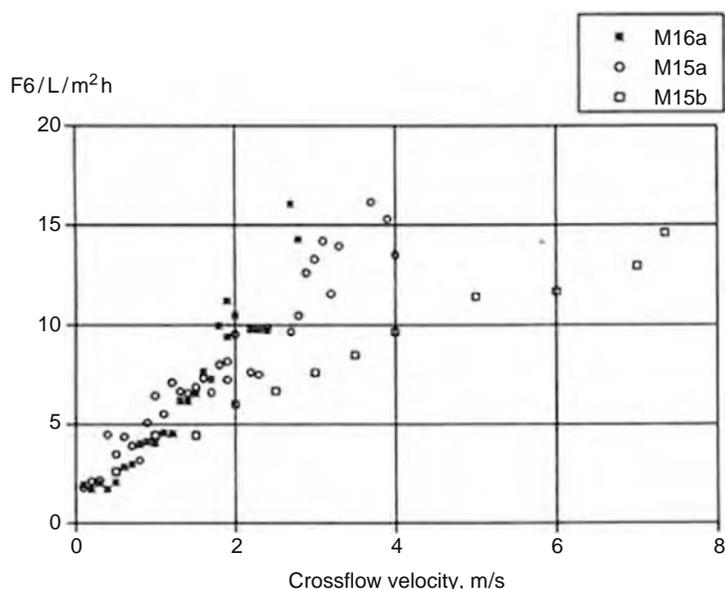

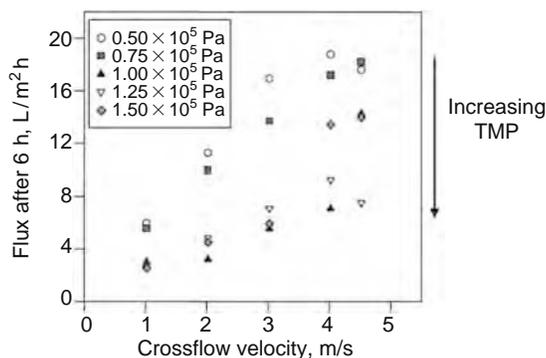

FIGURE 20.10 Pressure profiles in conventional and UTP configurations in membrane separation.

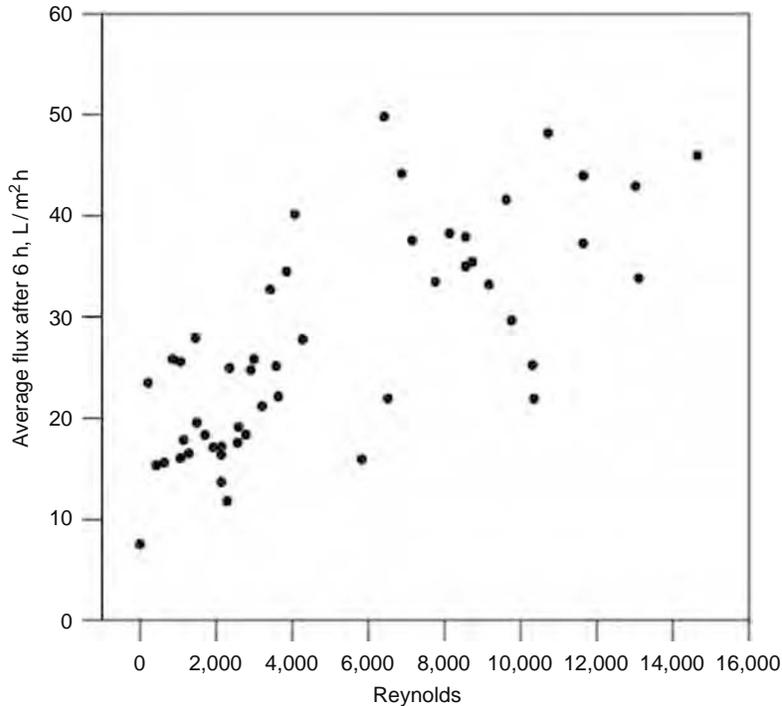

**FIGURE 20.11** Effect of crossflow velocity on the 6 h permeate flux in CMF of beer. Experiments were performed at  $0^{\circ}\text{C}$  and  $\text{TMP} = 1$  bar using  $0.45\ \mu\text{m}$  cellulose acetate membranes. Membranes used: M15a: Cellulose acetate with support,  $d_h = 7.67$  mm; M15b: cellulose acetate with support,  $d_h = 3.92$  mm; M16: cellulose acetate without support,  $d_h = 7.67$  mm ( $d_h =$  hydraulic diameter). (From Gans, U., Die wirtschaftliche Crossflow-Mikrofiltration von Bier. Fortschritts-Berichte VDI Reihe 3 Nr. 385. Düsseldorf, Germany: VDI-Verlag, 1995. With permission.)

The positive effect of velocity on the permeate flux is a result of enhanced hydrodynamic effects at the membrane surface, since high velocities lead to high shear and turbulent flow, which results in the formation of vortices and eddies that minimize the concentration polarization effects and the development of a fouling layer. The bigger the thickness of this layer, the higher its flow resistance and the smaller the permeate flux through the membrane becomes. Under turbulent flow conditions, shear effects induce hydrodynamic diffusion of the particles from the boundary layer back into the bulk, with a positive effect on the permeate flux.

Besides the velocity in the flow channel, the level of turbulence also depends on channel diameter, viscosity, and density of the retentate. The flow hydrodynamics can be characterized by calculating the Reynolds ( $Re$ ) number in the retentate stream.  $Re > 4000$  indicates turbulent flow, while  $Re < 2000$  indicates laminar flow. Gan reported that at  $Re < 2500$  the change of crossflow velocity had little, albeit positive, effect on the overall flux performance. It is important to note that Gan's conclusions are based on only three flow regimes, covering a relatively narrow range of hydrodynamic conditions [32]. A stronger correlation between the permeate flux and  $Re$  was reported both by Moraru [30] and Gans [12], who performed experiments in a much wider range of  $Re$  values. Figure 20.13 shows an overall positive effect of enhanced flow hydrodynamic conditions on the average permeate flux in beer CMF, although in the turbulent regime ( $Re > 4,000$ ) a weaker correlation and more data scattering were observed. In Figure 20.14, the clear correlation between the 6 h flux and  $Re$  in the laminar and transient regime can be observed.

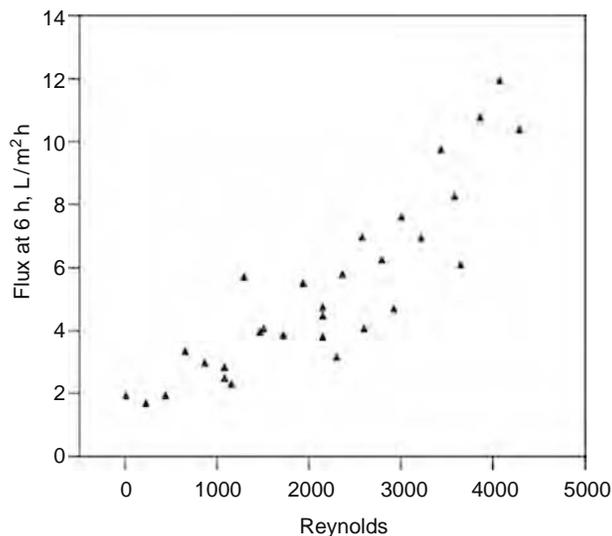

**FIGURE 20.12** Effect of crossflow velocity on the 6 h permeate flux in CMF of beer performed at various TMP values, a process temperature of  $0^{\circ}\text{C}$ , and cellulose acetate membranes of  $0.45\ \mu\text{m}$  pore size. (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University "Dunarea de Jos" Galati, Romania, 1999.)

**FIGURE 20.13** The interdependence between average flux and hydrodynamic conditions in a wide range of  $Re$  numbers for beer CMF performed at  $0^{\circ}\text{C}$  and  $\text{TMP} = 1$  bar. (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University “Dunarea de Jos” Galati, Romania, 1999.)

The relationship between permeate flux and the flow characteristics in microfiltration processes is often described using the film model, which is based on the concentration polarization concept [38]:

$$J = k \cdot \ln\left(\frac{C_m}{C_s}\right) \quad (20.1)$$

**FIGURE 20.14** Instant flux at 6 h vs.  $Re$  under laminar and transient flow conditions in beer CMF experiments performed at  $0^{\circ}\text{C}$  and  $\text{TMP} = 1$  bar. (From Moraru, C.I., Optimization and membrane processes with applications in the food industry: Beer microfiltration. PhD thesis, University “Dunarea de Jos” Galati, Romania, 1999.)

where

$J$  is the permeate flux (m/s)

$k$  is the mass transfer coefficient (m/s)

$C_m$  is the concentration of the separated species at the membrane level (g/L)

$C_s$  is the concentration of the separated species in the feed (g/L)

The mass transfer coefficient  $k$  in Equation [1] can be estimated using the following correlation [38]:

$$Sh = c \cdot Re^n \cdot Sc^m \quad (20.2)$$

where

$Sh = k \frac{d_h}{D}$  is the Sherwood number

$Sc = \frac{\nu}{D}$  is the Schmidt number

$Re = \frac{w \cdot d_h}{\nu}$  is the Reynolds number

$w$  is the velocity in the flow channel (m/s)

$D$  is the diffusion coefficient (m<sup>2</sup>/s)

$d_h$  is the hydraulic diameter of the flow channel (m)

$\nu$  is the kinematic viscosity of the product in the boundary layer (m<sup>2</sup>/s)

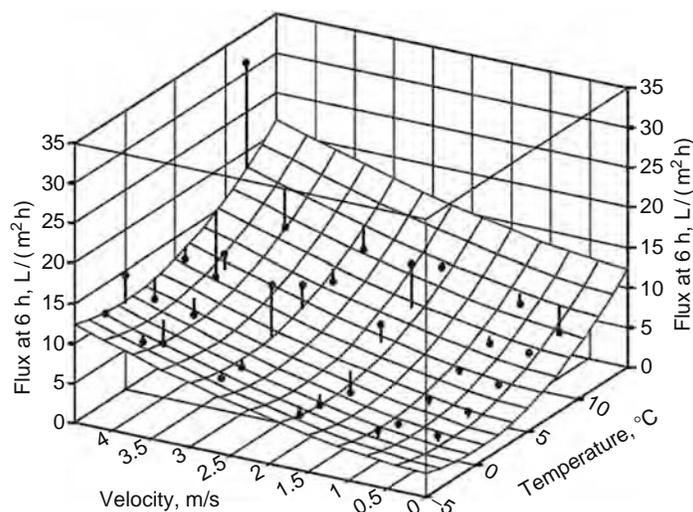

$c$ ,  $m$ ,  $n$  are the numerical coefficients

This leads to the fact that the mass transfer coefficient, and thus the permeate flux, is related to velocity according to the relationship:

$$k \sim w^n \quad (20.3)$$

According to Blatt et al. [39], the value of  $n$  can vary from 0.3 to 0.8 in laminar flow and from 0.8 to 1.3 in turbulent flow, with the lower limit of the range applying to low-particle concentration of the feed, and the upper limit applying to high-particle concentration of the feed. This behavior has been explained by the so-called tubular pinch effect, which enhances the movement of particles away from the boundary layer as turbulence increases, thus reducing the concentration polarization effect [36]. Moraru reported that in CMF of beer  $k \sim w^{0.8}$  for the laminar flow regime, but the dependence of the mass transfer coefficient on crossflow velocity was much weaker in the turbulent range, with  $k \sim w^{0.33}$  [30].

While higher process temperatures do have a positive effect on permeate flux in membrane separation (Figure 20.15), due to lower product viscosity and enhanced hydrodynamics at the membrane surface, in beer microfiltration the value of this parameter is dictated by the technological requirement that beer be filtered cold, typically at temperatures between  $-1.5^\circ\text{C}$  and  $+2^\circ\text{C}$ .

**FIGURE 20.15** Increase of permeate flux as a function of crossflow velocity in beer CMF experiments performed at  $\text{TMP} = 10^5$  Pa. ## 20.3 SOLUTIONS FOR INCREASING THE PERMEATE FLUX IN MEMBRANE SEPARATION OF BEER

### 20.3.1 BACKWASHING AND BACKFLUSHING

Prevention or minimization of fouling and concentration polarization represents one of the main challenges that confronts membrane processing in general and membrane filtration of beer in particular. Various approaches have been developed to control membrane fouling and increase the permeate flux in CMF, including membrane selection and modification, boundary layer control, use of turbulence inducers, or pretreatment of the feed. The two main strategies that are currently used in beer CMF are proper membrane selection and boundary layer control.

Membrane fouling is primarily a result of membrane–solute interaction that is generally irreversible and requires chemical cleaning to restore the original separation properties of the membrane. Fouling effects can be accentuated or minimized by proper selection of membrane material properties such as hydrophobicity/hydrophilicity or surface charge, as well as membrane pore size. A discussion on the membranes that are typically used in beer processing was included in Section 20.2.2 of this chapter.

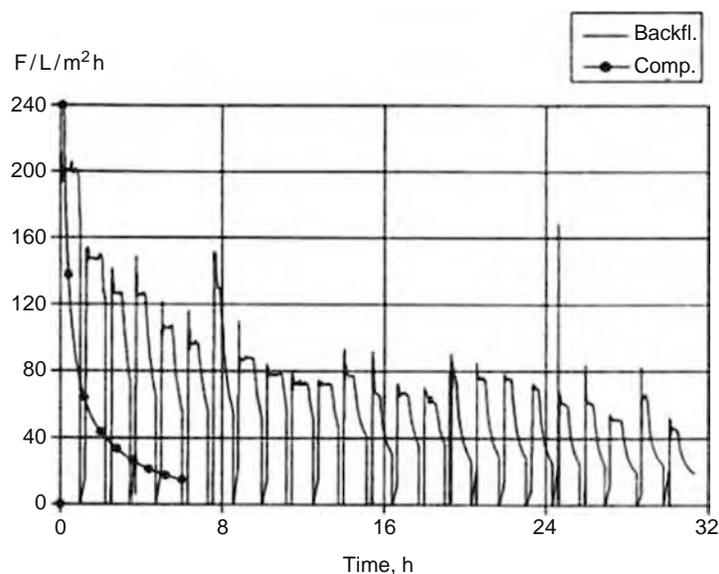

Concentration polarization and membrane fouling are the main factors that limit the commercial application of membrane filtration of beer. Small permeate fluxes increase the capital costs, because larger membrane surface area is necessary to achieve the desired production capacity, and may also result in poor product quality due to the undesirable retention by the membrane of some compounds that are critical for beer quality. The boundary layer can be controlled by backwashing or backpulsing, which consists of applying a negative pressure to the membrane by pushing a certain volume of permeate back through the membrane, with the purpose of reopening the clogged pores and membrane surface. The main difference between these two techniques is the speed and force utilized to dislodge accumulated matter on the membrane surface. In backpulsing, a high permeate backpressure (up to 10 bar) is applied periodically, typically in a fraction of a second, while backwashing uses permeate backpressure values of up to 3 bar for a few seconds. Backwashing is commonly used with polymeric membranes, due to their lower pressure limitation, while backpulsing is mostly used with inorganic membranes [36].

When using these techniques, it is recommended to start the backpulsing/backwashing procedures simultaneously with the filtration process, as they are no longer effective after the boundary layer is fully formed. For maximum economical benefits, it is recommended that backpulsing or backwashing is applied for the shortest duration possible. Since a certain amount of permeate is used by the backpulsing/backwashing programs, minimizing the duration of backpulsing/backwashing minimizes the permeate volume used in this process, thus minimizing the loss of productivity. The permeate volume typically used in such applications is about 1%–3% of the total permeate [36].

Gan reported the development of flux-enhancement techniques by taking into consideration the specific nature of fouling and the synergistic relationship between fouling and flux reduction that occur in beer CMF [32]. He tested a range of techniques, such as (i) enhancing surface hydrodynamics and producing secondary flow vortices through two-way reversing flow pulsation; (ii) superimposition of a helical-flow pattern to the bulk feed flow by installing helically wound baffle inserts within the flow channel; and (iii) an automated multistage backflush facility that generates backpulses of controllable frequency and strength. The author highlighted the predominant in-pore fouling formation in beer CMF and the ineffectiveness of hydrodynamic techniques in tackling this type of fouling. Application of the two-way reversing flow pulsation had little effect except when used in combination with a superimposed helical flow pattern. Backflushing was identified as a more effective technique in reducing the fouling caused by pore-entrance blockage and in-depth particle plugging. Among the multiple backflushing variables, frequency and strength of the backpulse were found to be the two most influential factors in determining the overall effectiveness of the backflush program. The author achieved an even greater flux improvement when applying high-frequency backflushing at reversed membrane morphology, which was achieved by changing port configuration so that the process fluid was fed to the substructure side of the membrane. When coupling backflushing and reversed membrane configuration, a flux increase of more than 870% as compared to the normal CMF was obtained. The author attributed the higher and steadier flux to the progressive interception and holding of particles inside the membrane's open matrix and support sublayer. This particle-holding mechanism was presumably able to prevent particles from directly approaching and blocking membrane pores, thus protecting the pores downstream.

Gans [12] combined the backwashing technique with chemical cleaning in beer CMF experiments performed with polymeric membranes. Such a program involved alternating 60 min filtration cycles with 15 min backflushing cycles (Figure 20.16). The backwashing cycle consisted of a caustic soda (0.05 mol/L) backwash, neutralization with hydrochloric acid, and then rinsing with water. This program was extremely efficient, with the average flux stabilizing at around 80 L/(m<sup>2</sup> h) after 4 h of filtration, which is more than 4 times the permeate flux obtained in the absence of the backwashing program (Figure 20.17). Such a procedure requires extreme caution to avoid the risk of mixing the chemical washing stream with the product stream, and requires special process control measures, preferably automation.

Blanpain-Avet and coworkers [40] reported that the use of oscillatory flow was also capable of permeate flux enhancements in CMF of beer due to disturbing concentration polarization and cake layer formation.

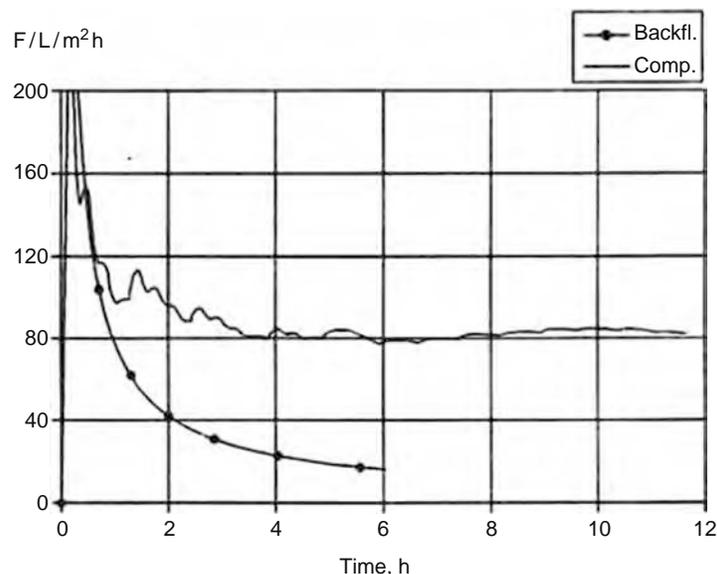

**FIGURE 20.16** Flux recovery using a caustic backwash program in beer CMF experiments performed with a polyethersulphone membrane of  $0.45\ \mu\text{m}$  pore size. Backfl. = CMF using the backwash program; Comp. = comparison experiment without backwashing. (From Gans, U., *Die wirtschaftliche Crossflow-Mikrofiltration von Bier*. Fortschritts-Berichte VDI Reihe 3 Nr. 385. Düsseldorf, Germany: VDI-Verlag, 1995. With permission.)

When such programs become relatively ineffective in preventing the abrupt flux decline, this indicates that irreversible fouling of the membrane has taken place, and this can only be corrected by chemical and thermal cleaning.

### 20.3.2 CHEMICAL CLEANING

The regeneration of membrane properties is key to maintaining its selectivity and yield. Without a safe, practical, reproducible, cost-effective, and efficient cleaning procedure, the viability of crossflow filtration is highly questionable [36]. The use of the mechanical means discussed above can help extend the membrane performance over a limited period of time, but the complete

**FIGURE 20.17** Effect of the caustic backwash program on the average flux in beer CMF experiments performed with a polyethersulphone membrane of  $0.45\ \mu\text{m}$  pore size. Backfl. = CMF using the backwash program; Comp. = comparison experiment without backwashing. (From Gans, U., *Die wirtschaftliche Crossflow-Mikrofiltration von Bier*. Fortschritts-Berichte VDI Reihe 3 Nr. 385. Düsseldorf, Germany: VDI-Verlag, 1995. With permission.)

removal of membrane foulants requires the use of chemical cleaning. A flush of warm water or ambient caustic is sometimes performed during the production in the form of an intermediate short-CIP, similar to the procedure designed by Gans [12] and described in Section 20.3.1. The purpose of such a program is not cleaning of the membrane but a mere loosening of the linkages between the gel-like fouling layer and the membrane structure, followed by subsequent flushing and removal with ambient water flush. With this short-CIP most of the membrane characteristics may be regenerated. Even with such programs in place, all membrane-based filtration processes require periodic cleaning that must remove both external and internal deposits.

Gan and coworkers [41] suggest that the most effective cleaning programs for membranes used in beer separations are those that combine the effect of temperature, oxidative agents, and caustic soda. Oxidation proved effective in removing the residual fouling due to the cleavage of covalent and hydrogen bonds by the oxidative attack. The  $\alpha$ -1,4 bonds in polysaccharides and peptide bonds in proteins are also susceptible to oxidative cleavage, and these compounds are degraded down to small molecules such as oxidized di- or monosaccharides, peptide segments, or amino acids. This breaks up the foulants from the membrane surface and opens up the deposit for further attack by the caustic. Such a combination of caustic cleaning and oxidation, when applied at a temperature of 80°C, was able to recover 87% of the original water flux within 8 min [41].

The development of an effective cleaning process has to take into account the nature of the foulants, the thermal and chemical resistance of the membrane material, membrane housing and seals. Typically, membrane manufacturers make specific recommendations regarding the cleaning agents and cleaning procedures that need to be used for different membranes and applications.

Membrane cleaners specifically formulated to remove the organic and inorganic foulants found in food and beverage applications, including beer, include a variety of acid, alkaline, surfactant blend, oxidizer, enzyme, and solvent-based membrane cleaners. Inorganic foulants such as precipitated salts of Ca and Mg can be removed with acidic cleaners, while protein and other biological residues can be removed with alkaline cleaners, with or without bleaching agents or enzyme cleaners. Many acidic and alkaline cleaners also contain small quantities of detergents, which act as complexing or wetting agents to solubilize or remove insoluble particles and colloidal matter. Oxidizing agents such as peroxide or ozone are also sometimes used to remove hardy foulants such as polysaccharides.

For many polymeric MF membranes, material considerations limit the use of high cleaning temperatures and strongly acidic, alkaline, or oxidizing solutions. With time and repeated cleaning, polymeric membranes undergo progressive degradation, which limits their service life to 2–4 years, depending on the polymer. On the other hand, inorganic membranes can be cleaned at high temperatures in strongly alkaline, acidic and oxidizing solutions, and can have a useful service life of 10 years or longer [36].

The useful life of membranes can be significantly extended using suitable cleaning, operating, and maintenance procedures, which will have a major economical impact for the processing plant. Recent developments in improved cleaning of the membrane surface resulted in an increase of the economic efficiency of the membrane separation of beer. The CMF equipment seen in the first industrial installations has been transformed into an integrated combination of filtration and cleaning installations. In some fully automated plants membranes can be switched from production mode to cleaning mode in very short time intervals.

## 20.4 USE OF MEMBRANE SYSTEMS IN BEER PROCESSING

### 20.4.1 BEER FILTRATION

After the fermentation and aging steps the beer is cloudy, despite the fact that after aging the beer is separated from most of the sedimented yeast and tank bottoms. This cloudiness results from the remaining yeast cells—yeast concentrations of approximately 200,000 cells/mL are common for beer after separation from the tank bottoms—and from the haze-forming components of beer.

The size of the haze-forming matter starts at the size of large clusters that are directly visible as particles suspended in the liquid or at the bottom of the bottle, and ends with colloidal haze particles that are not visible as sole particles but at higher concentrations scatter the light and give the beverage a turbid appearance. A certain fraction of the colloidal haze is temperature dependent, meaning that it is fully dissolved in beer at temperatures above +10°C but becomes visible at lower temperatures. To give beer the desired clear appearance, as well as longer stability, a filtration step is typically required. Since the formation of chill haze is temperature dependent, beer filtration is normally performed at low temperatures so that chill haze can be filtered out as large aggregate particles.

The removal of yeast cells and haze-forming colloids without unnecessarily removing other components of beer, especially some of the dissolved proteins, is the task and challenge of the beer filtration step. The efficiency of the main filtration of beer is measured by its removal of the yeast cells and by the remaining turbidity of the filtered beer. A common standard is that

the concentration of yeast cells in the filtered beer should be reduced to <5 yeast cells/100 mL of filtered beer.\* The turbidity of the filtered beer should be less than 1–2 NTU (nephelometric turbidity unit)<sup>†</sup>, depending on the specific beer recipe.

#### 20.4.1.1 Traditional Methods for Beer Filtration

The industry standard method for beer filtration is using diatomaceous earth (DE)<sup>‡</sup>, a sand-like powder with a very high internal surface area and a fine porous structure, as a filter aid in depth- and cake-type filtration. Conventional beer clarification employs filter presses or pressure vessel filters that are pre-coated with porous diatomaceous earth particles as filter aids. In order to minimize clogging of the filtration media and maintain a porous cake, and thus extend the duration of the filtration runs, filter aid is continuously metered into the unfiltered beer as body feed [42].

Nowadays an estimated 95% of the annual volume of beer is clarified using this filter aid. The use of DE in the beer industry has several disadvantages. First of all, this difficult to handle dry powder contains crystalline silica dioxide, a potential health hazard for those who handle it, and therefore it is necessary to prevent its inhalation.<sup>§</sup> Further, the wet filter aid known as DE slurry needs to be disposed after use. In most countries, including the United States, this slurry is simply disposed as landfill. There are, however, some facilities where a thermal recovery of the diatomaceous earth is used to decompose its organic content, and the processed diatomaceous earth can then be reused for filtration purposes. Such a processing facility is Tremonis GmbH in Dortmund, Germany. It is expected that the cost of using filter aids will increase in the future due to more stringent requirements for the disposal of the diatomaceous earth slurry that contains entrapped organic matter.

Sometimes, additional haze removal techniques are used in conjunction with diatomaceous earth filtration to ensure the long-term stability of beer. Based on the knowledge of what causes haze formation, two basic approaches to stabilize beer have been developed: reducing the concentration of haze-active proteins, or reducing haze-active polyphenols, or both. The most common stabilizer used for removing proteins during filtration is amorphous silica gel, while polyvinylpyrrolidone (PVPP) is typically used for removing polyphenols. Since beer has a significant excess of haze-active proteins over haze-active polyphenols, reducing the polyphenol content by adsorption using PVPP is considered an efficient way to haze stabilize beer [43].

The authors of this chapter are unaware of any existing filtration equipment that uses filter aid and is able to completely prevent the bleed of filter-aid particles into the filtered beer in a single filtration step. A small amount of the filter aid dosed into the liquid upstream will always be found in the filtered liquid downstream of the filtration equipment, as clearly shown in a recent paper by Hartmann and coworkers [44]. This bleed is technically inevitable, and a second filtration step is applied normally to remove the filter-aid particles from the filtered beverage.

#### 20.4.1.2 Use of Membrane Separation

Crossflow microfiltration membrane technology represents the best alternative to DE filtration available to date. Among the advantages of CMF as compared to DE filtration one could mention: use of materials (the membrane) that are inert to the product, easy to operate and environmental friendly, regeneration of the filtration media as well as the potential for high final product quality. As compared to DE filtration, membrane filtration does not use any filter aid and, therefore, there are no particles added in the process, rendering the filtered liquid free of foreign particles. Another advantage is that the CMF equipment occupies a much smaller volume than a traditional DE filter. At the initial stage of the process both types of filters are filled with water. The smaller equipment produces a smaller volume of water–beer mix at the outlet. This volume of water–beer mix (called pre- and last-running) is difficult to reuse economically, and therefore the smaller volume produced by a crossflow membrane filtration plant requires less cost to reprocess and reuse.

On the other hand, there are also several challenges associated with the use of CMF for beer clarification: slight variability of permeate quality (either higher turbidity, or protein and aroma retention) between different types of beer filtered with the same equipment and parameters, variability in fluxes due to varying ingredient concentrations in different batches or in different beer brands, and the need for intensive cleaning due to membrane fouling.

Beer clarification by microfiltration requires a fine balance between the retention of large particles and the transmission of soluble macromolecules such as carbohydrates, proteins, as well as flavor and color compounds, which contribute to beer quality. Proteins and carbohydrates are known membrane foulants, but they are also essential for beer quality. Sufficient

---

\* 100 mL equals 0.026 US gal or approximately 3/128 US gal.

<sup>†</sup> In Europe, the use of European brewing convention (EBC) units is more common. 1 NTU = 0.25 EBC.

<sup>‡</sup> Diatomaceous earth is known as kieselguhr, diatomite, or filtration sand. Diatomaceous earth is a nonmetallic mineral composed of the skeletal remains of microscopic single-celled aquatic plants called diatoms. These microorganisms have the unique ability to absorb water-soluble silica present in water and thereby form a skeletal framework of amorphous silica.

<sup>§</sup> IARC monographs on the evaluation of carcinogenic risks to humans. Volume 68 (1997, IARC Press CH-Geneva): Silica, some silicates, coal dust, and para-aramid fibrils. ISBN 92–832–1268–1. The IARC working group decided to classify crystalline silica to class 1 (human carcinogen). This classification has been given only to treated or calcinated diatomaceous earth, which may contain higher levels of crystalline silica. Natural diatomaceous earth, which might contain none or low levels of crystalline silica, has not been considered as a carcinogen to humans (group 3).

transmission of these molecules through the membrane is critical for obtaining a satisfactory quality of the filtered beer. Therefore, the membranes used for the removal of haze, yeast, and bacteria cells from beer require special physical properties to ensure that the separation process is highly selective, and only the desired components in the rough beer pass through the membrane.

One of the main challenges when using membrane filtration at a commercial scale is its limited flexibility, which means the inability of changing the setup or operating conditions according to the properties of the products to be filtered. It is known that the flow of the filtered beer through the membrane (the permeate flux) is influenced by the following main factors:

1. *Applied Transmembrane Pressure and Velocity along the Membrane Surface:* These process parameters may be varied extensively at the laboratory scale to achieve the optimal combination of process parameters for a given beer or application. Variations in industrial installations are normally possible, but limited due to given sizes of the connecting piping, pump capacity etc., which might not allow the process to be conducted under desired process conditions for each individual application.
2. *Interaction between the Product to be Filtered and the Membrane:* The product–membrane interaction plays a dominant role in the membrane filtration of beer. The contribution of the membrane to this interaction is defined by the membrane material, surface structure (i.e., pore size), and the three-dimensional structure of the membrane. Beer is the other major element in this interaction. Since beer is a product made from natural ingredients, its properties can vary significantly, even for the same type of beer. Variations between different types or brands of beer are even larger. Yet, it is expected that the characteristics of the final filtered beer are always the same. When filtration applications are designed, the membrane type and installation are chosen based on given average properties of the beer to be filtered. For economic reasons the membrane elements are only replaced if they are damaged, and cannot be changed according to the varying properties of the rough beer. This might lead to variations in the filtered product throughput and quality, which is obviously undesirable.

The use of membranes for beer filtration was identified as a possible choice some years ago, but the costs have until now been higher than the competitive method of using a filter aid. Intensive research and development efforts have been employed to turn this method from laboratory into industrial scale. Some of the first examples of industrial applications have been recently reviewed by Noordman [45]. These applications have been installed in the Heineken brewery, in Zouterwoude, The Netherlands. Such installations were characterized by a high degree of developmental effort per installation in the brewery. Still, this technique is just becoming available in a repetitive industrial scale. The major membrane manufacturers have reacted to the increasing interest of the brewing sector in membrane technology, and as a result several membrane filtration systems are now commercially available for beer main filtration applications. In the most recent exhibition of brewery equipment held in Munich, Germany (Drinktec 2005) three manufacturers displayed membrane filtration equipment to be used for the main filtration step in breweries: Norit (formerly known as X-Flow, The Netherlands), Pall/GEA, and Alfa Laval/Sartorius.

The crossflow filtration system distributed by Alfa Laval/Sartorius (Figure 20.18) employs a polyethersulphone membrane with an asymmetric pore pattern developed specifically for beer filtration. This system is built on a modular basis, using plate and frame cassettes (Sartocon CFB filtration cassettes) of 0.7 m<sup>2</sup> of filtration area each. Due to its modular design, the system can be sized by combining multiple cassettes into filtration stages to provide the desired filtration area. The systems that are currently being commercialized are capable of handling throughputs of up to 500 hL/h (*Source:* www.alfalaval.com).

To establish a continuous, around the clock operation, an integrated approach to maintain the membrane characteristics using intermediate CIP intervals is applied. The technique consists of reversing the flow and varying the TMP until reaching the point where the membrane surface in one of the filtration stages needs to be cleaned. A possible diagram for this is shown in Figure 20.19. The intermediate CIP can be performed using a cold water rinse, a warm water rinse, or a short-term ambient caustic contact. This intermediate CIP is applied only to one filtration stage of the equipment and consists of displacing the nonfiltered and the filtered product from this stage using carbon dioxide gas or water, then applying the CIP solution (warm water or ambient caustic) to the membranes. After a defined contact time with the membrane, the CIP solution is drained and after intensive rinsing the stage is filled again with product and its status changes to stand-by.\* To perform these steps in the correct and timely manner, automation is required.

#### 20.4.2 FINAL FILTRATION OF BEER

Besides colloidal stability, it is also necessary to ensure the microbiological stability of the bottled product. Even if the primary filtration has been done with utmost care, an additional processing step might be necessary to achieve microbiological safety of

---

\* The described processes may be in part or entirely subject to existing patents held by the equipment manufacturer.

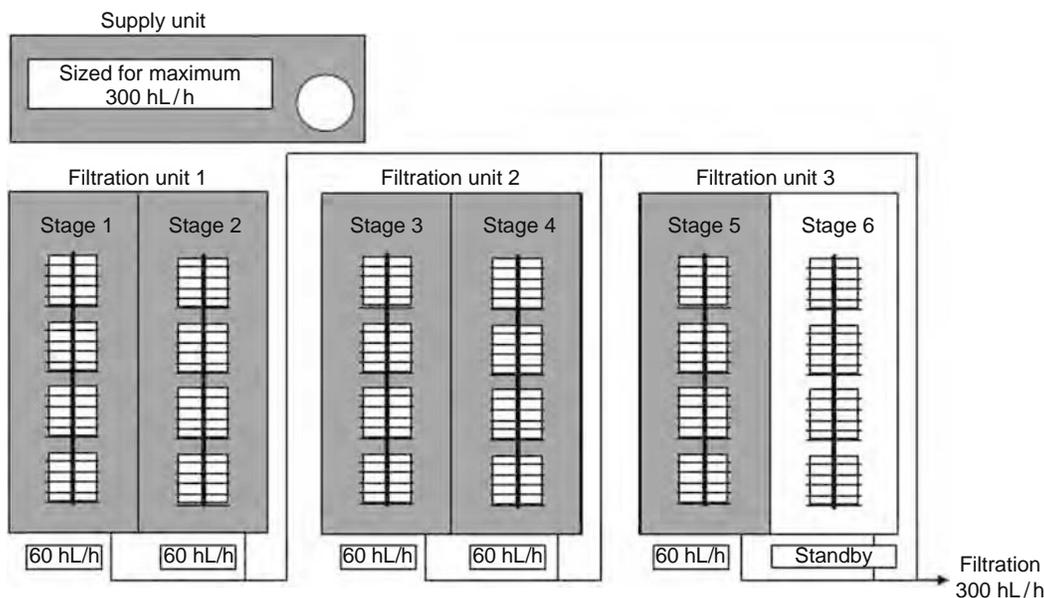

**FIGURE 20.18** Membrane filtration equipment for beer filtration. (Courtesy of Sartorius GmbH, Göttingen, Germany. With permission.)

beer. As illustrated in the overview diagram (Figure 20.2), there are two different techniques that can be used to ensure the microbiological stability of beer: thermal pasteurization or final filtration.

The microorganisms of concern in beer (all of them spoilage microorganisms, as there are no known pathogens in beer) can be inactivated by pasteurization. Two types of pasteurization techniques are typically used by breweries: (i) flash pasteurization, in which bulk beer is continuously pasteurized in a plate heat-exchanger before bottling and (ii) tunnel pasteurization, used for the in-pack treatment of bottles and cans. In flash pasteurization, beer is heated to 71°C–74°C (160°F–165°F) for 15–30 s, while tunnel pasteurization consists typically in applying temperatures of about 60°C (140°F) for a given time interval—typically 10 min. Sometimes, even if short holding times are used, the flavor of the final product is considered to be altered, and beer loses its freshness.

Final filtration has been used as an alternative to pasteurization for many years. It must be noted that sometimes the term “sterile filtration” is used instead of “final filtration,” but this is a misnomer because this processing step achieves only the

**FIGURE 20.19** A simplified layout/operation scheme of beer filtration equipment using six stages. Stage 6 is in standby mode. As soon as one of the first 5 stages reaches the condition for cleaning, it is switched into cleaning/regeneration mode and stage 6 is switched into filtration mode.

reduction of yeasts and bacteria to levels that do not result in spoilage of the beer during its shelf life, not microbiological sterility. As compared to pasteurization, final filtration has the advantage of eliminating the possible flavor changes caused by the heat treatment. The beers obtained using this technology are marketed and sold as cold filtered or non-pasteurized.

The final filtration step is not meant to remove significant amounts of particles or to reduce turbidity. For economic reasons, there should not be many particles left from the first filtration step when entering into the second (final) filtration step. Only if this condition is maintained the costs for the secondary filtration can be kept low. Also, the filtration should only remove microorganisms, and not retain other useful components of beer, i.e., those proteins that have a role in foam formation and stability. On the other hand, bacteria, which should be separated from beer during final filtration, typically have sizes down to 0.5  $\mu\text{m}$ . This small difference in size between the desirable ingredients and those particles that should be removed, such as bacteria, shows that the selection of the filtration technique and media needs to be done very carefully.

The typical pore size for the membranes used in final filtration of beer is 0.45  $\mu\text{m}$ . The membrane filter systems are installed in the beer processing line between the bright beer tank and the filling machine.

Since final filtration is used to physically remove as many contaminating microorganisms as possible from beer, the membranes have to be checked to be free of defects before and after the filtration process. It should be noted that the integrity of the large surface area of membranes applied in beer filtration applications cannot be tested directly using the bubble-point method, since it is difficult to differentiate between the first bubble of gas passing through the biggest pore in a huge surface area and the diffusion of the same gas through the wet membrane. To monitor the integrity of a large membrane surface, it is either necessary to use special equipment (i.e., particle counters), or to divide the available membrane area into smaller units and test them separately.

To check the ability of various membranes to remove bacteria, they need to be tested in the laboratory. Normally, a sample of the membrane is used to filter a suspension of bacteria of known concentration. *Serratia marcescens* is used as challenge bacteria for such tests. The results of laboratory bacteria challenge tests are commonly reported in the membrane specification sheets. Such tests include detecting the bacteria that pass through the membrane and determining the ratio of cell concentration found on the feed side vs. the concentration on the permeate side of the membrane. This ratio should be high, indicating a high microbial retention. Some membrane manufacturers guarantee a removal rate for bacteria. Typically, the membranes used for beer applications can achieve a reduction greater than 6 log cycles ( $10^6$  CFU\*) for *S. marcescens*.

Back [46] describes a method to check the microbial reduction capability of an installed filtration line. This method employs the use of five different types of microorganisms, which are suspended in water, and consists of inoculating a suspension of about  $10^{12}$  microorganisms the non-filtered beverage with a batch size of 100–500 hL. The ratio of the microbiological count found between the inlet to the first main filtration equipment and the outlet of the final filtration equipment should be higher than  $10^7$ , typically higher than  $10^8$ .

The most common practical method to check the efficiency of filtration or to detect the damage of a membrane filter consists, however, of monitoring the turbidity of the filtered beer using an in-line haze-meter.

#### 20.4.2.1 Traditional Methods for Final Filtration

Two filtration methods can be used for the final filtration of bright beer: depth filtration, which uses filter sheets or pads, and membrane filtration.

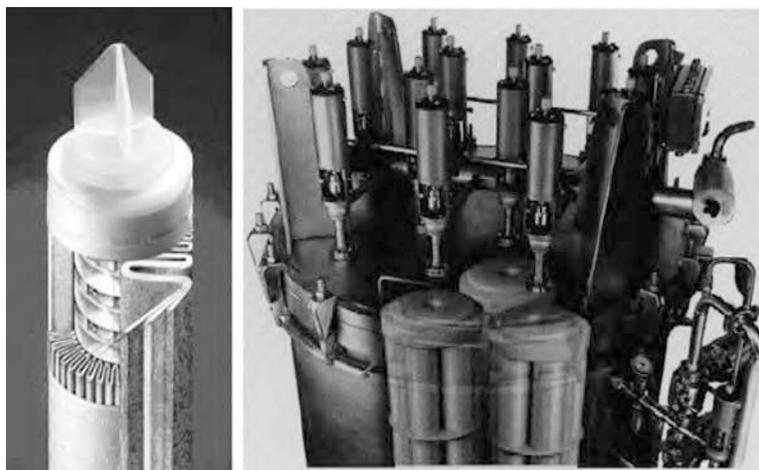

Sheet filter media for depth filtration are typically made from cellulose fibers and diatomaceous earths compressed into a thin mat. These sheets are typically mounted in plate and frame filters. There are also some special filters available that consist of filter sheet discs stacked and sealed in modules, which fit in closed filter vessels. The filter sheets can be regenerated several times until they need to be (manually) replaced.

#### 20.4.2.2 Use of Membranes for Final Filtration

The membrane filtration system uses a large number of filter elements that may look like filter cartridges or stacked flat membranes. The filter elements are organized in groups or clusters. Filter clusters are able to handle a significant product flow and can be installed directly upstream of the filling line without any requirement for a buffer plant. Cleaning, sterilization, and integrity testing are done cluster by cluster. A significant advantage of the clustered systems is that the integrity of each cluster is tested separately, which makes it possible to isolate and exclude any “bad” cluster before processing. Figure 20.20 illustrates a final filtration system manufactured by Pall Corporation. Several clusters are installed in one filter vessel using a common product inlet, but each cluster is equipped with its own outlet valve. A membrane cleaning unit (CIP), as well as the integrity testing unit, is connected to the fully automated filtration system. Other systems that can be used for the same purpose are available from Alfa Laval/Sartorius (Göttingen, Germany).

---

**FIGURE 20.20** Typical filter element showing the membrane in the middle of two supporting layers. Seven of these filter elements are arranged into a cluster. Several of these clusters are incorporated into one pressure vessel. The pressure vessel is equipped to connect or disconnect each of these clusters individually to the filtration outlet. (Courtesy of Pall Corporation. With permission.)

The brewers have the choice to ensure the quality of the finished product using different techniques (e.g., final filtration and pasteurization as mentioned in Figure 20.2). Their choice is mostly driven by economical and marketing considerations. There are breweries, both small and large, known for successfully producing and marketing “cold-filtered” beer in different parts of the world for many years.

### 20.4.3 RECOVERY OF SPENT BEER FROM YEAST AND TANK BOTTOMS

The fermentation of beer is done using different strains of the yeast *Saccharomyces cerevisiae*. At the end of fermentation of lager type beers, the yeast cells sediment at the bottom of the fermentation tanks. At the bottom of the tank the yeast cells are highly concentrated, still suspended in a small amount of beer. This yeast is normally removed from the tanks and sold to other biotechnological industries. For economical reasons, it is necessary to recover as much beer as possible from the tank bottoms, since otherwise a significant amount of beer would be lost with the yeast slurry. The next processing step, aging, is carried out at very low temperatures, typically below 0°C (32°F). During aging, even more yeast settles at the bottom of the tank. The yeast layer formed during aging is smaller than the yeast layer settled after fermentation and this yeast is considered to be less valuable, because the cells are weak after the long and cold treatment.

The volume of yeast slurry harvested from the tanks after fermentation and after aging is estimated to be ~2.5% of the fermented product volume.

#### 20.4.3.1 Traditional Techniques Used for Tank Bottoms Recovery

The most common method to recover the spent beer from the yeast slurry is centrifugation. In this process, beer is separated from the yeast using a centrifuge, based on the difference in specific gravity between beer and yeast. The dry matter content of the centrifugally separated yeast is usually ~22%–25%. An alternative method to recover the beer used by some breweries consists of mechanically pressing the yeast between sheets of cloth.

#### 20.4.3.2 Use of Membrane Separation

The membrane filtration systems are typically completely closed, preventing excessive contact of beer with air or oxygen. Thus, the filtered product is recovered at high quality, which allows it to be used directly in subsequent process steps or in the aging process. In certain instances, a slight change in the quality of the beer recovered from tank bottoms is observed. For example, Eagles and Wakeman [27] reported an increase in the concentration of some yeast metabolic products (ethyl acetate, butyl alcohol, and amyl alcohol) in the permeate obtained by the microfiltration of beer tank bottoms through a 0.45 μm alumina membrane. Such increases were attributed to the leaching of material from the yeast cells and to the secondary fermentation that took place during filtration. Practical experience shows that processing of the tank bottoms should be done as early as possible to minimize the deteriorating effect of storing the harvested yeast slurry over a long period of time.

The typical membranes used for tank bottoms recovery are tubular ceramic membranes. These membranes are available from different equipment suppliers, particularly since they have proven their rigidity against temperature variations, pressure,

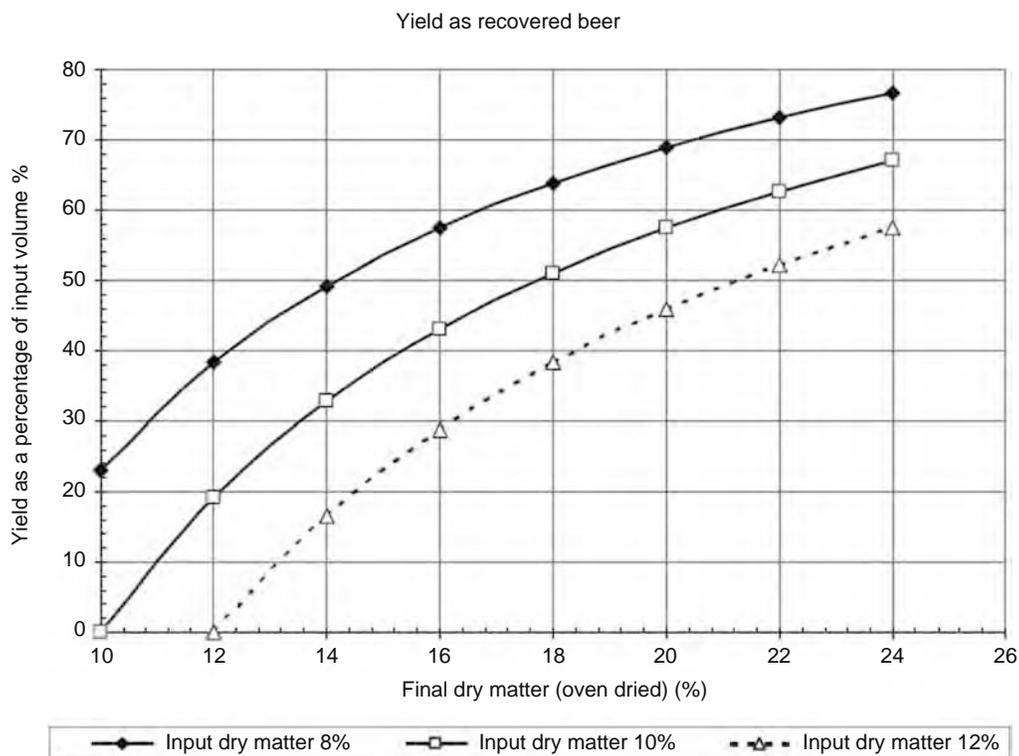

and abrasion. Compared to the main beer filtration step, the membranes used for filtration of tank bottoms have larger pore sizes ( $\sim 0.8 \mu\text{m}$ ) and the flow channels have larger diameters.

One important challenge that needs to be taken into account during recovery of beer from tank bottoms is that centrifugal pumps are used, and these pumps can only handle fluids up to a certain viscosity. Additionally, the rheological behavior of the yeast slurry varies with its concentration. The more concentrated in yeast the slurry becomes, its viscosity departs from a Newtonian behavior and gains a shear thinning behavior, which means that its apparent viscosity decreases significantly when the slurry is subjected to higher shear rates (i.e., at high velocities). This effect keeps the concentrated yeast slurry pumpable as long as the pumps keep running. If the pumps stop, for example, due to a power failure, the viscosity of the yeast slurry becomes extremely high and the slurry in the pipe system becomes solid-like. This behavior needs to be taken into consideration, as plants need to have in-place solutions for removing the yeast slurry from the membrane system even after a power failure.

The viscosity of the yeast slurry must be sufficiently low to allow pumping through the recovery membrane equipment, particularly through the narrow membrane channels. At around 30% dry matter the yeast slurry has a consistency comparable to that of the wet sand used to build sand-castles at the beach. In most cases, 18%–20% dry matter is the limit for yeast processing using membranes. In order to increase the recovery yield, the cells can be washed using diafiltration, which consists of replacing the beer suspending the yeast cells with water. Another way to do this is to add water to the concentrated yeast slurry and then filter it again. Figure 20.21 shows the yield of recovered beer as a function of the tank bottom concentration. The diafiltration step enhances the amount of product recovered significantly, but the recovered product is diluted with water. This dilution of the recovered product limits the amount of water to be used during diafiltration.

### 20.4.3.3 Costs of Tank Bottoms Recovery Using Membrane Separation

The main cost factors are represented by equipment depreciation, membrane replacement, and electric power consumption. The other costs (man power and water consumption) are of minor influence. Membrane filtration plants equipped with a low level of automation require only a few hours of attention and direct surveillance by the operator per day. Direct surveillance of membrane filtration equipment is necessary at times when batches need to be changed or during membrane cleaning. The electric power consumption is associated with the use of pumps to move the viscous yeast slurry over the membrane surface, and its estimation is relatively straight forward.

**FIGURE 20.21** Theoretically possible yield as a function of the concentration of the yeast slurry entering and exiting the tank bottoms recovery system, without diafiltration.

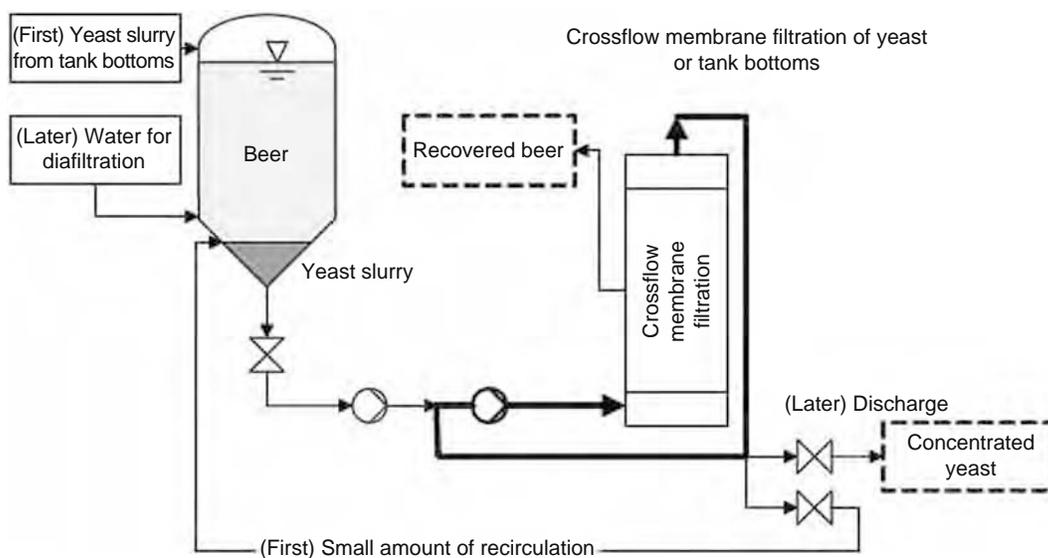

FIGURE 20.22 Process flow diagram of membrane filter plant for tank bottoms or yeast.

The replacement of membranes needs to be done at certain time intervals and membranes are costly. To the knowledge of the authors the ceramic membranes used in one of the oldest tank bottom recovery systems are running for some 10 years now. Sometimes, a membrane replacement in a 5 year time interval is assumed. This long time, which is equivalent to the long-term planning horizon of some companies, and the relatively high membrane prices, makes it difficult to accurately estimate the contribution of this cost factor properly.

#### 20.4.3.4 Examples of Commercial Installations

The general diagram for a tank bottom recovery system that includes a crossflow filtration unit is presented in Figure 20.22. The CMF setup shown in Figure 20.23 is manufactured by Filtrox AG, St. Gallen, Switzerland, and is equipped with 10 vertically mounted membrane units, comprising of ceramic membranes with 90.8 m<sup>2</sup> surface area each. This equipment

FIGURE 20.23 Installation of crossflow membrane filtration for filtration of yeast and tank bottoms in a German brewery. (Courtesy of König-Brauerei GmbH, Duisburg, Germany and Filtrox AG, St. Gallen, Switzerland. With permission.)

is dimensioned for processing 2500 hL yeast slurry per week. When the yeast slurry concentration reaches a final value of 18%–20% dry matter, water is added to increase the total amount of beer recovered (diafiltration). The equipment shown in Figure 20.23 was installed in October 2002 and is running since. A small CIP unit is included in the background for cleaning the membranes.

Another example of CMF equipment used for tank bottom recovery is the Keraflux beer recovery system produced by Pall Corporation. Keraflux systems are available both as a batch version and as a continuous version, the latter being used for larger processing capacities. Other types of membrane systems have also been used for this purpose [47] but the tubular ceramic membrane systems are the current state of the art.

#### 20.4.4 ALCOHOL REMOVAL FROM FERMENTED BEER

Alcohol-reduced beer can be obtained using two different processes. On one hand, it is possible to produce beer with a low ethanol concentration ( $<0.5\%$  v/v) by stopping the fermentation very early, i.e., by keeping the contact time between the wort and the yeast short and the temperatures low, both during fermentation and aging. This can be achieved in a batch process using regular brewing equipment. Some breweries produce alcohol-reduced beer by running a continuous flow of wort through immobilized yeast cells [48].

On the other hand, the ethanol can be removed from the beer after the regular sequence of fermentation, aging, and main filtration steps has been completed. Ethanol removal from fermented beer can be done either by direct heating and ethanol evaporation, or by membrane separation. The use of membranes is meant to avoid the heat treatment of beer, to ensure the desired sensory quality of the final product.

The membrane process used for alcohol removal from beer is dialysis. In dialysis, the driving force for the transport of chemical components through the membrane is the difference in concentration of those components between the two sides of the membrane, unlike the microfiltration processes involved in the applications described so far, which are pressure-driven processes. Dialysis membranes are very tight and allow some of the dissolved ingredients (such as ethanol) and water to pass through, but do not allow the transport of larger molecules. The porous structure of these membranes is similar to ultrafiltration membranes [49]. The dialysis membranes used to process filtered beer are often of the hollow fiber type. Glaser [50] reported the use of a hollow dialysis membrane with an inner diameter of 215  $\mu\text{m}$  and a wall thickness of 16  $\mu\text{m}$  for alcohol removal from beer. A bundle of these hollow fibers (up to 50,000 fibers) are housed in a single membrane module. The static pressure difference across the dialysis membranes is typically kept small, in the range of 3–5 psi (20–35 kPa).

The diagram of a typical installation for the removal of alcohol from finished beer using dialysis is presented in Figure 20.24. The process may be described as follows: the equipment is first filled with water. As soon as the bright beer replaces the water from the product side, alcohol is transported to the intermediate water cycle. The intermediate water–alcohol solution is heated up and then the ethanol is removed in the distillation column using vacuum. Other low molecular ingredients and the dissolved carbon dioxide of the bright beer are partly transported into the recirculated water until the concentration of those ingredients becomes equal on both sides of the dialysis membrane. Since the content in dissolved carbon dioxide gas is

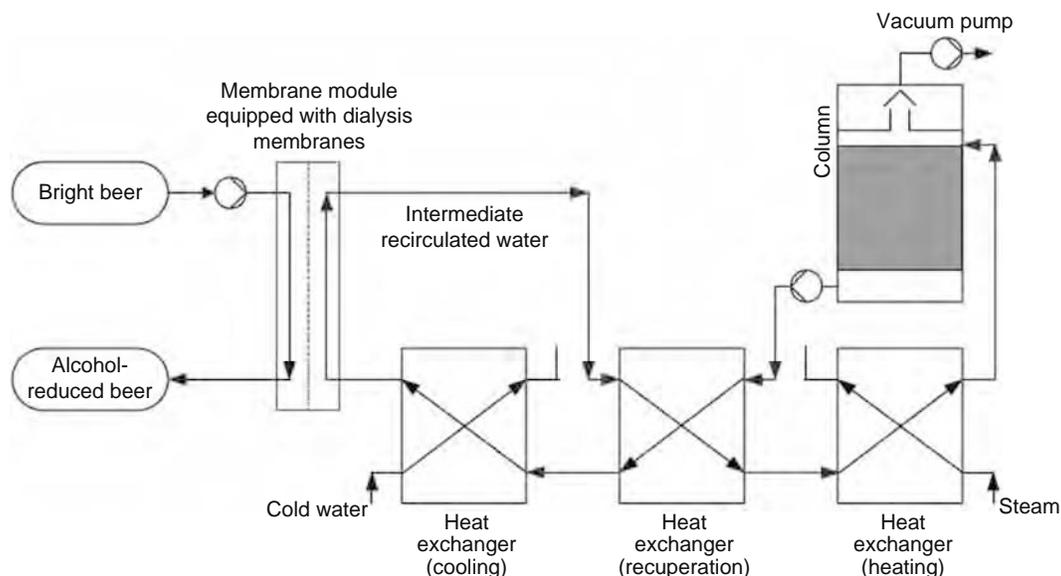

FIGURE 20.24 Schematic of alcohol reduction using dialysis membranes.

constantly reduced in the column due to the higher temperature and lower pressure inside the column, the carbon dioxide content of the low alcohol beer needs to be readjusted downstream of the dialysis process. Such membrane installations are capable of running for about 12 days with a constant throughput until the membranes need to be regenerated using a special CIP procedure.

While very attractive from a product quality point-of-view, it is important to note that alcohol removal by dialysis has to compete economically with thermal evaporation to be adopted by breweries.

## 20.5 OTHER USES OF MEMBRANE SEPARATION IN THE BREWING INDUSTRY

### 20.5.1 PURIFICATION OF BREWING WATER BY REVERSE OSMOSIS

The basic ingredient of beer is water (Figure 20.2), which must meet the highest standards of purity for potable water, and should also have an acceptable taste and odor. In most cases, the water found in natural resources, such as wells or in some countries, rivers does not have the desired composition for direct use in brewing processes. At least a purification step is necessary to remove suspended, colloidal, or dissolved solids from water before processing. The lowering of hardness, which is given by the concentration of calcium bicarbonate, can be done using ion exchange or wet chemistry, i.e., by adding lime to the water, followed by sediment removal.

Reverse osmosis offers the possibility of achieving more than one purification purpose in one step. It simultaneously reduces the hardness and the concentration of other salts, as well as organic molecules, bacteria or viruses. The higher the concentration of undesired ingredients in the well water, the more economic the membrane filtration becomes as compared to the ion exchange treatment. RO for water purification is one of the oldest applications of membrane separation and has been extensively discussed in literature over the years.

### 20.5.2 UTILITIES FILTRATION

Besides its direct use in the final product, water is used in breweries as a utility, for purposes such as cleaning, steam generation, etc. Another common utility in breweries are gases, such as air and carbon dioxide, which sometimes might contain impurities that need to be removed in order to ensure the quality and uniformity of the final product. Besides traditional methods, i.e., activated coal treatment, purification of utilities can also be successfully done by membrane filtration. Some membrane manufacturers (i.e., Pall Corporation, Donaldson Ultrafilter Inc., Sartorius, Millipore, CPM, etc.) offer commercial membrane separation equipment that is specifically designed for the purification of water, steam, air, or carbon dioxide. This enables breweries to produce sterile and particle-free utilities for the brewing processes.

### 20.5.3 BEER DECOLORIZATION

Alcopops and spirit mixed drinks are gaining much popularity in the Western world, reaching impressive growth rates in recent years. Due to its specific color and taste, beer cannot be directly used in such applications. Recently, NORIT process technology (NPT) has developed a method of beer decolorization that enables breweries to produce clear alcohol–water mixtures that can be used in premixes or alcopops (*Source*: <http://www.noritpt.nl>). For beer-based drinks, the NPT membrane-based technology is able to produce a water–alcohol mixture with the taste and smell of beer. For premixes, alcopops, and comparable products, the taste and smell can also be removed in an additional step, using activated carbon.

### 20.5.4 MICROBIOLOGICAL QUALITY CONTROL OF BEER

The microbiological quality of the packaged product is of major concern for beer manufacturers, and therefore needs to be checked before the final product hits the target market. Typically, testing the microbiological quality of beer is done by passing at least 100 mL of beer through a 0.45  $\mu\text{m}$  membrane, followed by plating of the membrane on specific media, incubation, and counting of the microbial colonies that grow on the media. Membranes for microbiological testing are available from companies such as Pall, Millipore, Sartorius, Schleicher & Schuell, and Whatman.

## 20.6 AN ECONOMICAL PERSPECTIVE ON THE USE OF MEMBRANE SEPARATION IN BREWING

These days more and more equipment manufacturers are advertising their membrane filtration equipment for main filtration of beer as a true possibility. This shows that nowadays there are economic circumstances for breweries that facilitate or even induce the switch from the filtration with filter aids to the use of membranes for this purpose. The first installations in small- or medium-sized breweries, as well in a large brewery, are already in successful operation. A higher number of installations is expected.

The global cost for beer filtration is significant, and for the year 2003, it was estimated that a total of  $0.4 \times 10^9$  USD was spent to filter the total volume of  $1.4 \times 10^9$  hL beer produced that year (*Source: www.e-malt.com*). Therefore, the economics of the process will have a decisive role in the expansion of membrane separation as a commercial filtration technique. As all processing methods, CMF will have to cope with the ever-changing economical conditions, such as membrane prices, the cost of electric power, as well as the changing ratio between these costs and the disposal costs of spent diatomaceous earth. Since these costs, as well as the cost of man power, differ at least from country to country, global answers to this are not accurate.

For CMF to be deemed a successful replacement of traditional clarification methods for the main filtration process, a high beer flux is required (generally, a minimum of  $100 \text{ L}/(\text{m}^2 \text{ h})$  is considered necessary), with power costs that do not exceed those associated with the traditional filter aids [37]. Gan [32] considered that an average flux rate of  $40 \text{ kg}/(\text{m}^2 \text{ h})$  over 10 h of continuous filtration is of commercial interest.

Membrane filtration as a technique for final filtration of beer is widely used today, and companies use the term “cold-filtered” and “not pasteurized” for selling their products.

In the area of beer recovery from tank bottoms the use of membranes is a competitive possibility and has been known for some years now. There are numerous breweries using this technique, and the size of the equipment is of a smaller scale than those intended for main filtration.

Briefly, the use of membrane filtration by breweries has been slowed down by the difficulties in filtering this very special beverage made from natural ingredients. To overcome these problems intensive research and resources have been spent, mostly because the market is promising. The bottom line is that membrane filtration produces a high-quality filtered product without the use of filter aids that need to be disposed of, membrane processes are easy to automate, and their operation is more continuous-like as compared to the filter-aid methods.

Membrane separation is becoming increasingly attractive to the beer industry and, as advances that will minimize or even eliminate some of the current challenges associated with membrane separation of beer are made, it is expected that more and more breweries will adopt this technology in the not so distant future.

## 21.1 INTRODUCTION

Membranes may be hastily classified according to the driving force at the origin of the transport process: (1) a pressure differential leads to micro-, ultra-, nanofiltration, and reverse osmosis; (2) a difference of concentration across the membrane leads to diffusion of a species between two solutions (dialysis); and (3) an electric potential difference applied to an ion-exchange membrane (IEM) leads to migration of ions through the membrane (electrodialysis, membrane electrolysis, and electrochemical devices) [1,2].

Today, electrodialysis (ED) is one of a group of membrane-based separation technologies which are finding increasing use in agri-food industries to concentrate, purify, or modify foods. The low-energy consumption, modular design, efficiency, and ease of use as well as the heat sensitivity of many food products are among the reasons for their rapid growth. ED uses an electric field as the driving force and charged membranes to perform the separation: electrodialysis is a combined method of dialysis and electrolysis [3].

Electrodialysis can be performed with two main cell types: multi-membrane cells for dilution–concentration and water dissociation applications, and electrolysis (or electro-electrodialysis [EED]) cells for oxidoreduction reactions. In multi-membrane cells, only the membrane transport phenomena intervene, while electrochemical reactions occurring at the electrodes do not interact with the separation process: the electrodes are simple electrical terminals immersed in electrolytes allowing the current transfer. The electrolysis cell operates with only one membrane that separates two solutions circulating in each electrode compartment. This application is based on electrode redox reactions, which are electrolysis specific properties. The anode induces oxidations, and reductions occur at the cathode [4].

Electrodialysis is a well-proven technology with a multitude of systems operating worldwide. In Europe and Japan, electrodialysis dominates as a desalting process with total plant capacity exceeding that of reverse osmosis and distillation [3]. Electrodialysis with monopolar membranes is applied to different food systems, to demineralization of whey [5–8], organic acids [9], and sugar [10,11], separation of amino acids [12] and blood treatments [13], wine stabilization [14–16], fruit juice deacidification [17–19], and separation of proteins [20–22]. These applications use the sole property of dilution–concentration of monopolar IEMs in a stack of as many as 300 in an electrodialysis cell.

Electrodialysis with bipolar membranes (EDBMs) [23] was applied recently to the production of mineral and organic acids [24–36], inhibition of enzymatic browning [37–39], and separation of protein [40–44]. These applications are based on water dissociation at the interface of a bipolar membrane (BPM) coupled with monopolar membrane action. A recent up-to-date overview gives the possibilities and the economic relevance of BPM technology [45].

In the domain of food industries, EED was used to reduce oxygen in fruit juice [46], to extract cytoplasmic proteins from alfalfa [47,48], to coagulate proteins [49], and to reduce disulfide bonds in proteins [50]. These applications are based on the electrode redox reactions coupled with monopolar membrane action.

This review summarizes the monopolar and BPM principles of operation. Moreover, this review presents shortly the main applications in chemical processing, pollution control, and resource recovery, and details the specific applications of electrodialysis with BPMs to food and bio-industries.

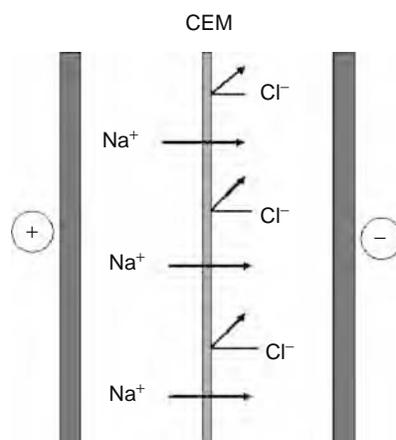

## 21.2 PRINCIPLES OF ELECTROMEMBRANE PROCESSES

### 21.2.1 ION-EXCHANGE MEMBRANES

Two kinds of IEMs are used in electrodialysis (ED): homopolar membranes bearing charges of same sign and BPMs bearing positive and negative charges located separately on each side of a same plane.

#### 21.2.1.1 Homopolar Membranes

These are sheet-shaped materials through which a selective ion transport can be established under a driving force, generally an electric field or a concentration gradient. Most of them are of a polymeric nature. They are constituted by reticulated macromolecular chains forming a tridimensional structure. In this network, ionizable functionalized groups are borne by the polymeric matrix and are at the origin of the membrane selectivity. For example, cation-exchange membranes (CEMs) contain fixed negative charges and mobile cations that can be exchanged with other cations present in an external phase in contact with the membrane. The ions balancing the fixed exchange sites are called counterions. The concentration of counterions within the membrane is relatively high; therefore, counterions carry most of the electric current through the membrane. The fixed charges attached to the polymer matrix repel ions of the same charges (co-ions). This exclusion, which is a result of electrostatic repulsion, is called Donnan exclusion, named for Donnan who first reported the phenomenon in 1911 [51]. However, as the membrane selectivity is never ideal, the membrane material can be penetrated by a non-negligible amount of electrolyte. A schematic structure of such a homopolar IEM (CEM) is depicted in Figure 21.1. Under an applied electric field, the CEM bearing sulfonic exchange groups ( $-\text{SO}_3^-$ ) mainly allows the transport of counterions.

**FIGURE 21.1** Schematic process of transport of counterion ( $\text{Na}^+$ ) through a CEM.

### 21.2.1.2 Bipolar Membranes

Bipolar membranes (BPMs) are composed of two layers of ion exchangers joined by a hydrophilic junction. The diffusion of water from both sides of the BPM allows it dissociation under the electrical field to generate protons and hydroxyl ions, which further migrate from the junction layer through the cation- and anion-exchange layers of the BPM. The principle of this water-splitting phenomenon is depicted in Figure 21.2.

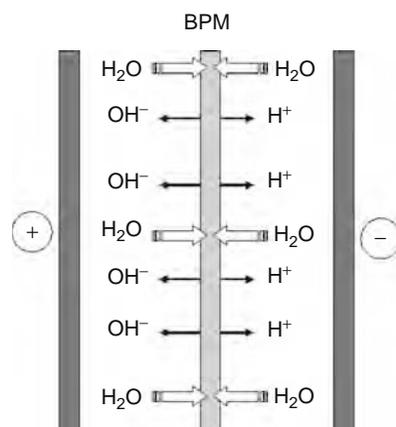

The requirements for suitability of homopolar IEMs for industrial applications are the following:

1. High-ionic conductivity with a concentration of fixed charges
2. High-ionic permselectivity combining simultaneously a high conductivity and a moderate water uptake
3. Chemical stability of the fixed ions and a good mechanical resistance
4. Reasonable cost

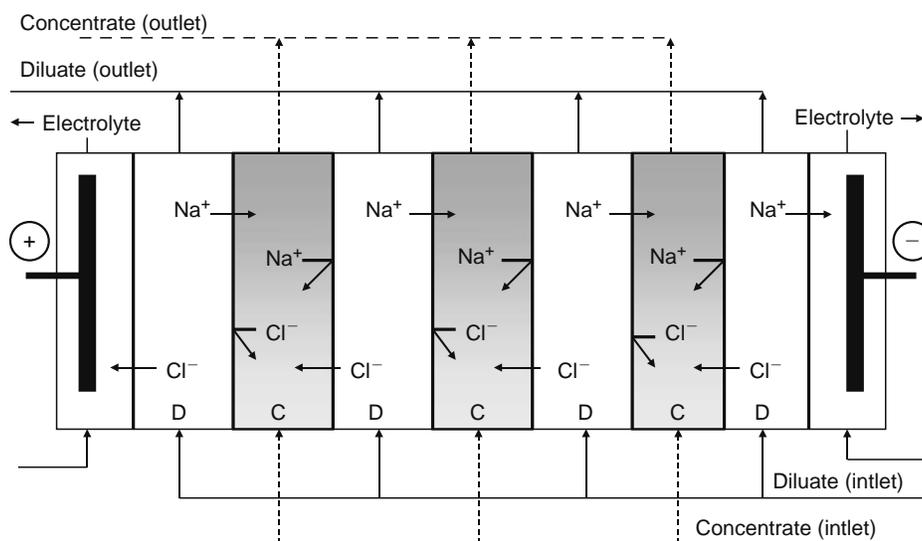

In addition, BPM must have an experimental potential to achieve the water-splitting capability as close as possible as the theoretical value equals 0.83 V at 25°C. Nowadays, superior styrene–divinylbenzene copolymer membranes can be easily purchased, perfluorinated membranes with great chemical stability are on the market, and BPM with an industrial-scale lifetime (>10,000 h) is available.

### 21.2.2 PRINCIPLE OF CONVENTIONAL ELECTRODIALYSIS

Electrodialysis can be organized in two, three, or four compartments. Figure 21.3 depicts the schematic configuration of a conventional two-compartment electrodialysis applied to the reconcentration/dilution of NaCl solutions. C and D are the concentrate and diluate, respectively. When an ionic feed solution (e.g., a sodium chloride solution) flows through the channels of the electro dialyzer, the positively charged sodium ions migrate to the cathode and the negatively charged chloride ions

**FIGURE 21.2** Schematic principle of water dissociation by a BPM.

**FIGURE 21.3** Schematic configuration of a conventional two-compartment electrodiagnosis applied to the reconcentration/dilution of NaCl solutions. C and D: concentrate and diluate.

migrate to the anode. As the chloride ions cannot pass the CEM and the sodium ions cannot pass the AEM, the overall effect is a simultaneous ionic concentration increase in alternating compartments and ionic concentration decrease in the other compartments. Consequently, alternate dilute and concentration solutions are formed. A set of two compartments (diluate [D] and concentrate [C]) form a cell pair. In commercial applications, several hundred cell pairs are assembled in a stack.

### 21.2.3 PRINCIPLE OF ELECTRODIAGNOSIS WITH BIPOLAR MEMBRANE

#### 21.2.3.1 $H^+$ and $OH^-$ Generation

The conventional method for generating  $H^+$  and  $OH^-$  ions from water utilizes electrolysis. Electrolysis also generates  $O_2$  and  $H_2$ , and the overvoltage for this generation consumes about half of the electrical energy of the process. Nowadays, special IEMs are available for splitting water directly into  $H^+$  and  $OH^-$  ions without generating gases. Membrane water-splitting technology is a general-purpose unit operation for converting water soluble salts to their corresponding acids and bases. This process uses BPM in conjunction with conventional CEM and AEM, respectively. The separation and rearrangement of ions is effected by a direct current driving force. EDBM is therefore an alternative method to electrolysis for the generation of  $H^+$  and  $OH^-$  ions, which can be used to generate acid and base from salts, without the production of oxygen and hydrogen gases. The application of BPM reduces the energy costs associated with electrode polarization in the more conventional electrolytic approach.

#### 21.2.3.2 Water Dissociation in Bipolar Membrane

The origin of the water-splitting phenomenon in BPM is still a matter of controversy. In fact, ordinary water dissociation cannot explain the magnitude of the electric current and the changes observed in the pH of the solutions in contact with the membrane [52–54]. It is generally believed that the  $H^+$  and  $OH^-$  ions originate in a very thin region at the interface between the two ion-exchange layers [55]. Nevertheless, it is not known exactly which mechanism is responsible for this enhanced dissociation, and up to now three physical models have been proposed: the second Wien effect [56–58], a model based on protonation–deprotonation phenomena [53–58], and recently a more global model [59].

##### 21.2.3.2.1 Second Wien Effect

According to Ohm's law, the conductance of electrolytes in aqueous solutions increases with the applied electric field. However, Wien [56] observed that at high-electric field densities ( $>10^5 \text{ V cm}^{-1}$ ), Ohm's law is no longer valid for electrolyte solutions. In weakly dissociated electrolytes, the ion mobility as well as the degree of dissociation are increasing with increasing field density. This phenomenon is known as the second Wien effect. The deformation of the ion atmosphere and its relaxation time [57] lead to an increase in ion mobility of approximately 20%–30%. The second Wien effect model for BPM considers that water in the space-charge region at the bipolar junction behaves as a weak electrolyte, and uses Onsager's theory

[60] for the increase of the dissociation rate constant of a weak electrolyte in the presence of an external electric field [55,58]. Its application for BPM can be written as

$$k_d^E = \frac{I_1(\sqrt{-b})}{\sqrt{2b}} k_d^0$$

where

$k_d^E$  is the dissociation rate constant of water under the influence of an electric field

$k_d^0$  is the dissociation rate constant of water in the absence of an external electrical field

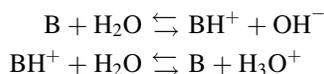

$I_1$  is the first-order Bessel function

$b = 0.09636 E/\varepsilon_r T^2$  with  $E$  the electric field density,  $T$  the temperature, and  $\varepsilon_r$  the relative permittivity

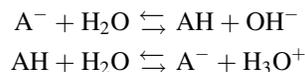

Some limitations of the model should be pointed out. Although the water dissociation rate is increased significantly with increasing electric field density due to the second Wien effect, the calculated values are still at least three orders of magnitude smaller than the experimentally from current densities determined values [57]. In addition, Onsager's theory has been successfully applied only up to  $10^7$ – $10^8$  V m<sup>-1</sup>, and theoretical estimations show that fields as high as  $10^8$ – $10^9$  V m<sup>-1</sup> could exist in the narrow space-charge regions existing in IEMs [53,61]. Hence, some effects not considered in this theory (e.g., the rotation of water molecules) should be included in the model [53]. Furthermore, if the accelerated water dissociation would only be due to the second Wien effect, it should be identical for both anion- and cation-exchange layers forming the BPM while it has been observed that water dissociation is usually larger for AEMs than for CEMs [53,61–63].

#### 21.2.3.2.2 Protonation–Deprotonation Phenomena

Theoretical considerations and experimental evidence strongly support a hypothesis that the accelerated water dissociation is also caused by a reversible proton-transfer reaction between the charged groups and water. In the presence of ionic groups, the water dissociation rate constant may be several orders of magnitude higher than in free solution. The experimental results showing that water dissociation occurs mainly at the surface of the AEMs [53,62,64] indicate that the water splitting does not take place in the solution but in the membrane phase. Furthermore, Simons [52–54,63] showed that (1) water splitting can be eliminated by methylation of the tertiary amines resulting in quaternary amines, (2) degradation of quaternary ammonium groups in strongly basic environment leads to tertiary amines, and (3) water splitting at CEMs can be obtained only when weak acids (proline, phenol) are present in the solution next to the membrane surface, or when the membrane contains weakly acidic groups, such as carboxylic acid [59]. Based on these results, Simons suggested that with AEMs the water dissociation is caused by reversible protonation of weakly basic groups (tertiary amines). For the BPM, both the cation- and anion-exchange groups of the membrane polymer adjacent to the interphase layer can react with the water molecules at the membrane surface by the following mechanisms for water dissociation [59,63]:

and

where

$B$  is a neutral base

$BH^+$  is the catalytic active center (usually the AEM fixed charged group)

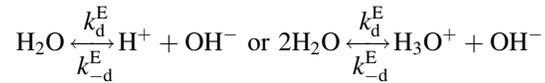

$A^-$  is the CEM fixed charged group

$AH$  is a neutral acid

#### 21.2.3.2.3 Global Model

This water dissociation model developed by Strathmann et al. [59] is described as being a combination of the second Wien effect, the protonation–deprotonation phenomena of functional groups in the membrane, and the reaction zone thickness  $\lambda$ . This model was developed under some assumptions [59]:

- Water dissociation occurs in the transition or depletion layer of the membrane and the dissociated ions removed from this region are replenished by the following water dissociation equilibrium:

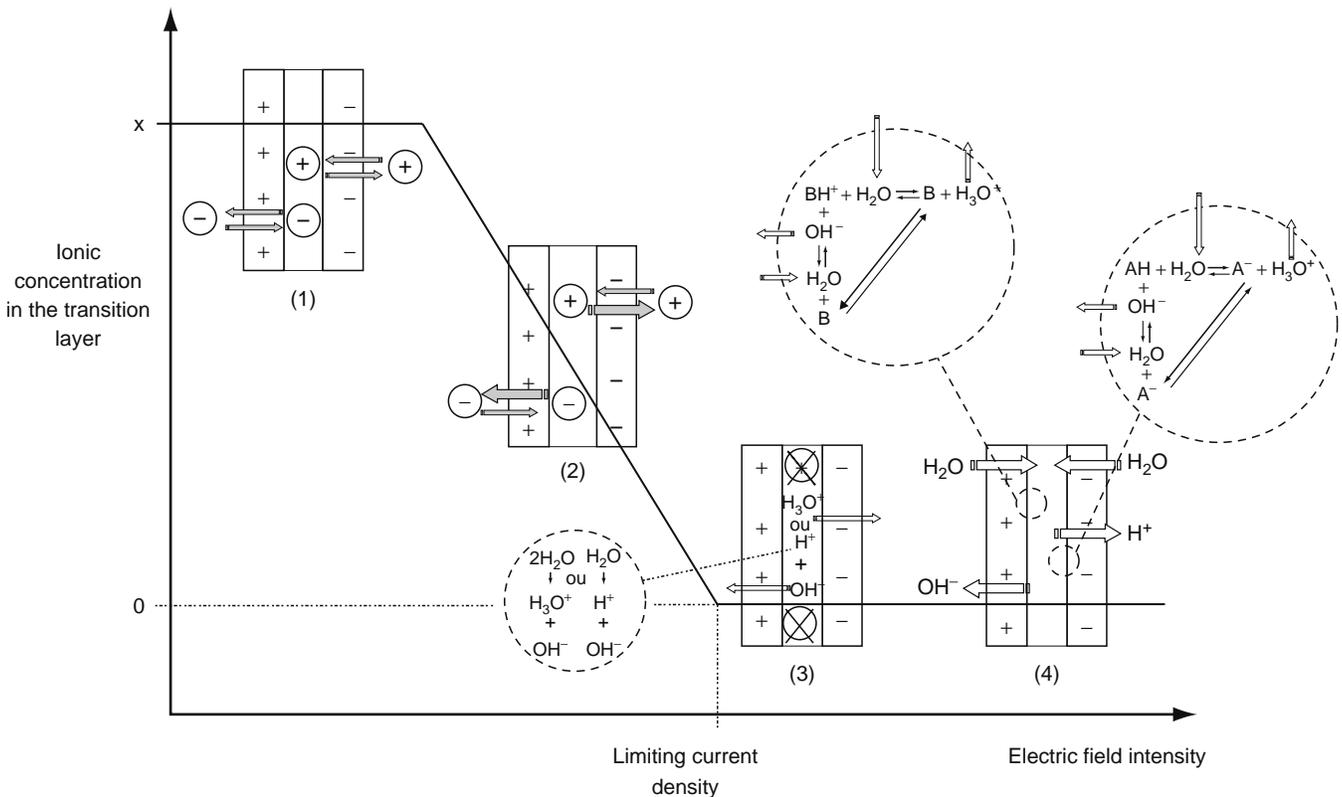

- Water dissociation is accelerated by the electric field according to the second Wien effect, which describes the influence of a strong electric field on the water dissociation rate constant  $k_d^E$ , while the recombination rate constant  $k_{-d}^E$  is not affected by the electric field:

$$\frac{k_d^E}{k_d^0} = \left(\frac{2}{\pi}\right)^{1/2} (8b)^{-3/4} \exp\left[(8b)^{1/2}\right]$$

- The generated protons and hydroxyl ions are removed from the transition region by migration and the consumed water can be compensated timely by diffusion from the bulk solution.
- The electric current is calculated from the migration flux of either protons or hydroxyl ions.
- The voltage drop across both anion- and cation-exchange layers of the BPM is neglected, so that voltage across a BPM is equal to that across the transition layer  $U^{tr}$ , and the driving force for the migration of protons and hydroxyl ions is  $U^{tr}/\lambda$ , since the Donnan potential is in equilibrium with the diffusion of ions into the transition region.

Hence, according to Strathmann et al. [59], under the influence of a low-electric field, the salt ions ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^- \dots$ ) initially present in the transition layer of the BPM migrate out of the transition region between the two ion-exchange layers. These ions are replaced by salt diffusing and migrating from the bulk solution into the transition region resulting in a steady state with a constant salt concentration in the transition region (Figure 21.4, step 1). When the electric field is increased, the migration from the transition region can no longer be compensated by the diffusive flux into the transition region. In fact, the transition layer becomes completely depleted of salt ions, since all salt ions were removed from the transition region, and a limiting current density is reached (Figure 21.4, step 2). The limiting current density depends on the permselectivity of the BPM as well as on the diffusion

**FIGURE 21.4** Exchange mechanisms leading to water molecule dissociation inside BPM. (Adapted from Bazinet, L., *Industries Alimentaires et Agricoles*, 10, 7, 2003.)

coefficient of the salt in the membrane. When limiting current density is exceeded, water dissociation begins and the current is now carried by protons and hydroxyl ions. These ions are available in very low concentrations ( $10^{-7}$  mol L<sup>-1</sup>) in completely demineralized water. The protons and hydroxyl ions removed from the transition region are replenished by the water dissociation equilibrium (Figure 21.4, step 3). This induces a water concentration gradient between the transition layer and the adjacent compartments, which results in diffusion of water molecules into the hydrophilic layer (Figure 21.4, step 4) [65].

In the BPMs, the water splitting takes place in a very small region of the monopolar ion-exchange layer where uncompensated fixed charges exist [66]. The protonation and deprotonation can take place at basic and acidic groups. According to the global model, the authors demonstrated that for strongly basic groups, the protonation is very fast but the deprotonation is very slow, so that the groups in the membrane remain in the protonated form. For strongly acidic groups, all groups remain in the dissociated, deprotonated form. Consequently, the proton-transfer reactions are capable of explaining the enhanced water dissociation. Because of their higher mobility, the protons will first move faster than the hydroxyl ions. This disturbs the electroneutrality in the transition layer and leads to an additional electric field, which increases the migration of the hydroxyl ions and slows down the protons. The thickness of the transition region between the ion-exchange layers, which includes the reaction zone, is a few nanometers. Due to the roughness of the polymer surfaces, in some cases there might be thin neutral regions (water layer) between the ion-exchange layers. The presence of these regions depends on the production of the BPM.

### 21.2.3.3 Catalysts for Improving Water Dissociation

The theoretical potential to achieve the water-splitting capability is 0.83 V at 25°C. Due to the addition of catalysts, the actual potential drop across a BPM is quite close to this being in the range 0.9–1.1 V for current densities between 50 and 150 mA/cm<sup>2</sup>, which is the general region of practical interest. Examples are the iron(III) as presumably introduced in the cation permeable layer of the Tokuyama Soda membrane [67], and the chromium(III) ion used in the WSI membrane [68,69]. The value of the membrane potential drops equates to theoretical energy consumptions of the order of 600–700 kW h/ton of NaOH. Of course, the actual energy consumptions are significantly higher because of the ohmic resistances in the other cell stack components, in practical operating units.

To enhance water molecule dissociation in BPM, catalysts are required to reduce the electric potential of a BPM. The addition of a catalyst in the contact or transition region increased the water dissociation rate for a fixed electric potential across this region because the activation energy of the overall dissociation reaction is reduced [70]. Catalysts provide alternative reaction paths for the dissociation reaction by forming very reactive, activated complexes [54,69]. The water dissociation is a disproportionation or proton-transfer reaction that is catalyzed by weak acids and bases [45].

It is assumed that the best catalytic effect can be achieved if the  $pK_a$  or  $pK_b$  value of the interphase material is close to 7 [71]. Some weak ion-exchange groups such as tertiary amines, phosphoric acid, carboxylic acids, or pyridine show the required dissociation constant or  $pK_a$ -values. Certain heavy metal ion complexes, such as chromium(III)- or iron(III)-complexes, provide the required catalytic water dissociation effect. In principle, there are many more suitable metal ions available. The metal ions or complexes are immobilized by either including an insoluble salt in the casting solution of the interface layer between the ion permeable layers or by converting a soluble form by a follow-up treatment [45]. An additional requirement for the catalytic material is to be effective and stable for a long period. It must also remain in the interphase, where it is the most active, for the anticipated lifetime of the membrane.

Some metal hydroxides such as chromium(III) and iron(III) hydroxide are suited to be deposited as catalyst in the interphase between the cation- and anion-exchange layers of the BPM. Other catalytic components used in the preparation of BPMs such as tertiary amines or phosphoric acids are generally directly bonded to the polymer matrix of the membrane [45,72]. The most commonly used catalytic components in BPMs are listed in Table 21.1.

**TABLE 21.1**  
**Main Catalysts Used in BPMs**

Material	Remarks	$pK_a$ -Value	References
Cr(OH) <sub>3</sub>	After treatment in OH <sup>-</sup> , and as salt in the cation-exchange layer or the interphase		[69,73]

R-COOH/-COO <sup>-</sup>		4.8	[77]
Pyridine		5.2	[77]

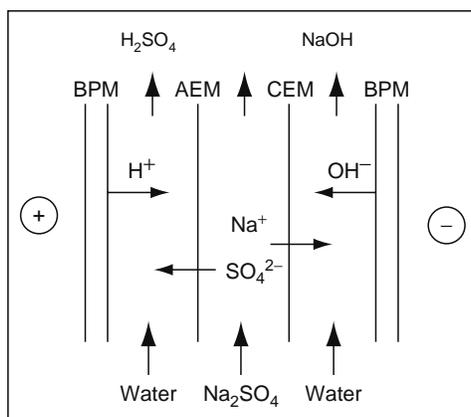

FIGURE 21.5 Generation of acid and base from a salt. The three-compartment configuration.

### 21.2.3.4 EDBM Configurations

The configuration of the EDBM process depends on the application. Typical use of BPM is in the treatment of concentrated salt solutions such as  $\text{Na}_2\text{SO}_4$  from the chemical industry to produce  $\text{H}_2\text{SO}_4$  and  $\text{NaOH}$ . A cell system consists of an anion, a bipolar, and a CEM as a repeating unit. In this case, the configuration is a three-compartment EDBM as illustrated in Figure 21.5. This elementary cell is repeated and placed between two electrodes. The  $\text{Na}_2\text{SO}_4$  solution flows between the CEM and AEM. When direct current is applied, water dissociates in the BPM to form the equivalent amounts of  $\text{H}^+$  and  $\text{OH}^-$  ions. The  $\text{H}^+$  ions flow through the cation-exchange side of the BPM and form  $\text{H}_2\text{SO}_4$  with the sulfate ions provided by the  $\text{Na}_2\text{SO}_4$  solution from the adjacent cell. The  $\text{OH}^-$  ions permeate the anion-exchange side of the BPM and form  $\text{NaOH}$  with the sodium ions permeating into the cell from the  $\text{Na}_2\text{SO}_4$  solution through the adjacent CEM. The final result is the production of  $\text{NaOH}$  and  $\text{H}_2\text{SO}_4$  from  $\text{Na}_2\text{SO}_4$  at a significantly lower cost than by other methods.

There are applications where high purity of both acid and base is not possible to be obtained, or even, may generate problems during the process. For example, in the splitting of a salt from a weak acid (sodium acetate), the pure acid is weakly dissociated, so its conductivity is low. It would not therefore be practical to achieve the splitting of sodium acetate in a three-compartment cell. Instead, a two-compartment cell with the acetate solution flowing between a BPM and a CEM is recommended (Figure 21.6a). When the conversion of the salt stream reaches 95%, the conductivity becomes very low. So, it is not possible to pursue the EDBM more deeply. The EDBM is then stopped and the residual  $\text{Na}^+$  ions are removed using cation-exchange resins. In a similar way, an ammonium or amine salt can be treated in a two-compartment cell with an AEM instead of a CEM (Figure 21.6b).

Moreover, the performance of the two-compartment cell can be enhanced by the introduction of a third chamber. For example, the multichamber cation cell now uses two CEMs [23]. In operation the salt solution is first fed to the chamber between the two CEMs and then passes to the acid compartment. This gives a salt/acid stream with a higher concentration of acid than the standard two-compartment cell. The multichamber anion cell is used in a similar way to that of the cation cell. Clearly, this multicell arrangement incurs a greater electrical energy cost due to the higher cell voltage than that needed in the two-compartment cell.

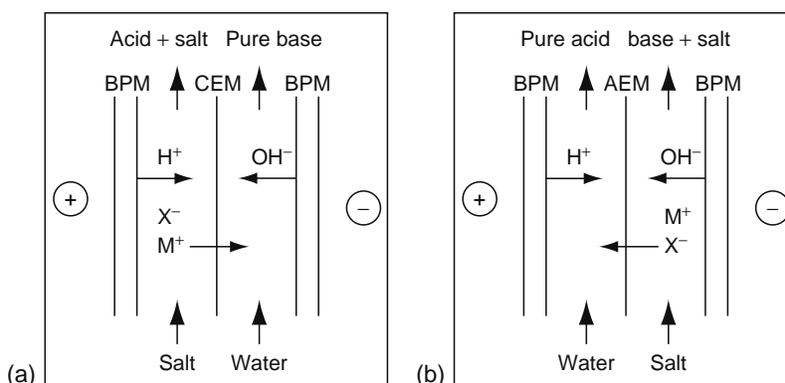

FIGURE 21.6 Two-compartment EDBMs for production of (a) only pure base and (b) only pure acid.

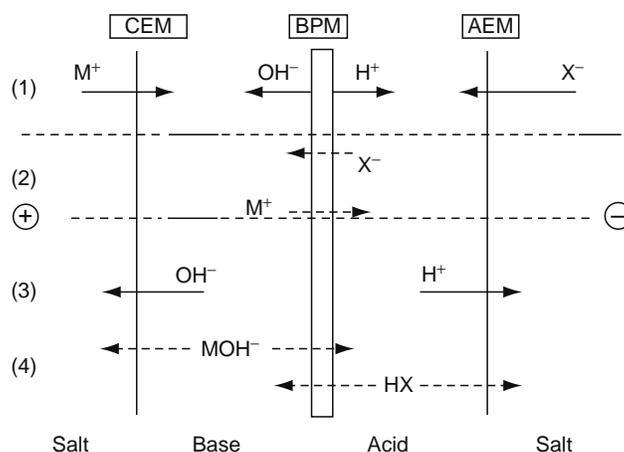

FIGURE 21.7 Processes occurring during EDBM.

### 21.2.4 FEATURES OF EDBM, DIFFERENCE FROM THE CONVENTIONAL ELECTROLYSIS, LIMITS

The main features of EDBM are

- The BPM can dissociate water into  $H^+$  and  $OH^-$  ions.
- Since no gases are generated during water splitting, the energy consumption is very low.
- Since no electrochemical reactions are running, there is no oxidation or reduction, which may generate undesirable products.
- BPM can be used in association with AEM and CEM to produce acids and bases from salts by electrodialysis.

However, and as for all the processes, EDBM presents limits [23]. The performances of a water splitter are controlled by the permselectivities of the individual component membranes and by diffusive transport. Figure 21.7 illustrates the various processes which contribute to the overall current efficiency. Zone 1 concerns the specific process which generates acid and base from salt and water. Competing with this are the undesirable processes, which reduce the current efficiency. Zone 2 represents the loss of permselectivity of each homopolar layers of the BPM. In the three-compartment configuration (Figure 21.5), this factor directly acts on the purity of the acid and base produced. Zone 3 represents the loss of permselectivity of the associated homopolar membranes. Zone 4 concerns the diffusional losses due to the concentration gradients, which significantly occur for poorly ionized small molecules ( $HF$ ,  $NH_3$ ,  $SO_2$ , etc.).

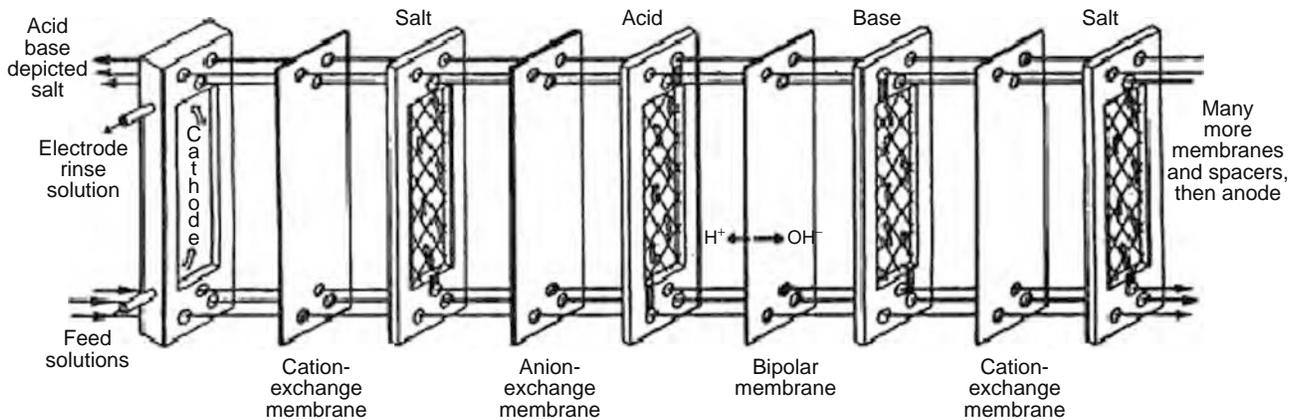

### 21.2.5 CELL EQUIPMENT AND PROCESS CONFIGURATIONS IN EDBM

The principle of the cell design is depicted in Figure 21.8.

The technical requirements of an EDBM module should fulfill the following criteria:

1. Minimal distance between membranes (0.5–1 mm) to reduce the ohmic drop
2. Appropriate hydrodynamic conditions with high superficial velocity for a better control of the concentration polarization
3. High value of the ratio (membrane area/volume of the EDBM module) for a reasonable material flux
4. Avoiding all leakages between the compartments
5. Reducing the short circuits and parasitic currents

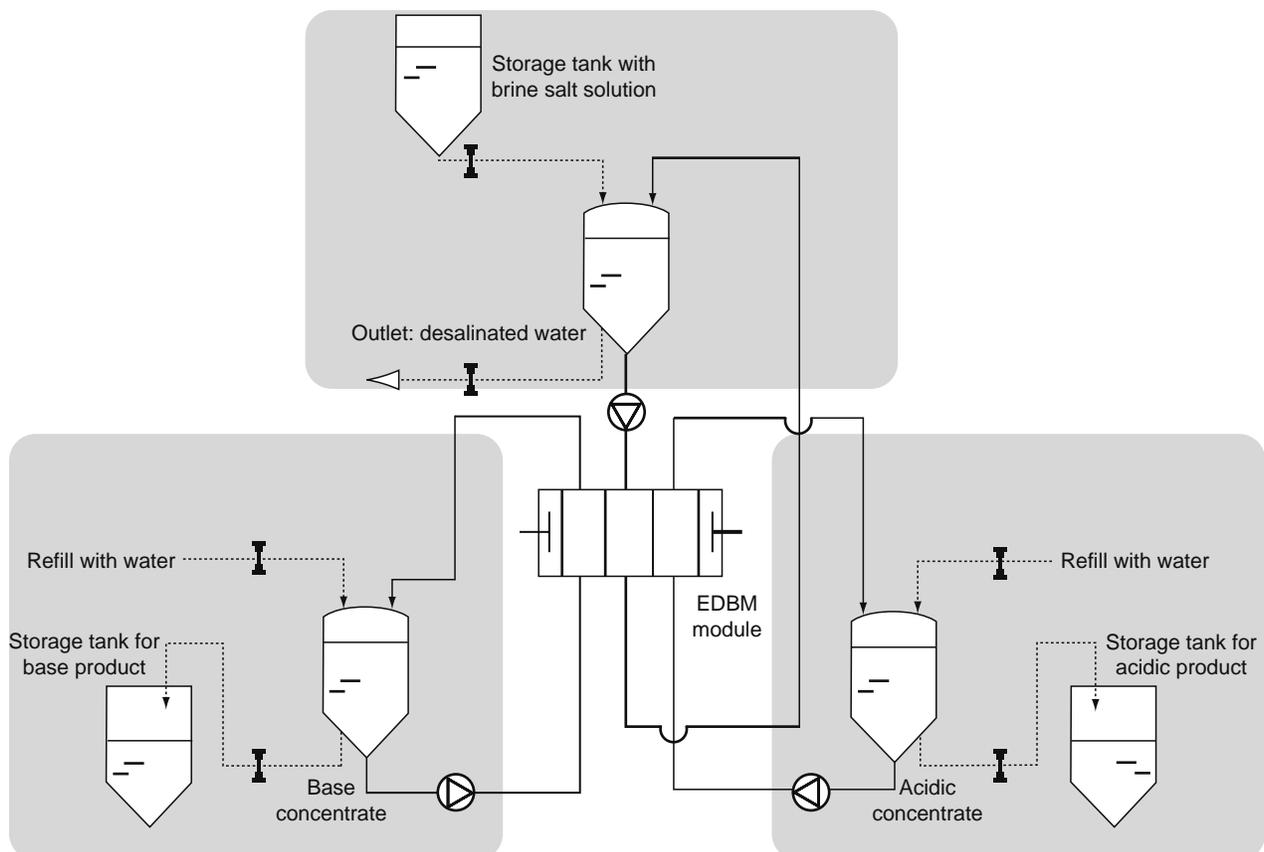

From a practical point of view, a filter press module of 30–50 elementary cells with a geometric surface area of 0.3–0.5  $m^2$  seems to be a good configuration [45]. The corrosion stability of the EDBM stack components such as bodies, frame, turbulence promoters, gaskets, and electrodes is of great importance. The corrosion resistance of the electrodes and of course their prices are also decisive elements. Stainless steel is the cheapest choice of material for anode and cathode and is suitable in weakly alkaline or neutral aqueous electrolytes [66]. Nickel electrodes are much more expensive and used when an enhanced passivity is required. Titanium electrodes have excellent stability against acid and slightly basic media. A coating layer of metal oxides (such as  $RuO_2$ ) reduces significantly the overpotential for oxygen or chlorine evolution.

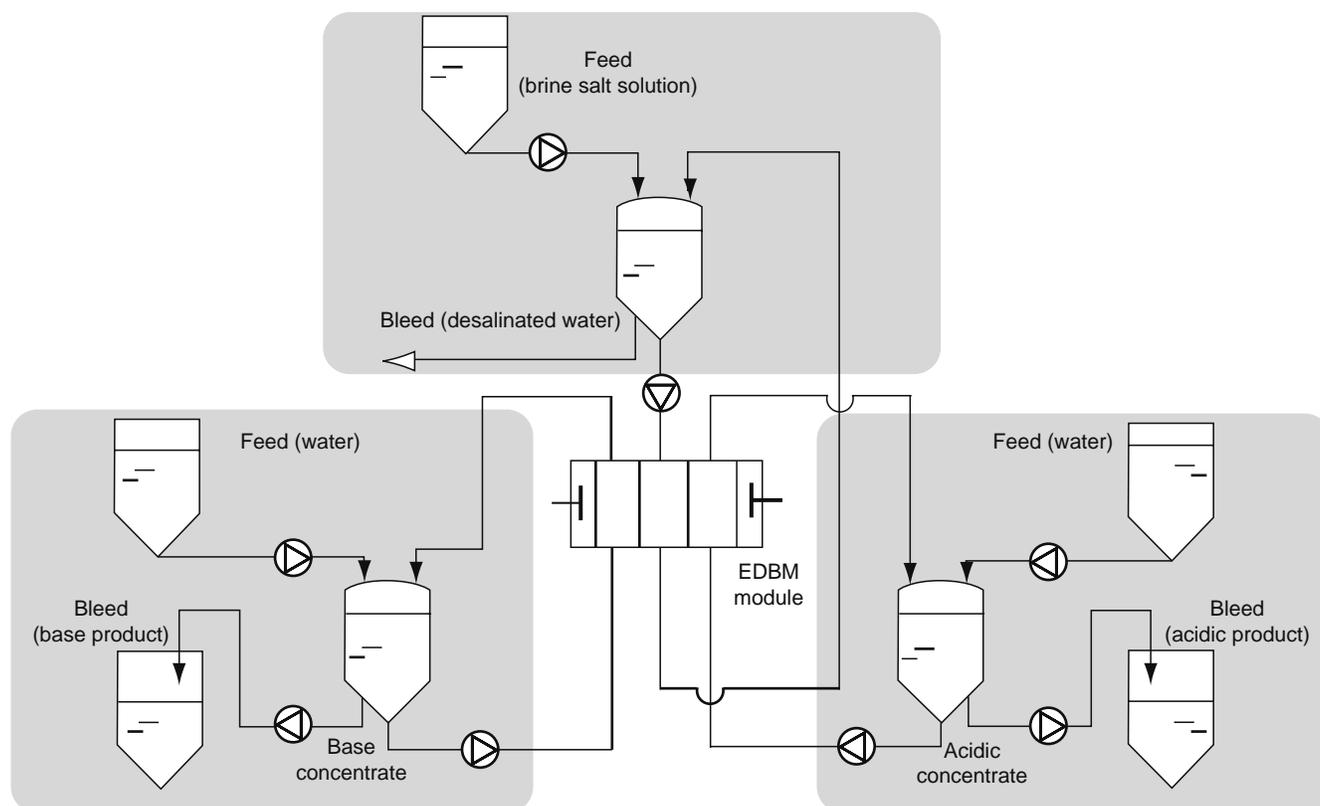

**FIGURE 21.8** EDBM cell assembly. (Reprinted with permission from Kemperman, A.J.B., Ed. *Handbook of Bipolar Membrane Technology*, Twente University Press, Enschede, The Netherlands, 2000. Copyright 2000 Twente University Press, p. 162.)

Three common process configurations are used.

1. The batch mode for small- and medium-scale applications (Figure 21.9). In this case, the process can be easily adjusted to the individual demands with respect to product concentration and mass flow. However, it requires a high expenditure for buffer tanks and tubing and instrumentation.
2. The feed and bleed mode for medium- and large-scale applications (Figure 21.10). In this case, the process can also be easily adjusted to the individual demands with respect to product concentration and mass flow. It is appropriate for a

continuous production and steady operation conditions. However, it requires also a high expenditure for buffer tanks and tubing and instrumentation.

3. The single-pass continuous flow configuration (Figure 21.11) for medium- and large-scale applications. This mode is suitable for a continuous production and is cheaper than the two previous for buffer tanks, tubing, process control instrumentation, and energy consumption. However, a later adjustment of unit to altered process conditions is not easy.

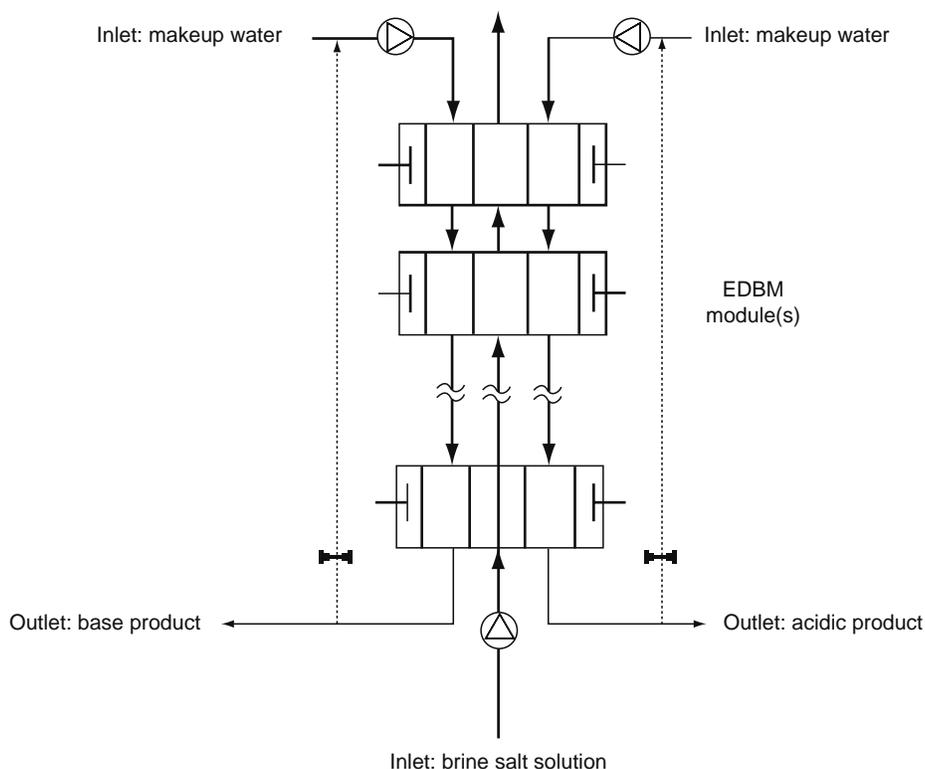

### 21.2.6 SCALING-UP AND EXPLOITATION PARAMETERS OF THE BPM TECHNOLOGY

To optimize a BPM process, the following parameters have to be respected:

- Purity of the effluent to be treated: organic pollution and multivalent cations must be avoided: (1) IEM and BPM swell in the presence of aromatic compounds and (2) metallic hydroxides precipitate in the membranes when the divalent cation concentrations reach 1 ppm.
- Concentrations of the products: Due to the proton leakage through associated AEMs, the maximum concentration of mineral acid products is 2–3 and 5 N for organic acids. Due to the hydroxide ion leakage through the associated CEM, the maximum concentration of the base produced is 4.5 N.
- The voltage drop per elementary cell has to be maintained in the range 1.5–3 V for 1000 A/m<sup>2</sup>. The applied current density is in the range 50–100 mA/cm<sup>2</sup>.
- The minimal conductivity of the salt loop is 20 mS/cm at 40°C.
- The conversion ratio for organic salts is in the range 95%–98%.

Taking into account the previous recommendations, scale-up of EDBM is really quite simple. In most cases, the operating conditions in a lab-scale EDBM can be reproduced on a commercial scale.

The product concentration (i.e., wt% NaOH resp, HCl) influences the energy demand and throughput. The higher the product concentrations, the lower is the throughput and the higher the energy. The purity of the product is dependent on its

**FIGURE 21.11** EDBM setup for single-pass flow configuration with hydraulic staging. (Reprinted with permission from Kemperman, A.J.B., Ed. *Handbook of Bipolar Membrane Technology*, Twente University Press, Enschede, The Netherlands, 2000. Copyright 2000 Twente University Press, p. 184.)

concentration. The higher the concentration, the higher is the salt contamination of the acid and base. To get high-purity products at a high throughput level, the current density should be as high as possible ( $>100 \text{ mA/cm}^2$ ). Moreover, a well-designed pretreatment is of importance to reduce scaling and fouling.

An example of performance of an EDBM pilot plant is reported in Table 21.2 [79]. It concerns the production of caustic soda from an NaCl waste stream from an amino acid production process. Apart from organic components, this salt stream

**TABLE 21.2**

<sup>a</sup> The CE is defined for each transported ionic species. It is the ratio of the actual molar transport calculated by Faraday's law with the actual current density  $j$  according to  $\text{CE} = F \cdot z_i \cdot n_i / j$  with  $n_i$  the molar flux density (mol/m<sup>2</sup> s) and  $F$  the Faraday's constant.

<sup>b</sup> The SEC is given by the relation  $\text{SEC} = \Delta E \cdot I = \Delta E \cdot j \cdot A = \Delta E \cdot (z_i \cdot F \cdot n_i / \text{CE}) \cdot A$  with  $I$  the current (A),  $A$  the total membrane area (m<sup>2</sup>),  $\Delta E$  the potential difference (V) applied to the EDBM unit.

contains about 500 ppm of Ca<sup>2+</sup>, Mg<sup>2+</sup> ions. A pretreatment including polishing with ion-exchange resins reduces this amount to less than 0.5 ppm. The waste stream is then processed in a three-compartment EDBM unit designed for both batch and feed and bleed mode. The total membrane area is 1.78 m<sup>2</sup> (16 repeating unit cells, each membrane with an area of 0.12 m<sup>2</sup>).

### 21.3 MAIN APPLICATIONS OF THE EDBM

A large number of applications of EDBM have been identified. A classification under two broad categories of pollution control/resource recovery and chemical processing is reported in Table 21.3 [45].

This chapter deals with developments of EDBM technology in food industries and only a short review is devoted to other application domains. The oldest industrial application of EDBM in the pollution control/resource recovery is the recovery of HF and HNO<sub>3</sub> from a stream containing KF and KNO<sub>3</sub> generated from a pickling bath in a steel plant. This first commercial use of BPM began operations in 1987 at Washington Steel in Pennsylvania [80]. This application was stopped in 2000. Among the other examples, one can quote the regeneration of sodium sulfate in a rayon plant [23], a gas absorption process for the conversion of amine in air, the treatment of flue gas for removal of SO<sub>2</sub> [81], the electrodialytic dissociation of alcohols to produce sodium methoxide [82], or the recovery of methanesulfonic acid from sodium methanesulfonate solutions [45]. While the applications of EDBM in the pollution control/resource recovery seem to reach a stage, those concerning chemical processing and food industries are growing [78].

### 21.4 APPLICATIONS OF EDBM TO FOOD INDUSTRIES

In 1990, Hatzidimitriu [83] patented a process for adjusting the pH of aqueous fluids. This process can be used for adjusting the acidity of an edible fluid (specifically sugar syrups, fruit and vegetable juices, wines, sauces, and tomato paste) by electrodialysis in a cell containing membrane pairs comprising a BPM and an ion-selective membrane. More specifically, Dykalo et al. [84] used bipolar membrane ED to control the acidity of dairy products containing an aqueous phase. To control

the pH of dairy products, the solution was circulated on the cationic side of the BPM, where the  $H^+$  ions are generated, to lower the pH and on the anionic side of the BPM, where  $OH^-$  ions are generated, to raise the pH. These applications point the way to new applications for BPMs beyond the production of acids and bases. Recently, EDBM has been applied to protein precipitation and purification, enzymatic browning inhibition, simultaneous recovery of coagulant agent and protein, fruit juice deacidification, and dairy wastewater purification.

### 21.4.1 PRODUCTION OF SOY PROTEIN ISOLATE

A large proportion of the soy protein used in the food industry is in the form of protein isolates (>90% protein). Separation of proteins by isoelectric precipitation at the isoelectric pH range 4.2–4.6 is the recognized industrial process. The isoelectric point is the pH value at which the net global charge of the protein is neutral. At this pH value, the solubility of the protein is minimal and can result in complete precipitation.

The conventional precipitation procedure involves five steps: extraction, precipitation, washing, resolubilization, and drying. The defatted soy flakes are dissolved in water at  $pH\ 9 \pm 2$  in a ratio ranging from 6:1 to 20:1 at  $<80^\circ C$ . The extraction step usually takes ~30 min. Once the extraction is finished, the proteins are precipitated by lowering the pH of the solution to the isoelectric point, ~4.5, using hydrochloric acid. Centrifugation is used to separate the protein-containing curd from the supernatant (or whey) containing the soluble materials and low-molecular-weight compounds. The curd is then washed with water to remove soluble impurities (salts and sugars). After washing, it is neutralized with NaOH to obtain a proteinate, a soluble form of protein. The final product is spray dried, and packaged as a dry material [2].

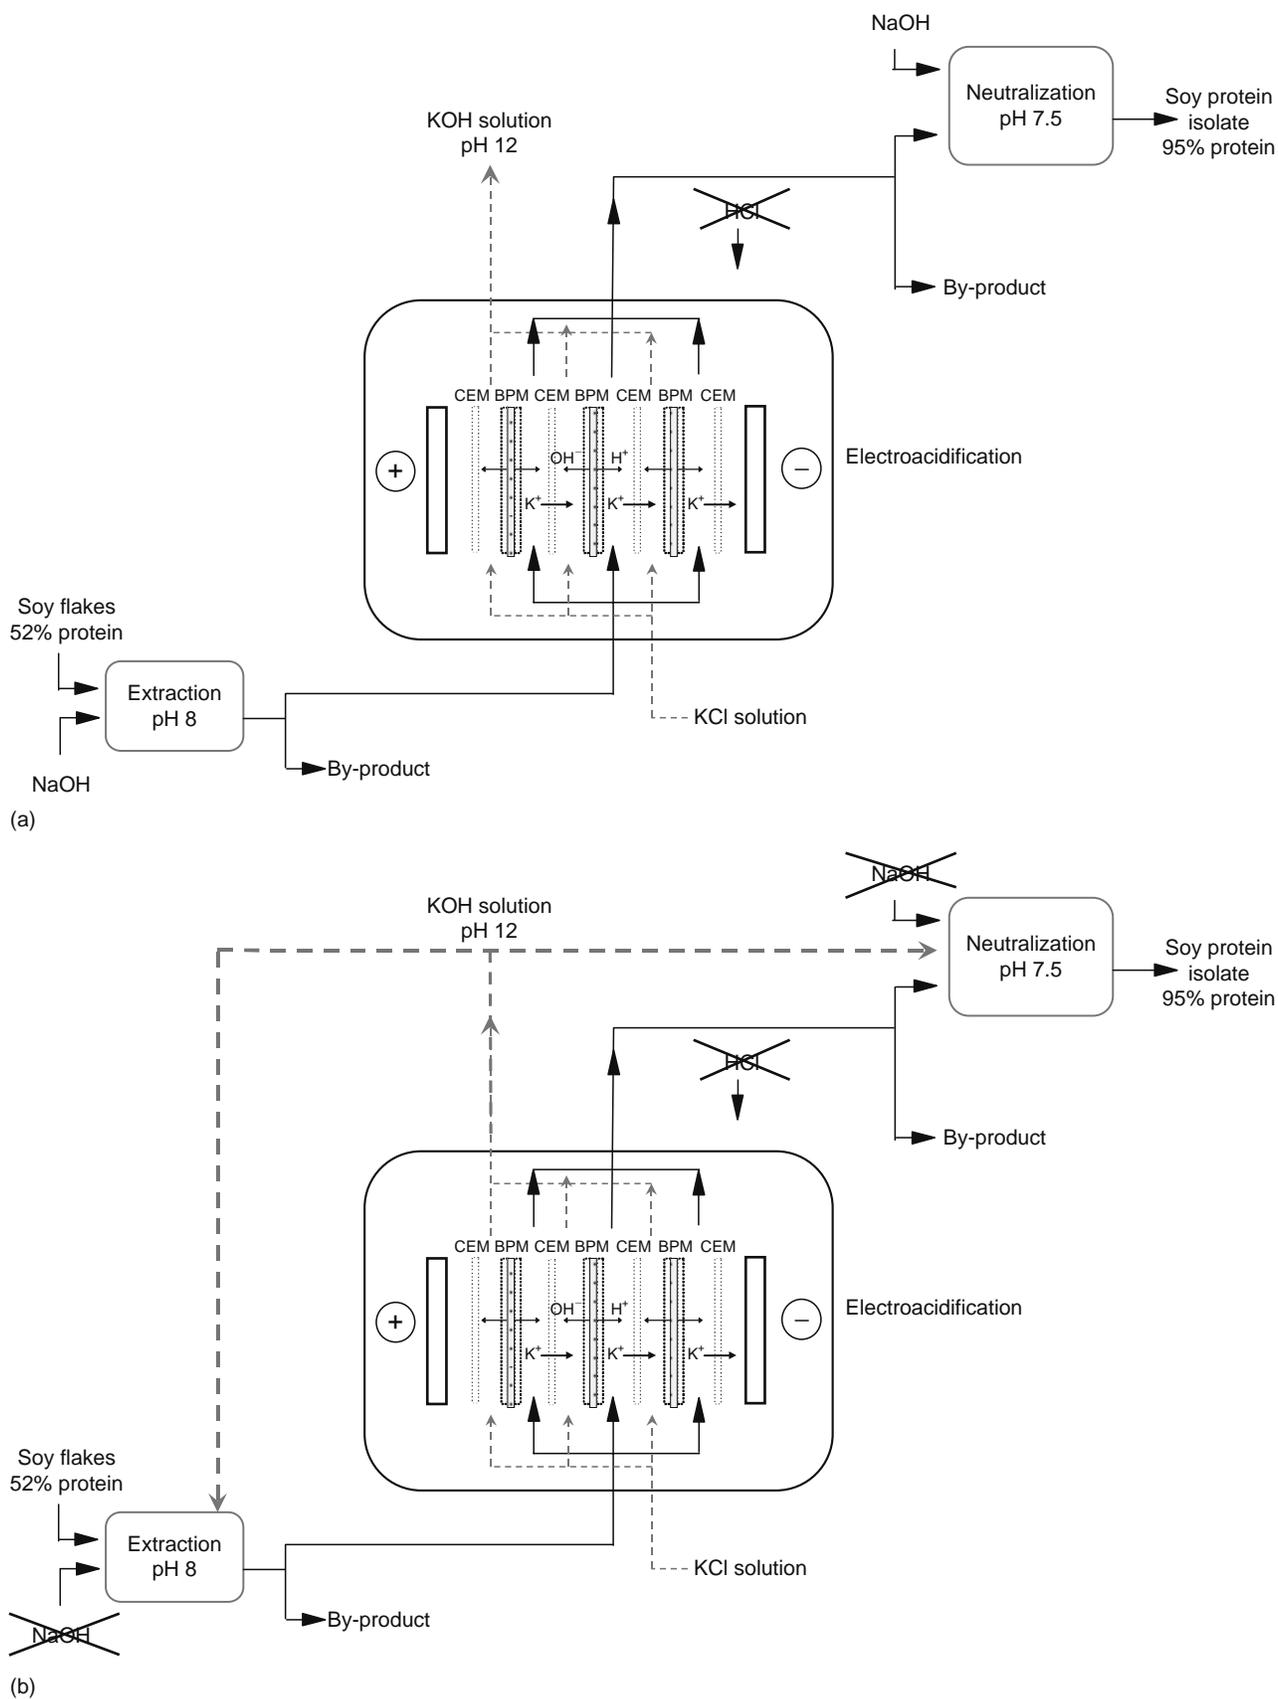

Most commercial soy protein products have been developed from the acid-precipitated fraction [85]. However, local extremes in pH can cause irreversible denaturation of the proteins [85]. The disadvantages of this method include denaturation of protein on exposure to alkali and acid treatment, high-ash content, and alteration of protein solubility after rehydration [86].

In this context, Bazinet et al. [41] developed a procedure using BPMs to precipitate soy proteins (Figure 21.12a). The protons generated by the BPM come into contact with the protein, bringing them to their isoelectric point resulting in selective separation. Centrifugation can then be used, as in the conventional process for separation of the proteins. To lower the pH of the protein solution, this solution was circulated on the cationic side of the BPM. The pH of the protein solution was lowered from 8.0 to 4.5 in a cell of  $100\text{ cm}^2$  effective electrode surface, at a constant current of  $25\text{ mA/cm}^2$ . Lowering the pH to 4.5 allowed a precipitation of 95% protein. The energy and electroacidification parameters are affected by various factors such as the number of BPMs, the initial concentration of soy protein concentrate (SPC) and KCl in the protein solution, and the temperature.

Electroacidification of soy proteins was related to the generation of  $H^+$  at the surface of BPMs, and increasing the membrane surface accelerated the electrochemical precipitation quasi-linearly: Doubling the number of membranes decreases, by about one-half, the duration of the electroacidification procedure. Increasing the number of BPMs in the electro dialysis cell increases the electrical efficiency of the system while decreasing the time required, but not in a linear fashion. The stacking has no effect on the final protein precipitation rate. The time required to lower the pH to 4.5 is determined primarily by the SPC concentration and the temperature [41]. This is due to the larger quantity of  $H^+$  required from the dissociation of water to overcome the higher buffering capacity associated with a higher protein concentration [87].

When the initial SPC concentration is increased, a change in the percent soluble protein as a function of pH is observed: at 15 g/L a quasi-linear precipitation occurs whereas at 60 g/L the protein precipitation curve takes on a sigmoidal form. From initial pH to 7.0, no real difference is noted; the percent soluble protein was about 100%. A high-protein concentration slows the electroacidification process as a result of the intrinsic buffering capacity of the protein [88,89]. However, the final percent soluble protein is not affected by an increase in the SPC concentration.

Temperature is another factor affecting EDBM. By increasing the temperature, the mobility of the ions is increased and consequently the overall resistance of the system is decreased [90]. The energy required to decrease the pH to 4.4 rises as the SPC concentration is increased, and drops with an increase in the KCl concentration (Table 21.4). With an increase of  $25^\circ C$  in temperature (from  $10^\circ C$  to  $35^\circ C$ ), a 53% decrease in energy consumption was observed. By expressing the energy consumed relative to the production of 1 kg of protein isolate, a drop in energy is observed with an increase in the SPC concentration. In parallel, a drop in energy consumed occurs as the KCl concentration and the temperature rise. This indicates that the SPC concentration and the temperature are the primary factors influencing the energy consumption of the BPM electroacidification cell. At low SPC concentrations, a high level of KCl will improve the overall efficiency of the system. The effect of the SPC concentration is not related to the protein concentration but rather to its intrinsic salt concentration. The proteins have a minor effect on the energy efficiency compared to salts, because the proteins represent a minute proportion of the electrical charges in solution, and possess an extremely limited mobility. In fact, the effect of the SPC concentration is related to a high concentration of minerals, approximately 5% of the dry weight of SPC [91], of which 50% is potassium [91]. Thus, an increase in salt concentration results in a lower resistance of the medium because the added salt supplies the ions necessary to maintain the conductivity of the solution during the production of  $H^+$  by the membrane. The resistance of the solutions depends mainly on the concentration of electrolytes in the medium [92]. Increasing the temperature increases the energy efficiency of the

electroacidification procedure, but in a nonlinear fashion. This increase in efficiency is lower between 20°C and 35°C than between 10°C and 20°C and is related to an increase in ion mobility, the result of a decrease in viscosity brought about by the temperature increase [93]. Viscosity is one of the important parameters for a protein solution undergoing electroacidification, since it affects the hydrodynamics of the system. In an electroacidifier, a high viscosity changes the overall electrical resistance by slowing diffusion and migration of ions in the solution being treated [92].

The authors also compared the chemical and electrochemical acidifications to identify differences between both acidification procedures. During chemical acidification of protein solution, the conductivity increased, while it decreased in electroacidification. In fact, the addition of acid corresponds to an addition of H<sup>+</sup> and Cl<sup>-</sup> ions: their respective conductivities are 349.6 and 76.4 S cm<sup>2</sup> mol<sup>-1</sup> [94]. Consequently, this addition of ionic species contributes to an increase in the overall conductivity of protein solution (Figure 21.13). Electroacidification decreases the conductivity of the solution due to the

**FIGURE 21.13** Effect of SPC concentration and acidification procedure, 0.25 N HCl (●), 0.5 N HCl (□), 1.0 N HCl (▲), 2.0 N HCl (▽) and electroacidification (◐), on the conductivity measured during the pH decrease of electrochemical and chemical acidifications of soybean protein solutions, with 0.06 M KCl added and maintained at 25°C. desalination phenomenon by electro dialysis [8,95,96]. As the pH decreases, the variation of conductivity depends both on the SPC concentration and the acidification procedure. As the pH is dropped from its initial pH to 4.5, in electroacidification, the variation in conductivity is inversely proportional to the SPC concentration while, in chemical acidification, this variation is proportional (Figure 21.13) [88]. These effects are the results of an increase in buffering capacity of the protein solution coupled, in electroacidification with the migration of cationic species, and in chemical acidification with the addition of ionic species [88].

A comparison of the soluble protein evolution during the pH decrease revealed that there is a difference between the chemical and the electroacidification (Figure 21.14). The protein precipitation curve obtained during electroacidification shows a shift in comparison with those of chemical acidification levels; from initial pH to 6.8, the soluble protein percentage was about 100% for chemical and electrochemical acidification. At pH 6.4, a difference appears between the two procedures of acidification, with 85.1% and 94.9% of soluble protein, respectively, for chemical and electroacidification. This difference increases between pH 6.0 and 5.6 with 57.1% and 32.6%, respectively, of soluble protein for chemical acidification compared to 69.4% and 43.9% for electroacidification. Then, the difference drastically decreases until it disappears; at pH 5.2, 4.8, and 4.4 the soluble protein percentages were 14.5%, 5.7%, and 5.1% compared to 17.4%, 6.4%, and 5.5%, respectively, for chemical and electrochemical acidification. The final precipitation extent of protein is not influenced by the acidification procedure; however, the precipitation is slower during electroacidification. The difference in precipitation of protein between chemical and electrochemical acidification could be related to a lower local excess of acid in electroacidification. In fact, the conventional chemical acidification process to produce protein isolates is known to denature protein by local excesses of acid [85] while electroacidification was demonstrated to precipitate protein with a low extent of protein denaturation [40,92].

The variation of precipitation as a function of pH is related to the different precipitation profiles of the two protein fractions, 7 S and 11 S [97]. According to Thanh and Shibasaki [97], protein concentrations (up to 4%) are favorable for the separation of the two globulin fractions. They noted that the 7 S fraction is not very sensitive to an increase in protein concentration, whereas the 11 S fraction started to precipitate earlier with a higher protein concentration. This correlates with the large change in soluble protein observed for pH 6, a point close to the isoelectric point of the 11 S fraction and the inflection point of the protein solubility curves. The electroacidification process influences the precipitation curve of the 11 S fraction; the electroacidified 11 S fraction precipitation curve presents a slight shift in comparison with the chemical acidification curves (Figure 21.15a and 21.15b). The lower precipitation for the electroacidified proteins is the result of the lower extent of precipitation obtained for the 11 S fraction [88].

Separation of soy protein by EDBM has specific advantages over the conventional isoelectric precipitation used industrially for the production of soybean protein isolates. This technology does not use any added acids or bases during the process to adjust the pH of the protein solution, and the chemical effluents generated during the process could be reused at different stages in the

**FIGURE 21.15** Size exclusion HPLC chromatograms of (a) chemically and (b) electrochemically acidified soybean protein solutions, with 0.06 M KCl added and maintained at 25°C, at different pH values. (Reprinted with permission from Bazinet, L., Lamarche, F., and Ippersiel, D., *J. Agric. Food Chem.*, 46, 2013, 1998. Copyright 1998 American Chemical Society.)

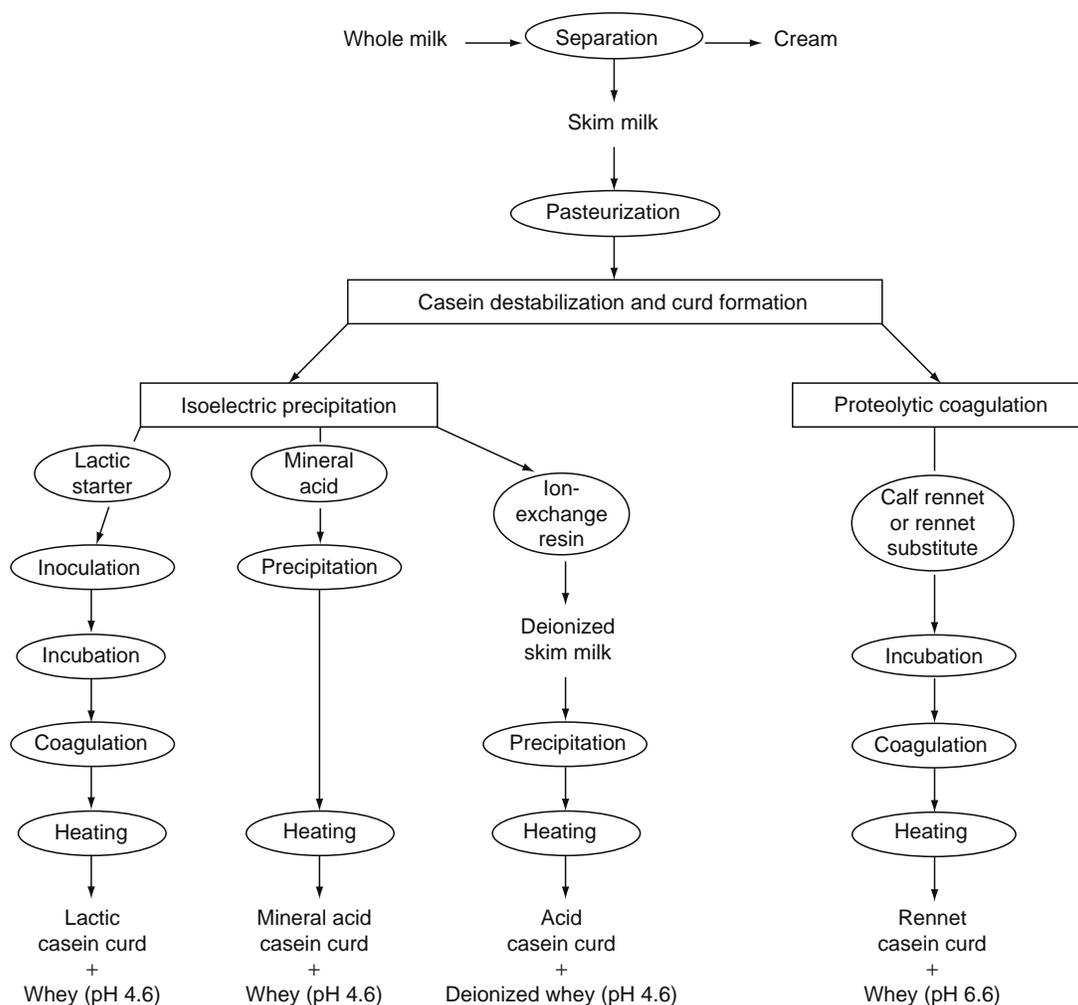

process. The water consumption is decreased by reusing the effluents generated, and the cell electrical energy consumption for protein precipitation is low (~0.3–0.7 kW h/kg of isolate). After washing the precipitate, it is possible to resolubilize the proteins by reusing the sodium hydroxide generated on the anionic side of the BPM, or by recirculating the precipitated protein solution on the anionic side during the acidification of another protein solution on the cationic side of the BPM (Figure 21.12b). In addition, the chemical composition of bipolar-membrane electroacidified samples was demonstrated to be superior or equal to that of commercial standards, with functional properties comparable to these standards [40,92].

The application of soybean protein electroacidification at the industrial scale is limited because of gradual protein precipitation in the cell, which results in an increase of the cell resistance (decrease of the system efficiency) and loss of protein (decrease in yield). The blocking which can appear in EDBM of soybean protein is not a form of membrane fouling as in ultrafiltration and nanofiltration, but mainly due to spacer fouling, resulting from a nonoptimized hydrodynamic design of the electro dialysis cell. The fouling is due to the particles in suspension, which agglomerate in the spacers when their concentration is too high. An online centrifugation process has been proposed by Bazinet et al. [2] to allow the recovery of these particles and decreased fouling. More recently, Mondor et al. [98] proposed a combination of electroacidification and ultrafiltration to decrease this fouling.

#### 21.4.2 PRODUCTION OF ACID CASEINATE

Due to its nutritional quality and functional properties, casein is extensively used in the manufacturing of food products. However, pure casein can only be obtained by an insolubilization step followed by a centrifugation for a simple separation of the casein from the whey [99]. Two main types of casein are usually produced in the industry: rennet and acid caseins (Figure 21.16). In rennet casein, the underlying mechanism is identical to that of the production of cheese curd and depends on the unique sensitivity of the Phe<sub>105</sub>-Met<sub>106</sub> bond of  $\kappa$ -casein to hydrolysis by acid proteinases, the active components of rennet. For acid casein production, the three main procedures used are based on isoelectric precipitation of casein by chemical, physicochemical, or fermentation acidification [99–101]. Other techniques have been proposed for the production of acid casein: acidification of milk by ion-exchange plus acid [102] or by ion-exchange alone [103], electro dialysis of skim milk to pH 5.0 followed by acidification to pH 4.6 with acid [104], and acidification by water electrolysis at the surface of monopolar anion or CEMs stacked in an electro dialysis cell [105]. A specific advantage of these methods is the production of acid whey with reduced mineral content. This acid whey is more readily utilized than acid whey produced by the normal acidification process and may increase its value for further processing [101,106].

However, the procedures used in the dairy industry, rennet and acid casein, have the disadvantages to produce large volume of chemical effluents due to the addition of bases and acids during treatments, and to generate inherent risk linked to handling, stocking, and transportation of concentrated bases and acids. In acid casein production, milk pH is decreased to the isoelectric point of the casein by addition of strong acid (hydrochloric, sulfuric, nitric, lactic, etc.). H<sup>+</sup> concentration of milk is increased

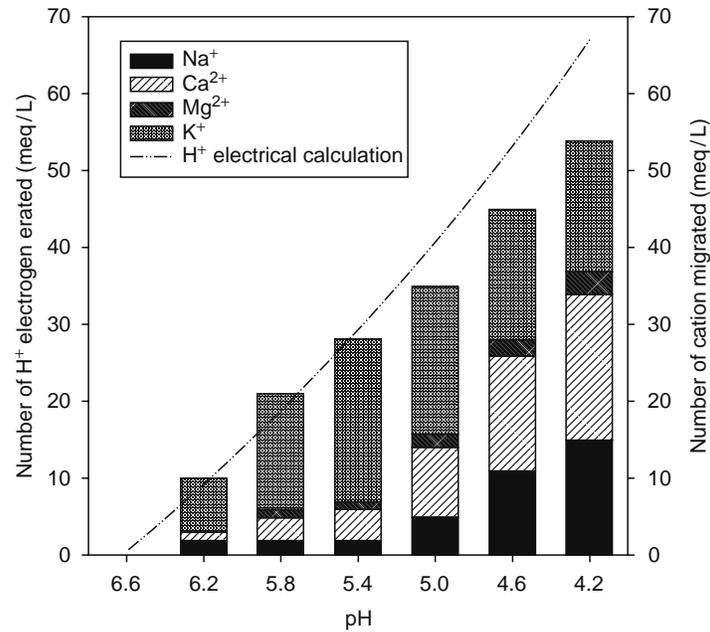

**FIGURE 21.16** Processes for casein and caseinate production. (Adapted from Mulvihill, D.M., Caseins and caseinates: Manufacture. In: Fox, P.F., Ed. *Developments in Dairy Chemistry*, Vol. 4, Elsevier Applied Science Publishers, London, 1989, pp. 97–129.)

with an increase of chloride, sulfate, nitrate, or lactate concentration.  $H^+$  cations are necessary in the process to decrease pH. However, anions are nondesired and contribute in an important manner to the mineral charge. These additional anions are present at the final step in the curd before washing and in the whey. To use whey from hydrochloric casein production it is necessary to demineralize it to decrease the mineral charge. A whey from hydrochloric casein contains 12% to 14% (w/w dry basis) of mineral and approximately 7% to 8% and more chloride. For fermentations, it is necessary to use mixed starter culture and to change them regularly to avoid contaminations by phages. Furthermore, during rennet casein production,  $\kappa$ -casein is denatured by formation of caseinomacropptide and para- $\kappa$ -casein [87,106,107]. In addition in water electrolysis with monopolar membranes, the electrical efficiency is lower than with BPMs [40,92].

In this context, EDBM was used for the precipitation of bovine milk protein, without adding acids, by decreasing the pH through electroacidification [42]. The skim milk was circulated in a three pair cell configuration on the cationic side of the BPM as for soy protein isolate production. The electroacidification was performed in batch process using a current density of  $20 \text{ mA/cm}^2$ . The pH of the solution was lowered from pH 6.6 to 4.4. Lowering the pH to 4.4 allowed a precipitation of 80%–85% of the total protein. The remaining proteins were whey proteins soluble at pH 4.4. This technology allowed the production of bovine milk casein isolates with a similar or higher protein content than those of commercial isolates (97% vs 95% on a dry basis). The protein profiles of the isolates obtained by HPLC showed that caseins represented 98.5% of the total protein precipitated.

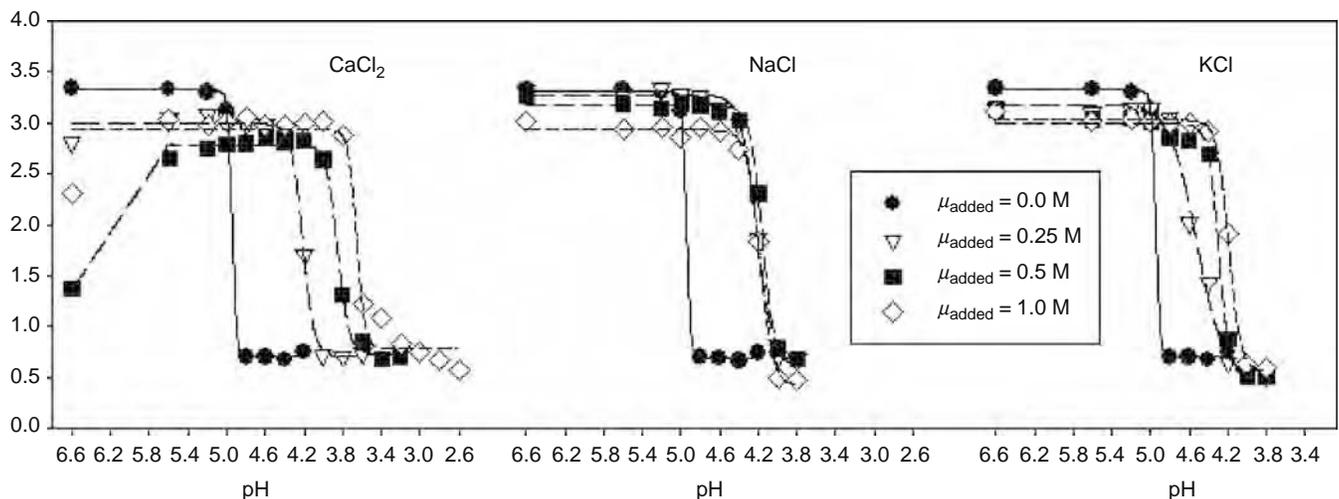

As in any electrochemical process, the products to be treated by EDBM must possess a relatively high mineral content to allow a good electrical conductivity to decrease the global resistance of the electroacidification cell. Moreover, Bazinet et al. [108] demonstrated that the electrical efficiency of skim milk electroacidification is decreased, due to a lack of sufficiently mobile ions such as potassium (Figure 21.17). Consequently,  $H^+$  ions have to migrate across the CEM to ensure the electroneutrality.

**FIGURE 21.17** Comparison of the amount of electrogenerated  $H^+$  (meq/L) and the amount of cations migrated (meq/L) during electroacidification of skim milk. (Adapted from Bazinet, L., Ippersiel, D., Gendron, C., Beaudry, J., Mahdavi, B., Amiot, J., and Lamarche, F., *J. Membr. Sci.*, 173, 201, 2000.)

These migrated  $H^+$  ions are lost for the process and decrease the electrical efficiency. Bazinet et al. [89] did not observe this phenomenon on soybean protein electroacidification due to the higher concentration in potassium ions in the raw material.

They suggested adding a certain amount of salt to the skim milk to obtain a better electrical efficiency. The performances of EDBM were then evaluated under different conditions of ionic strength added ( $\mu_{\text{added}} = 0, 0.25, 0.5, \text{ and } 1.0 \text{ M}$ ) and added salt ( $\text{CaCl}_2$ ,  $\text{NaCl}$ , and  $\text{KCl}$ ). The evolution of soluble protein during EDBM of skim milk was different according to the salt added and the ionic strength level (Figure 21.18). Moreover, for each added salt, the soluble protein curves had different evolution according to the ionic strength added. For  $\text{NaCl}$ , the soluble protein curves were the same with inflection points close to  $\text{pH } 4.20$  whatever the ionic strength added. In  $\text{CaCl}_2$ , the delay in precipitation increased with an increase in the ionic strength while for the  $\text{KCl}$ , the delay in precipitation was increased with the increase in ionic strength. For  $\mu_{\text{added}}$  ranging from 0.25 to 1.0 M, except for the  $\text{NaCl}$ , the  $\text{pH}_c$  value, at which all the caseins are precipitated, decreased with an increase in ionic strength by salting-in [87]. In  $\text{NaCl}$  addition, the different levels of  $\mu_{\text{added}}$  had no effect on the soluble protein profile;

**FIGURE 21.18** Effect of ionic strength (0, 0.25, 0.5, and 1.0 M) and type of salt added ( $\text{CaCl}_2$ ,  $\text{NaCl}$ , and  $\text{KCl}$ ) on soluble protein during BPM electroacidification of reconstituted skim milk, run at a constant current density of  $20 \text{ mA/cm}^2$ . (Adapted from Bazinet, L., Ippersiel, D., Gendron, C., Mahdavi, B., Amiot, J., and Lamarche, F., *J. Dairy Res.*, 68, 237, 2001.)

however, there is an effect of salting-in in comparison with soluble protein of skim milk without NaCl added (Figure 21.18). The results obtained for the KCl are in accordance with the data obtained by Bazinet et al. [41] on soybean protein electroacidification. Repulsive hydration forces between proteins and protein solubility are minimal at the isoelectric pH, unless the net charge on the proteins is controlled in part by highly hydrated cations such as  $Mg^{2+}$ ,  $Ca^{2+}$ , and  $Na^+$  [109]. In the latter situation, coagulation occurs when the  $H^+$  concentration is high enough to replace the hydrated cations. The more  $Ca^{2+}$  present, the higher the  $H^+$  concentration required to cause coagulation. Thus, the highest pH at which casein micelles coagulate decreased from 5.0 to 3.8 as  $CaCl_2$  concentration was increased from 10 to 100 mM [110]. The combination of KCl and  $\mu_{added}=0.5$  M was the best combination with a 45% decrease in energy consumption in comparison with EDBM of skim milk without adding salt. Addition of salt, except for  $CaCl_2$ , resulted in a decrease in energy consumption (Table 21.5) [111,112].

Differences in supernatant composition at pH 4.6 were revealed for  $\alpha_s$ -casein,  $\beta$ -casein, and whey proteins [113]. Thus, the supernatant composition results obtained at pH 4.6 showed that the supernatant of electroacidified milk had a higher whey protein content compared with the supernatants of chemically acidified solutions, with values of 95.0% and 87.2%, respectively. At this pH value, unprecipitated  $\alpha_s$ - and  $\beta$ -casein fractions were observed in the chemical acidification treatments, whereas in electrochemical acidification, there was no trace of these two casein fractions. The difference observed between the protein profiles confirms the results obtained previously for total protein and indicates a slight delay in precipitation of  $\alpha_s$ - and  $\beta$ -caseins during the chemical acidifications. This precipitation difference may be due to a salting-in effect from the addition of salts [114] during chemical acidifications with HCl. By contrast, in electroacidification the impoverishment of salts by electrochemical demineralization, combined with a dilution effect from the system's dead volume, promotes precipitation of the proteins. Indeed, at the isoelectric point (pH 4.5–4.7 for caseins), the proteins have a net charge of zero, and they precipitate due to the effect of hydrophobic interactions. Under these conditions, there are no electrostatic repulsions between the molecules. Hence, if the ionic strength is increased, as in chemical acidifications, the salting-in effect of salts on hydrophobic interactions tends to slow the formation of aggregates and increase their solubility, leading to slower protein precipitation [87,115]. Electroacidification, on the other hand, accelerates the formation of protein aggregates and their precipitation. The salt removal in the milk solution promotes the hydrophobic interactions.

The isolates produced by BPM electroacidification with different type of added salts and ionic strength except at 1 M  $CaCl_2$   $\mu_{added}$  showed similar physicochemical and functional properties than those chemically produced and three commercial sodium caseinates used as references. The chemical composition of the isolates produced by EDBM varied according mainly to the ionic strength of the skim milk solution treated (Table 21.4). At high concentration of added salt, whatever the salt, there was retention of salts and lactose in the isolates decreasing the total protein content of these isolates. For high-salt-concentration isolates, the washing conditions used were not sufficient to allow removal of most of the salts and lactose from the coagulum. Furthermore, the concentration of lactose in the isolates increased with the ionic strength; ionic strength might influence porosity and particle size of coagulum which affect contact with the washing solution, and effectiveness of lactose removal. Many authors have pointed out that processing variables such as heat treatment, number of washes to which the curd is

subjected, and the content of iron influence the quality of the rennet casein [116–118]. The type of salt and the ionic strength influenced the functional properties and the structure of the sodium caseinate produced by EDBM. Addition of the KCl and NaCl during EDBM decreased the viscosity of the protein solution but the foaming and emulsifying properties, and also the particle size and the solubility profile, were unchanged [112]. The  $\text{CaCl}_2$  acted in a different way from both previous monovalent salts. It decreased the particle size and the viscosity from 0 to 0.5 M  $\mu_{\text{added}}$  and thereafter increased back both factors. The solubility profile of the isolate produced with addition of  $\text{CaCl}_2$  from 0 to 0.5 M  $\mu_{\text{added}}$  was similar to those from both monovalent salts, while at  $\mu_{\text{added}}$  of 1 M the solubility was decreased. By addition of  $\text{CaCl}_2$ , whatever the ionic strength, the emulsifying and foaming properties were unchanged except for the foaming capacity, which was decreased [112]. As the isolate produced by EDBM with addition of 1 M  $\text{CaCl}_2$  showed a high-calcium content after dialysis, this caseinate could assimilate to a Ca/Na caseinate [119].

These recent results showed that EDBM is a new alternative process for production of high-purity casein bovine milk isolate. At the moment, two main problems limit the application of the EDBM at an industrial level: the fouling of spacers and the fouling of cationic membranes. During EDBM process, the protein curd formed can lead to a fouling of the cell spacers by recirculation and accumulation of protein aggregates in the turbulence promoters of the spacers. However, an online centrifugation at the inlet or outlet of the cell would limit this undesired formation in the system [2]. During long-time process of milk, there is formation of calcium carbonate on the membrane in contact with the base electrogenerated but also inside the membrane and on the surface of the membrane in contact with the milk solution (Figure 21.19) [120]. Calcium carbonate precipitate originated from the skim milk solution. Diffusion of  $\text{H}_2\text{CO}_3$  and migration of  $\text{Ca}^{2+}$  through the CEM toward the basified KCl solution explain the presence of  $\text{CaCO}_3$ , which is practically insoluble in water [121]. In addition, as some  $\text{OH}^-$  leach across the CMX membrane, part of the  $\text{CaCO}_3$  can precipitate inside and on the other side of the membrane [120] (Figure 21.19). This deposit affected the performance of the system and decreased drastically the lifetime of the membrane.

**FIGURE 21.19** Elemental configuration of EDBM cell used for skim milk solution, principles of CEM fouling formation, basified and acidified milk side microscopic photographs (magnitude  $\times 45$ ) of EDBM CMX membrane. (Adapted from Bazinet, L., Montpetit, D., Ippersiel, D., Amiot, J., and Lamarche, F., *J. Interface Colloid Sci.*, 237(1), 62, 2001.)

In this context, the KCl solution was replaced by a 0.25 N HCl solution to neutralize the  $\text{OH}^-$  electrogenerated by the BPM and to evaluate this neutralization effect on the integrity of the cationic and BPMs used [122]. It appeared from these results that the resistance of cationic membranes increased after 27 EDBM of which 13 were carried out with addition of  $\text{CaCl}_2$  at concentrations ranging from 8.9 to 47.3 g/L. This increase was due to an exchange of monovalent counter-cations of the membrane by divalent cations less mobile and to a slight fouling of 0.0103 mm. This fouling was identified as a protein fouling. No mineral fouling was observed on EDBM CEM. In addition, integrity and physical characteristics of EDBMs were preserved. Control of the basified stream compartment pH during EDBM did not result in complete protection of CEM characteristics since a small protein fouling of the membrane occurred during the process. However, when no pH control was applied, after one EDBM of skim milk with addition of 47.3 g/L of  $\text{CaCl}_2$  a mineral fouling thickness measurement of the CEM was up to 0.0431 mm.

### 21.4.3 INHIBITION OF ENZYMIC BROWNING IN CLOUDY APPLE JUICE

Cloudy or unclarified apple juice has increasing customer demand due to its superior sensory and nutritional qualities [123]. This light-colored juice contains a high proportion of pulp in suspension and preserves the flavor of freshly pressed apples [124]. However, production of high quality juice is difficult due to the presence of numerous compounds sensitive to oxidation reactions. In practice, soon after production, apple juice experiences enzymatic changes which modify its taste and color. These enzymatic changes are related to enzymatic browning reactions, which confer a dark color to the juice and have a negative impact on sales [125].

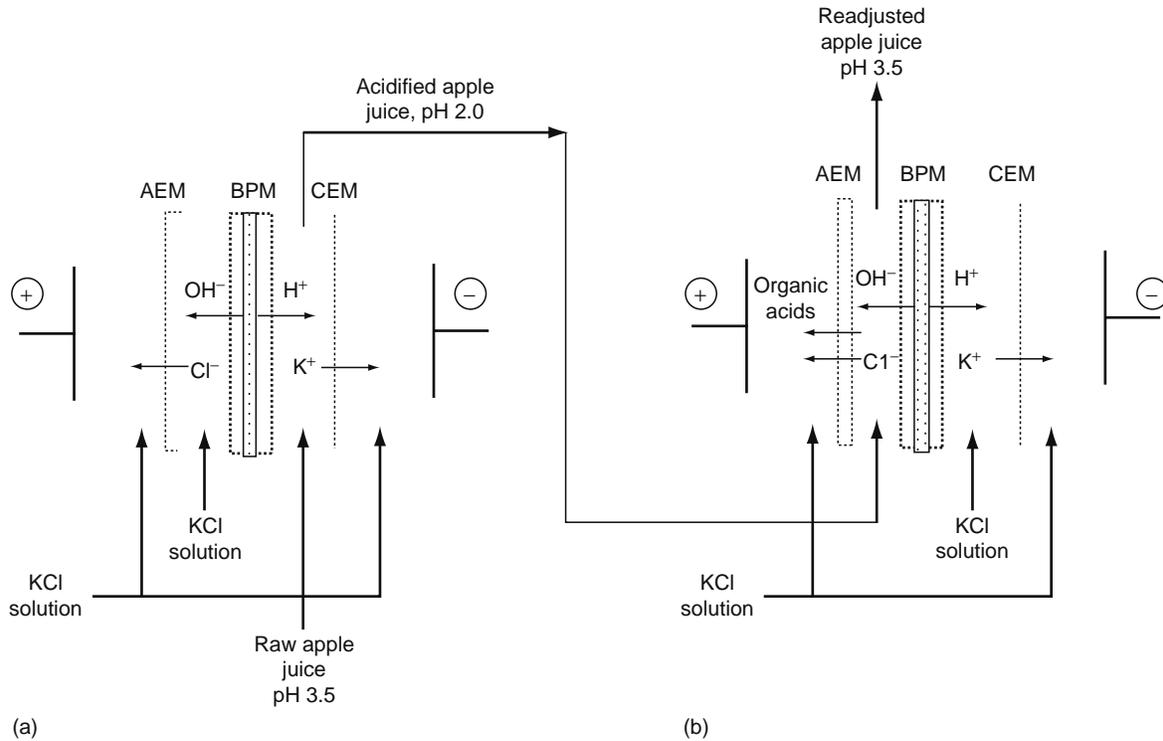

Cloudy apple juice is very sensitive to enzymatic browning since it contains considerable quantities of polyphenols and polyphenol oxidases (E.C.1.14.18.1, PPO) bound to suspended particles. Enzymatic browning reactions are catalyzed by PPO and result in oxidation of phenolic compounds into *o*-quinones which polymerize into complex dark-colored pigments [126]. To limit enzymatic browning and to provide a product with clear and appealing color, cloudy apple juice producers can use treatments such as thermal treatment, flash thermal treatment [127], or add large quantities of antioxidants such as ascorbic acid [128] or its derivatives [129]. In addition, these methods are coupled with an aseptic conditioning to allow the stabilization of the juice. However, such treatment can also alter the sensory and nutritional quality of the juice and induce, during extended storage, nonenzymatic browning reactions that are detrimental to product quality.

Zemel et al. [130] showed that PPO activity could be irreversibly inhibited by temporarily lowering the pH to 2.0 with HCl. According to McCord and Kilara [131], inhibition of PPO activity in acidic media is due to protonation of free carboxyl groups of the enzyme, which neutralize the negative charges of the protein. This change would result in electrostatic repulsion between acids and positively charged amino groups. Such repulsion would greatly affect the tertiary structure of the enzyme. A process solely for acidification of juice has limited commercial applications. To produce a cloudy apple juice preserving its organoleptic properties, it is necessary to readjust the pH to its initial value, pH 3.5. Zemel et al. [130] adjusted the pH to its initial value by adding an NaOH solution. This treatment inhibited enzymatic browning and stabilized the apple juice. However, the dilution effect due to addition of acid and base and the formation of salts rendered the juice flavor unacceptable.

Starting from the observations of Zemel et al. [130], Tronc et al. [37,38] used BPMs to lower the pH of cloudy apple juice. The apple juice was circulated on the cationic side of the BPM where the  $\text{H}^+$  ions are generated (Figure 21.20a). The pH of apple juice was reduced temporarily from 3.5 to 2.0 in 30 min in a small-scale unit at a constant current of 40 mA/cm<sup>2</sup>. However, this level of acidification required the addition of 12.3 mM  $\text{K}^+$  (KCl) every 5 min during the treatment. Exogenous  $\text{K}^+$  compensated for the  $\text{K}^+$  loss from the juice and maintained the electric charge at neutrality, which favored the accumulation of  $\text{H}^+$  in the juice [38]. Reducing the pH of the juice to 2.0 completely inhibited the polyphenol oxidase activity compared with the control. Following acidification, the pH of the juice was returned to its initial value by introducing  $\text{OH}^-$  produced by water splitting; the juice was circulated on the anionic side of the BPM where the  $\text{OH}^-$  ions are generated (Figure 21.20b). The pH readjustment of the juice partially reactivated the PPO, but browning inhibition was complete and irreversible. The treatment enhanced the color of cloudy apple juice during storage without modifying the flavor [38]. However, the ED treatment slightly reduced the malic acid content and substantially reduced the mineral contents.

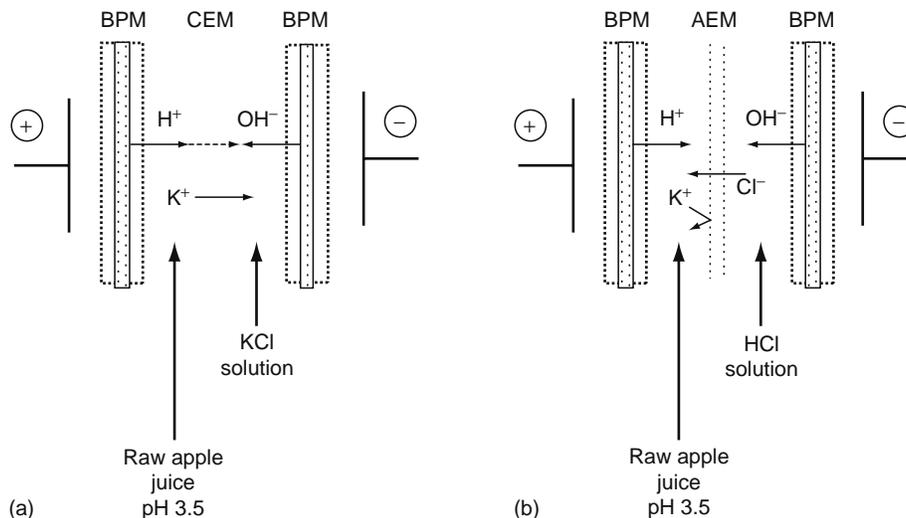

In these previous studies [37,38], the feasibility of acidifying cloudy apple juice and returning the pH to its initial value without altering flavor was demonstrated by using electrodialysis (ED) with bipolar and cationic membranes. However, the total process was too lengthy, about 90 min, and required the addition of exogenous KCl to the juice to reach pH 2.0. Furthermore, the voltage applied greatly exceeded the 2 V/membrane average and was not compatible with industrial constraints [39].

More recently, Lam Quoc et al. [39] replaced cationic membranes in the stack with anionic membranes and the KCl solution with 0.1 M HCl (Figure 21.21). In this configuration, acidification is still triggered by the introduction of protons generated by the BPMs, but the retention of these protons is more effective owing to the continuous introduction of  $\text{Cl}^-$  counterions from the HCl compartment. The  $\text{Cl}^-$  ions accumulated in the juice will subsequently serve as counterions for the introduction of  $\text{OH}^-$  ions, generated by the anionic side of the BPMs, during the return of the juice pH to its initial value. The accumulated  $\text{Cl}^-$  ions will thus be eliminated from the juice during the acidification period. The impact of this configuration was important on acidification speed. The authors demonstrated that with a 4-membrane stack, the juice pH decreased from 3.35 to 2.0 in 4.7 min. By increasing the number of membranes to 10, the required time dropped

**FIGURE 21.20** Electrodesialysis cells for inhibiting enzymatic browning in cloudy apple juice. (a) Electroacidification step and (b) electroalkalinization step. CEM, cation-exchange membrane; BPM, bipolar membrane; AEM, anion-exchange membrane.

to about 1.5 min. Treatment time is therefore inversely proportional to the number of membranes used, which boosts the introduction of  $\text{Cl}^-$  ions to promote the retention of  $\text{H}^+$ . The HCl solution also serves to neutralize  $\text{OH}^-$  produced by the anionic side of the BPMs by hindering their introduction into the juice. Hence, the juice acidification process is more effective and faster than before. This is confirmed by the conductivity results: conductivity is considerably higher because of the accumulation of ions in the juice. At a pH of 2.0, the  $\text{Cl}^-$  concentration reached 580 mg/L of juice in comparison with 0.7 mg/L in the control juice and 29 mg/L in the adjusted juice (Table 21.6). The increase in conductivity improved EDBM treatment by reducing the applied voltage and energy consumption. The latter was 4–5 kW h/m<sup>3</sup> of juice, which represents very low energy consumption from an industrial standpoint. The yield obtained with a BPM/anionic configuration, independent of the number of membranes used, was three times higher than that of BPM/cationic configuration with the addition of KCl [38].

**FIGURE 21.21** Electrodesialysis (ED) configurations used to modify pH of cloudy apple juice. (a) BPM/cationic membrane and (b) BPM/anionic membranes. (Adapted from Lam Quoc, A., Lamarche, F., and Makhoulouf, J., *J. Agric. Food Chem.*, 48, 2160, 2000.)

Furthermore, by doubling current density to 40 mA/cm<sup>2</sup>, the average applied voltage did not exceed 2 V/compartiment and ranged from 1.5 to 1.8 V. The time required to return juice pH to its initial value with BPM/anionic configuration, where the juice and HCl compartment were reversed, was longer than the time required to reach pH 2 (about 10 min vs 4.7 min) [39]. The difference is because this phase is achieved by replacing the Cl<sup>-</sup> accumulated in the juice with OH<sup>-</sup>. The low conductivity of Cl<sup>-</sup> compared to OH<sup>-</sup> (73.5 cm<sup>2</sup> Ω<sup>-1</sup> equiv<sup>-1</sup> vs 199 cm<sup>2</sup> Ω<sup>-1</sup> equiv<sup>-1</sup>) and the depletion of Cl<sup>-</sup> during treatment caused the low retention of OH<sup>-</sup> in the juice and made it difficult to eliminate Cl<sup>-</sup>. The membrane stacks reduced the time needed to achieve the initial pH of the juice, but the yield remained the same as in the previous study [38], i.e., 2.5 L of juice/m<sup>2</sup> of membrane/min.

The acceleration of acidification by EDBM provides better control over enzymatic browning compared with previous studies [37,38] (Figure 21.22). According to the changes in color of the control juice, enzymatic browning is very active after extraction, and it must be inhibited as fast as possible in the first few minutes following extraction to keep the color of the treated juice essentially like that of freshly pressed juice. The discrepancies observed between the colors of the control and the adjusted juices obtained by Lam Quoc et al. [39] were greater than those obtained by Tronc et al. [38] for the same storage time following extraction. After the acidification and pH adjustments, the color stabilized at about the level for freshly pressed juice, which demonstrates that browning is completely inhibited. However, the acidified juice has a tendency of more red color

**FIGURE 21.22** Impact of EDBM treatment on PPO activity in apple juice during storage. (Adapted from Lam Quoc, A., Lamarche, F., and Makhoulouf, J., *J. Agric. Food Chem.*, 48, 2160, 2000.)

than the adjusted juice. This is due to the presence of anthocyanins, primarily cyanidin 3-galactoside, whose red color depends on the acidic pH [132], giving acidified juice a red color. The intensity of this coloration, however, lessens when the juice is at a normal pH, as in adjusted juice.

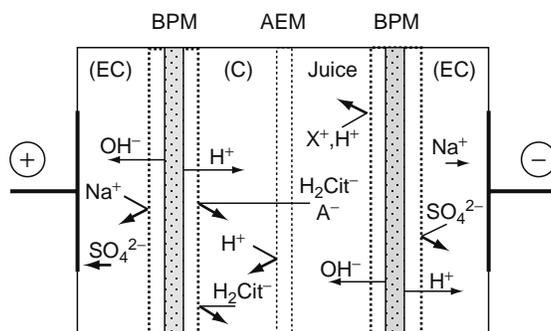

Chemical analyses demonstrated that EDBM treatments have variable effects on the composition of cloudy apple juice (Table 21.6). The percentage of adjusted juice ash remained unchanged by the treatment. A slight increase in ash in acidified juice is because the salts formed after the juice was heated to 600°C are chlorides not carbonates, owing to the accumulation of  $\text{Cl}^-$  ions in the juice during acidification. The main cation in the juice,  $\text{K}^+$ , is preserved owing to the layout of the anionic membranes, which prevent the cations from leaving the juice, representing an advantage from a nutritional standpoint. However, a slight loss in divalent cations ( $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ ) was observed, owing to their low solubility. They could be partially precipitated or adsorbed on the surface of the anionic membranes where the pH at the membrane–solution interface is higher [133]. There was no significant change in the concentration of sugars in the juice because the uncharged sugars do not migrate during electro dialysis. Only a major osmotic pressure gradient between two compartments could force them to migrate through membranes [134]. The malic acid concentration of the adjusted juice decreased by about 20%. The loss occurred through the anionic membranes because malic acid is negatively charged.  $\text{Cl}^-$  accumulated in the juice is not totally eliminated after the rise in pH. A residual quantity of 30 mg/L was found in the juice. The use of anionic membranes with greater monovalent anion selectivity would help limit the loss of malic acid and eliminate  $\text{Cl}^-$  more effectively. Sensory evaluation tests revealed that adjusted juice retained the characteristic flavor and color of freshly pressed juice. The presence of a residual quantity of  $\text{Cl}^-$  did not seem to affect the flavor of the EDBM-treated juice. Moreover, the treated juice was slightly fresher, more fruity and sweeter, with a taste of real apple [39].

The configuration with bipolar and anionic membranes provides several advantages over the first configuration. This treatment does not require the addition of exogenous KCl; furthermore, there is no chemical waste since all the electrolytes are reused. It accelerates the treatment and rapidly inhibits enzymatic browning, while preserving freshly pressed taste of cloudy apple juice. However, the concentration of some nutrients such as sugar and malic acid is decreased during the treatment. This pH modification should have other positive consequences on the stability of cloudy apple juice. It is possible that the pectin methyl esterase, responsible for the cloudy precipitate in the juice, can also be affected by the EDBM treatment. The very small loss of divalent ions such as  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  by electromigration should reinforce the stability of the suspended particles [125]. EDBM can be considered as a nonthermal stabilization which is simple, efficient, and applicable to the stabilization of food liquids.

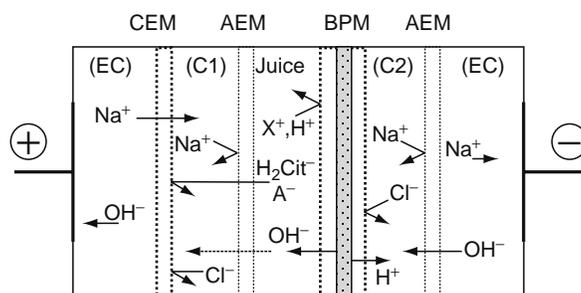

#### 21.4.4 DEACIDIFICATION OF PASSION FRUIT JUICE

The yellow passion fruit, *Passiflora edulis* f. *flavicarpa*, has intense and special aroma and flavor, which make it a desirable ingredient in the formulation of various food products. These fruits are processed and exported as concentrated juice at 50°Brix (500 g/kg of total solids) from several South American countries such as Ecuador, Brazil, Peru, and Colombia. For Ecuador, the principal exporter country [135], in 2000 the passion fruit occupied the second place in exports with 26,000 ton of concentrated juice and is a very important source of income (US\$ 28 millions) [136]. However, due to its high acidity, only limited amounts of juice can be added as an ingredient in the formulation of various preparations such as beverages, ice creams, marmalades, cocktails, pies, etc., which reduces their flavor intensity [137,138]. Addition of sweetening agents or simple neutralization by basic compounds is not a suitable method because they affect the flavor and natural taste of juices, resulting in poor palatability [19]. Therefore, it is important to find a deacidification process having very little effect on the chemical composition and aromatic quality of juice.

Based on these problematics, Vera Calle et al. [19] tested the deacidification of clarified passion fruit juice by EDBM. The stack was equipped with homopolar and BPM, forming two compartments (Figure 21.23). The reduction of acidity was

**FIGURE 21.23** Electro dialysis (ED) cell with BPM. (EDBM2C configuration; AEM, anion-exchange membrane; BPM, bipolar membrane.) (Adapted from Vera Calle, E., Dornier, M., Sandeaux, J., and Pourcelly, G., *Desalination*, 149, 357, 2002.)

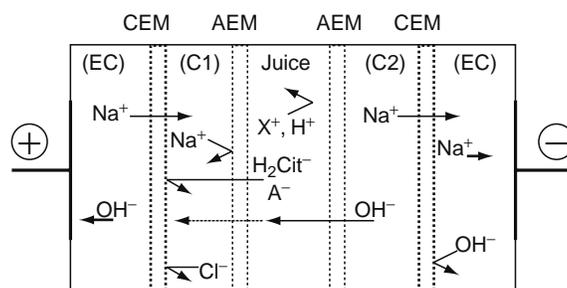

**FIGURE 21.24** Modified configuration of electrodesalination with bipolar and homopolar membranes for juice deacidification. (EDBM3C configuration; BPM, bipolar membrane; AEM, anion-exchange membrane; CEM, cation-exchange membrane.) (Adapted from Vera Calle, E., Ruales, J., Dornier, M., Sandeaux, J., Sandeaux, R., and Pourcelly, G., *J. Chem. Technol. Biotech.*, 78, 918, 2003.)

achieved by increasing the pH from 2.9 to 4.0. This pH limit was chosen to avoid microorganism growth and spoilage [19]. In this EDBM configuration only anions are able to pass through the AEM from the juice to the concentrate (C) compartment. The net effect was the extraction of anions, mainly citrate, and their replacement by hydroxyl ions provided by the BPM. Citric acid was formed in the concentrate (C) compartment by citrate ions extracted from juice and protons provided by the second BPM separating the (C) compartment and electrode compartments. This configuration allowed the production of citric acid with 89% purity and avoids the increase in the sodium concentration in the juice.

In a further study by Vera Calle et al. [136], the previous configuration was compared with a modified one, in which the stack was equipped with homopolar and one BPM constituting three compartments (Figure 21.24). The configurations were compared for their performances in terms of deacidification rate, current efficiency, energy consumption, and characteristics of deacidified juices such as concentration of inorganic and organic ions, color, and flavor. They observed that the deacidification rates and current efficiencies were similar for both processes. However, although the nonmodified configuration induces the greatest energy consumption (0.50 vs 0.38 kW h/L of juice), it offers the advantage of eliminating the consumption of chemicals. The  $K^+$ ,  $Ca^{2+}$ , and  $Mg^{2+}$  concentrations were not modified whereas the  $Na^+$  concentration was markedly increased by using the modified configuration (180 vs 50 mg/L). Both processes did not achieve citrate removal without elimination of other anions. The anions concentration was similar for the two processes. The inorganic ions were almost eliminated, 62% of the citrate ions and 48% of the malate ions were removed from the fresh juice. Nevertheless, the proportion of the anions kept the same value in the fresh and deacidified juices, the citrate ions remaining the major anionic species (about 90%) [136]. The color variations obtained for the configurations, in the  $L, a, b$  space calculated according to  $\Delta E = (\Delta L^2 + \Delta a^2 + \Delta b^2)^{1/2}$  and using the nontreated sample as a reference solution, were 0.5 and 0.2 for the modified EDBM3C and the nonmodified EDBM2C configuration, respectively. Finally, no difference between the untreated and the deacidified juices was observed following the sensory analysis. According to these authors, although the EDBM2C configuration leads to the highest energy consumption, it seems a very interesting option because of the elimination of the soda consumption and the production of citric acid [136], which can be used as a preservative or antioxidant in the food industry.

To assess the feasibility and to verify if the ED operations of the EDBM2C configuration could be expensive because of the NaOH and energy consumption, the authors recently published a work comparing this method with different methods used for deacidification of clarified passion fruit juice [18]. They compared EDBM with other physicochemical technologies, ion-exchange resins, and electrodesalination with homopolar membranes (Figure 21.25), as well as the conventional chemical method based on the precipitation of calcium citrate obtained by addition of calcium hydroxide or carbonate to the clarified juice.

**FIGURE 21.25** Configuration of electrodesalination with homopolar membranes used for juice deacidification. C1 and C2 are separated compartments while the two EC compartments are connected. EDBM2C	549	4.6	31	0.50

Source: Adapted from Vera, E., Ruales, J., Sandeaux, J., Dornier, M., Persin, F., Reynes, M., and Pourcelly, G., *J. Food Eng.*, 59, 361, 2003.

A commercial macroporous weakly basic ion-exchange resin, Amberlite IRA95 from Rohm and Haas, was tested in a column, 1.7 cm in diameter and 60 cm long with a bed volume of 50 mL. The resin matrix consisted of styrene–divinylbenzene. The tertiary amine functional groups were equilibrated in the OH<sup>-</sup> form before use. ED experiments were performed with a laboratory cell of 20 cm<sup>2</sup> of effective area at a constant current density of 400 A/m<sup>2</sup>. The principle of the two electrodialysis configurations used is the extraction of citrate anions from the juice and their replacement by hydroxyl ions provided either by the NaOH solution in the C2 compartment (ED3C configuration, Figure 21.25) or by the BPM sandwiched between the juice and electrode compartments (EDBM2C configuration, Figure 21.23). The performances of the two ED operations were compared (Table 21.7). For the conventional method, the calcium citrate was precipitated by adding calcium hydroxide or carbonate at pH 4.5. Then, the mixture was maintained for 24 h at 4°C, and the precipitated calcium citrate was separated by filtration. After filtration, the pH was adjusted to 4.0 by mixing the filtrate with fresh juice. They determined total soluble solids, acidity and color, as well as inorganic and organic ion concentrations. They completed their analyses by triangular tests to compare the aroma of the fresh juice with the deacidified juices.

The titrable acidity and total soluble solids varied up to 30% according to the deacidification method applied (Table 21.8). Resin treatment induced the greatest change in the total soluble solids and color. In all the deacidified juices, a decrease in the citrate and malate concentrations was obtained. The precipitation of calcium citrate is the most selective technique where citrate ions were preferentially eliminated—the chloride, sulfate, and phosphate concentration remaining unchanged. Nevertheless, a lower elimination of citrate and malate ions was induced by the use of CaCO<sub>3</sub>, 40% and 12.5%, respectively, than with Ca(OH)<sub>2</sub> where it reached 65% and 32%, respectively. The difference between extraction ratios of organic anions was lower for other methods, about 65% and 53% for citrate and malate, respectively. Moreover, the inorganic anions were partially extracted together with organic ions when using resin and electrodialysis. In the electrodialysis method, the elimination of anions is related to their mobility both in the solution and membrane, and consequently the extraction of inorganic anions is easier than that of organic anions. Almost all the chloride ions were eliminated and about 90% of phosphate and 70% of sulfate ions were extracted. Potassium and magnesium concentrations were not affected whatever the method used, while the calcium and sodium concentrations were significantly increased by using the precipitation method and electrodialysis with three compartments (ED3C), respectively [18]. There was no change in the cation concentration while using resins and EDBMs. According to the sensory properties of deacidified juices, the triangular tests did not highlight significant differences between the deacidified juices and the fresh juices. To classify the deacidified juices, a ranking test of degree of preference was done by directly tasting the juices. The juice treated by ion-exchange resin appeared as highly significant as the sample liked least, the precipitation method with calcium hydroxide giving the most liked sample by a narrow margin [18].

**TABLE 21.8**  
**Physicochemical Analysis of the Juices Deacidified by Different Methods and Comparison with Control Clarified Juice**

Deacidification Method	pH	Titrable Acidity (g Citric Acid per kg)	Total Soluble Solids (g/kg)	Color			
				<i>L</i>	<i>a</i>	<i>b</i>	DE
Clarified juice	2.93	43.3	132	30.8	-1.40	5.00	N/A
CaCO <sub>3</sub>	4.00	13.5	130	30.9	-1.50	5.14	0.2

All the methods tested allowed the deacidification of the clarified fruit juice in which pH was increased from 2.9 to 4.0. Nevertheless, these methods have some different advantages and disadvantages. The deacidification using  $\text{CaCO}_3$  is not recommended due to the liberation of  $\text{CO}_2$ , foam making, and poor pH control during the precipitation phase. The use of  $\text{Ca}(\text{OH})_2$  is easier and gives a good quality product. Besides, citric acid could be recovered by dissolving the precipitated calcium citrate in sulfuric acid, and converting the calcium citrate to calcium sulfate and citric acid [139]. However, the precipitation method has three limitations: the legislation of some countries, the precipitation problems in the final product induced by the increase in the calcium concentration, and the fact that consumers prefer natural product, without chemical addition. The ion-exchange process does not seem to be a good option, since it leads to changes in the organoleptic characteristics of the treated juice, and the large amounts of effluent produced during the regeneration phase of resins. The deacidification by electro dialysis has some advantages over the above methods, especially EDBMs. It is a continuous process without reagents added, giving a high quality juice in terms of physicochemical and sensorial analyses. It was observed that there was no change in the cation concentration, slight color variation, and good flavor. Only organic and inorganic anions were partially eliminated. Nevertheless, electro dialysis is more expensive than the other techniques but the citric acid simultaneously produced during the deacidification could improve the cost of this technique. Therefore, EDBM could be a promising alternative to the conventional calcium precipitation process for the deacidification of the passion fruit juice.

#### 21.4.5 PROCESS FOR PURIFYING DAIRY WASTEWATER

Whey is a by-product of dairy industry with a worldwide annual amount of 96 millions of tons (46 millions of tons in Europe) [140]. One possibility to use the whey is ultrafiltration to produce a protein concentrate for food and feed preparation. The filtrate is whey permeate and its disposal is still a problem because whey permeate contains almost the total lactose and salts derived from milk, resulting in a high chemical oxygen demand (COD) of 50–60 kg  $\text{O}_2$ /metric ton. Consequently, due to its high COD it is not economic and mostly not possible to treat it in communal sewage treatment plants. In addition, in conventional wastewater purification processes, degradable constituents are degraded either anaerobically to form methane and  $\text{CO}_2$  or aerobically to form  $\text{CO}_2$ , water, and biomass. In these processes, a considerable part of the energy contained in the wastewater constituents is lost [141].

In this context, an integrated bioprocess for the dairy sewage treatment, using bipolar membrane ED, was developed recently by Boergardts et al. [141]. They provided a three-stage process for purifying dairy wastewaters obtained from milk-processing enterprises (Figure 21.26). In the first stage, the wastewater was pretreated with base to precipitate out a portion, and

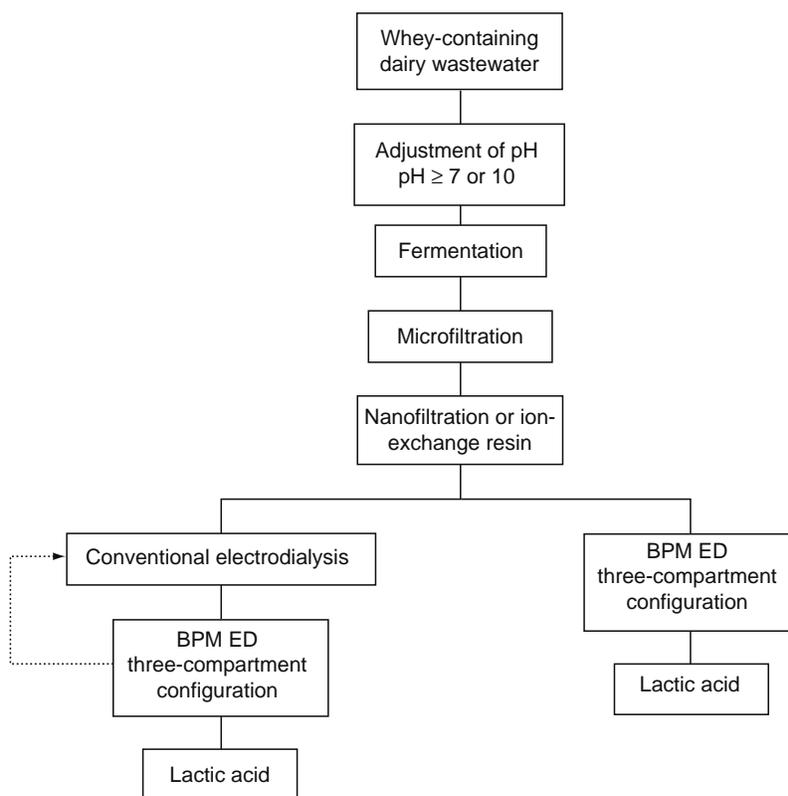

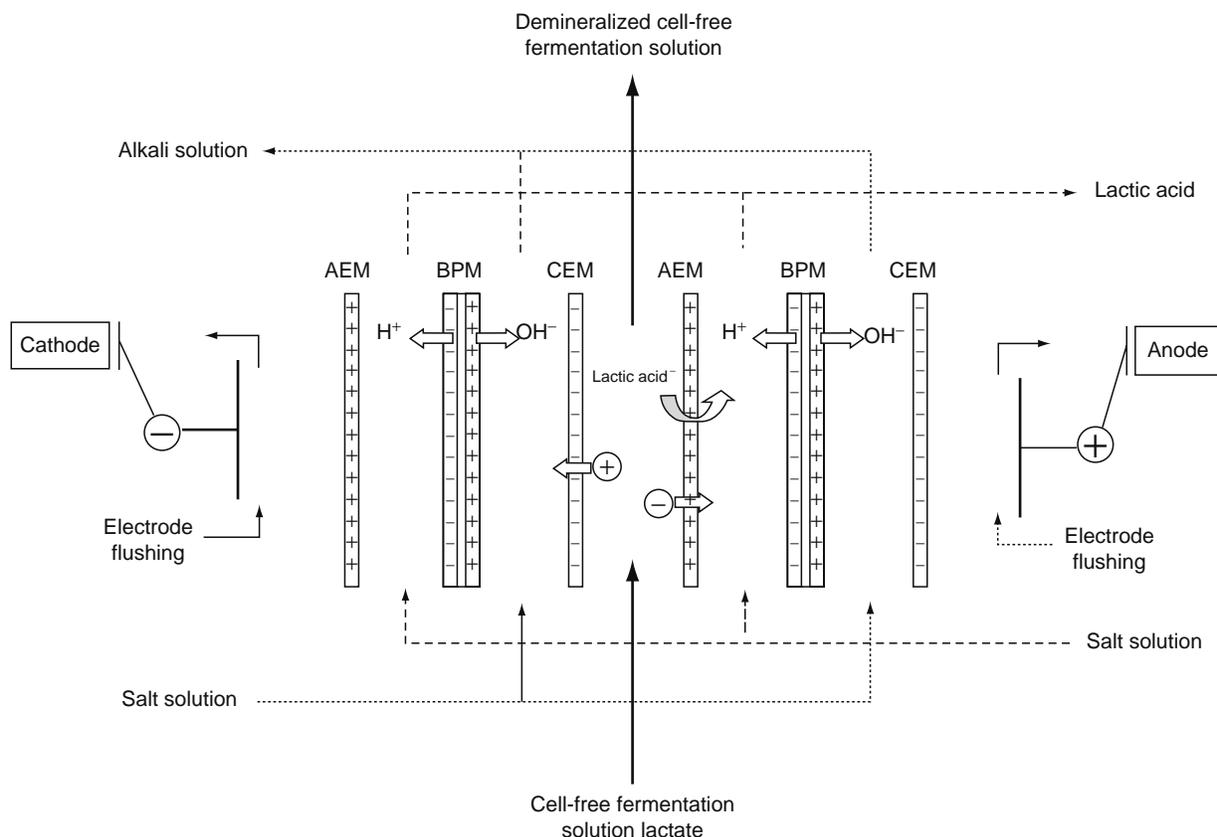

FIGURE 21.26 Process for purifying dairy wastewater. (From Bazinet, L., *Crit. Rev. Food Sci. Nutr.*, 45, 307, 2005.)

to the extent possible, the majority of the  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  ions and  $\text{PO}_4^{3-}$  ions present. In the second stage, the pretreated wastewater was then fed to a fermentation reactor and the fermentation broth formed was given a secondary purification. In the fermenter, the lactose and any other sugars present were converted homofermentatively to lactic acid using lactic acid bacteria. According to the authors, the use of a cell retention system could lead to significantly higher productivities. They used a cell retention system operated by microfiltration membrane unit fed by the circulating stream from the fermenter; complete removal of all components and higher transmembrane fluxes was achieved. However, the cells could be removed by membrane processes or centrifugation. In the third stage, the permeate was fed to the electrodialysis system via a nanofiltration unit or a selective ion exchanger to remove any calcium residues still present. In the third stage, the concentration of lactic acid in the wastewater was reduced and the wastewater produced had a very low COD load. The use of ED with BPMs also had permit isolation of free acid in high concentration and purity directly from the fermentation solution. As a third product in this case, alkali solution was formed which could serve to elevate the pH during pretreatment of the wastewater. Alternately, the alkali solution formed could be used to regulate the pH of the fermenter. The bipolar-electrodialysis configuration was the same as the one used by Van Nispen and Jonker [142] (Figure 21.27), wherein fermentation solution filtrate circulates in the diluate circuit. The pH in each of the two circuits was set by the BPMs. The free lactic acid was taken off from the acidic circuit and the alkali solution formed from the basic circuit. According to the authors, to achieve both low COD and pure lactic acid product with good results in each case, the bipolar ED may be carried out as follows. The fermentation broth is reduced in batchwise concentration to the desired wastewater concentration, and acidic and basic compartments are concentrated up to the maximum product concentration. During this process step, water is continuously transported through the membranes. Therefore, the product streams produced (alkali solution and lactic acid) can be taken off continuously and at constant concentration. Accordingly, the alkali solution produced can be continuously returned to the wastewater during a continuous wastewater pretreatment stage. The lactic acid produced can also be additionally purified in further continuous process steps [143].

In another embodiment of the invention, the authors suggested that the ED could be carried out in two stages. The fermentation broth is subjected in the first stage to bipolar membrane ED in which the broth is continuously reduced in concentration, to about  $10\text{--}15\text{ g L}^{-1}$  diluate concentration. In the second stage, a monopolar ED is carried out in which the concentration is further decreased to the desired wastewater concentration, preferably in a batch procedure. The sodium

**FIGURE 21.27** Operation of BPM ED using a three-compartment configuration for lactate migration. (From Bazinet, L., *Crit. Rev. Food Sci. Nutr.*, 45, 307, 2005.)

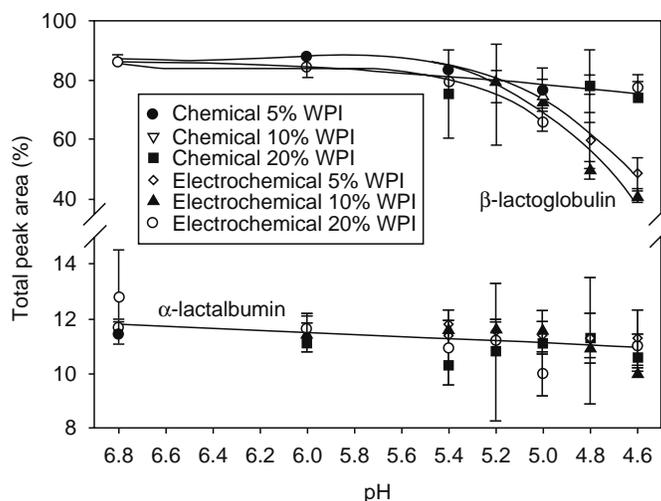

lactate produced in the second stage can be returned to the feed stream of the first ED stage to increase the starting concentration of lactate there (Figure 21.26). According to Boergardt et al. [141], the COD value may be decreased by 85%–95% and free lactic acid may be produced at a concentration of approximately 200 g/L. The alkali solution concentration can achieve about 2 mol/L.

#### 21.4.6 SEPARATION OF WHEY PROTEIN

Whey proteins have a high nutritional value and excellent functional properties [107,144]. When concentrated, whey proteins are interesting sources of proteins for young mammal and human nutrition [145]. According to their disponibility, their low cost (in comparison with others sources of proteins), and their characteristics, they are hugely used in the food industry [134]. However, knowledge about the property of the individual fractions of whey proteins commands more research about processes for separation of these fractions to use them separately and to optimize their respective properties in the food industry [146]. The fractionation research aimed at the major protein constituents  $\beta$ -lactoglobulin ( $\beta$ -lg) and  $\alpha$ -lactalbumin ( $\alpha$ -la), and numerous isolation methods for their separation have been proposed. Their fractionation may be performed by ion-exchange chromatography [147,148], metaphosphate complex precipitation [149], heat/acid separation [146,150–152], and ion depletion at low pH [21,22]. Amundson et al. [21] and Slack et al. [22] separated the two major whey protein fractions by demineralizing a concentrated whey solution and adjusting the pH chemically. This process was based on 90% volume reduction of whey by ultrafiltration, partial demineralization of the UF retentate by electrodialysis or diafiltration, pH adjustment of the UF retentate before and after demineralization to pH 4.65, and centrifugation of the retentate. With this method, they produced  $\beta$ -lg-enriched fractions containing 33% of the original acid whey proteins and 17% of the original sweet whey proteins.

Based on these data, Bazinet et al. [44] demonstrated the feasibility of EDBM to fractionate whey proteins from a whey protein isolate (WPI, BiPRO) and studied the effect of protein concentration on its performance in comparison with chemical acidification. The acidification method had a considerable effect on soluble protein as the pH decreased; chemical acidification did not allow precipitation of a large amount of whey protein, while electroacidification succeeded in precipitating up to 54% of the total protein. Effectiveness of electroacidification to precipitate whey protein was improved by increasing protein concentration, but at concentration higher than 10% WPI the conductivity of the solution became the limiting factor. These results were confirmed by protein profiles during acidification since only EDBM allowed a significant precipitation of whey protein (Figure 21.28). In comparison with results for the soluble protein, these results suggest that a part of the other whey proteins were precipitated with  $\beta$ -lg. According to the results of HPLC, the  $\alpha$ -la would be the main protein precipitating with  $\beta$ -lg at high WPI concentration. Since WPI was made from thermal treated milk, a part of the  $\alpha$ -la should have been denatured to form a complex with  $\beta$ -lg or BSA through thiol–disulfur interchange reactions [153–155]. These complexes should have co-precipitated with  $\beta$ -lg during EDBM.

To complete these information, the chemical composition of isolates obtained at pH 4.6 or 5.0 for 20% WPI EDBM was compared (Table 21.9). Isolates produced by EDBM had a lower ash content than isolates produced by chemical acidification (1.61% vs 2.37% dry basis, respectively). The protein content, on a dry basis, of electroacidified isolates was higher than that of chemically produced isolates: 97.2 vs 94.0, respectively. The difference in ash content may explain the difference in percent

**FIGURE 21.28** Effect of protein concentration on the evolution of protein fraction kinetic during chemical and electrochemical acidification. (Adapted from Bazinet, L., Ippersiel, D., and Mahdavi, B., *Innovative Food Sci. Emerg. Technol.*, 5, 17, 2004.)

**TABLE 21.9**  
**Ash and Protein Composition of the Isolates Produced at 5%, 10%, and 20% WPI**

	Chemical Acidification			Electrochemical Acidification		
	5	10	20	5	10	20
Ash content (% dry basis)	2.3	2.2	2.7	1.5	1.7	1.6
Total protein (% dry basis)	91.7	94.3	96.2	95.3	98.2	98.2

total protein observed for the isolates produced by EDBM vs chemically produced isolates. As expected, the protein content of the isolates increased with an increase in protein concentration. The isolate composition in terms of protein fraction was similar for both acidification methods, but the concentration of  $\alpha$ -la increased while the concentration of  $\beta$ -lg decreased with an increase in total protein concentration.

These results demonstrated the feasibility of EDBM for whey protein separation and the influence of the initial protein concentration on the purity and yield of the separated fraction. At 5% WPI initial concentration, this technology allowed the separation of 98% pure  $\beta$ -lg fraction with a 44% recovery yield, while at 10% WPI initial concentration a  $\beta$ -lg-enriched fraction was produced containing 97.3% of  $\beta$ -lg and 2.7%  $\alpha$ -la, for a 98% total protein purity. The 10% protein concentration seems to be the best level for electrodialytic parameters and protein recovery. Furthermore, EDBM of a 10% WPI solution, by precipitation of 53.4% of the  $\beta$ -lg, allowed the production of an  $\alpha$ -la-enriched fraction in the supernatant. Since the best pH to precipitate  $\beta$ -lg was demonstrated to be pH 4.65 [21], and that the protein yield increases with an increase in initial protein concentration in the solution, it was expected that electroacidification of a 20% WPI solution to pH 4.65 would allow the highest precipitation yield. However, the limiting factor of such a process at 20% was the low conductivity of the protein solution at pH 5.0.

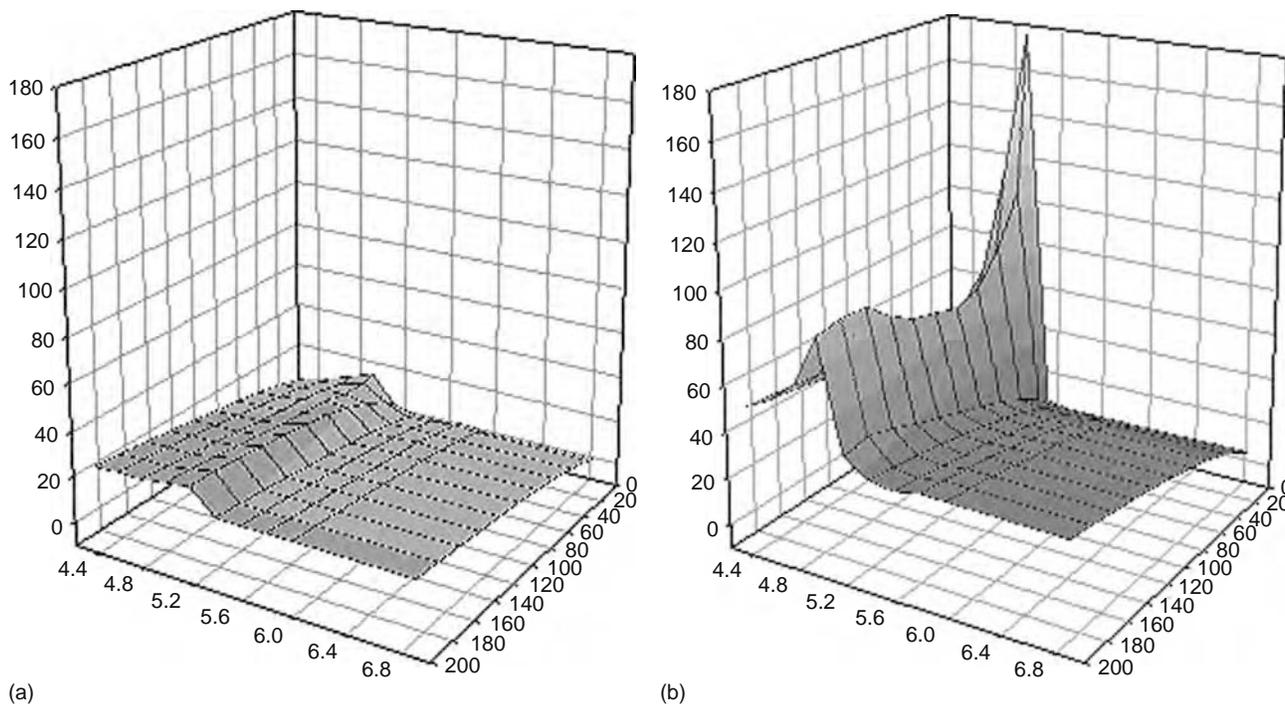

Since the limiting factor of electroacidification by EDBM process at 20% WPI was hypothesized to be the lack of mobile ion inherent to the protein solution at pH 5.0, the authors studied the effect of ionic strength on the precipitation behavior of whey protein [156]. In the first part of this study, electroacidifications of 10% (w/w) WPI solutions were carried out, in batch process using a current density of 20 mA/cm<sup>2</sup>, in different conditions of conductivity control, to evaluate the effect of the conductivity on the precipitation behavior of the whey protein. The highest protein precipitation with 10% WPI solution was obtained at pH 4.6 and at a conductivity level of 200  $\mu$ S/cm maintained with many 0.4 mL-additions of 1.0 M KCl (200  $\mu$ S[+]), with a 46% precipitation of the total protein;  $\beta$ -lg composing the main part of the precipitated protein. One global addition of 1.0 M KCl decreased the protein precipitation yield by resolubilizing protein. The protein fractions showed different trends (Figure 21.29).  $\beta$ -lg composed the main part of the protein-precipitated fraction and the maximum precipitation of  $\beta$ -lg appeared at pH 4.6 and 200  $\mu$ S[+]. The BSA did not seem to be affected during EDBM of 10% BiPRO solution, while a small amount of  $\alpha$ -la was precipitated at pH 4.6 and afterward. These results agreed with the literature [21,157] and previous results obtained for the soluble protein on the optimum precipitation pH of the whey protein at pH 4.65. In a previous work [44], a 40.5% of  $\beta$ -lg at pH 4.6 was obtained with a 25°C normalized conductivity value of 107  $\mu$ S/cm. The difference in  $\beta$ -lg precipitation observed between the present and the previous work may be explained by the different final conductivity levels reached: 200 or 250 vs 107  $\mu$ S/cm. The conductivity appears to influence strongly the extent of protein precipitation.

Since the conductivity control of a 10% WPI solution allowed to reach a lower pH than 4.6, in the second part of their study, Bazinet et al. [156] electroacidified a 20% (w/w) WPI solution with conductivity control: when pH 5.0 or 350  $\mu$ S/cm was reached, conductivity was maintained constant at 350  $\mu$ S/cm. This value was determined as the best combination of protein solubility and system resistance, according to a previous study [44]; at this point the protein insolubility curve was close to its optimum and the system resistance began to increase. With conductivity control at 350  $\mu$ S/cm of the 20% WPI solution, it was possible to reach pH 4.65. A 27% protein precipitation was obtained at pH 4.6. This value was higher than the 21% precipitated protein obtained previously for the same solution at pH 5.0 and at a normalized conductivity value of 161  $\mu$ S/cm [44]. However, this percentage was still low in comparison with the 46% protein recovery obtained with 10% BiPRO solution at 200  $\mu$ S[+]. The apparent viscosity of 10% and 20% BiPRO solution was determined during chemical acidification with 1 N HCl at different shear rates. It appeared that the 10% BiPRO solution should be modeled as a linear surface response regression (Figure 21.30a) while the 20% BiPRO solution should not (Figure 21.30b). Since the viscosity of the 20% whey protein dispersion was very different in comparison with 10% BiPRO and presented a Non-Newtonian profile, the change in viscosity as pH decreases observed at 20% WPI would decrease the precipitation rate of  $\beta$ -lg. Some factors have

**FIGURE 21.29** Effect of conductivity control on the evolution of the soluble protein during EDBM of 10% BiPRO. (Adapted from Bazinet, L., Ippersiel, D., and Mahdavi, B., *J. Agric. Food Chem.*, 52, 1980, 2004.)

an influence on the viscosity: particle size, polydispersity of diameters, and electroviscous effect in charged particles. Large monodispersed particles tend to give lower relative viscosities than smaller particles at equivalent volume fractions but the differences between them decrease as the mean diameter. This change in viscosity by the means of one or a combination of the three factors would decrease the precipitation yield of  $\beta$ -lg. An increase in the voluminosity of the particles related with an increase in viscosity would slow down the migration or diffusion of the  $\beta$ -lg and consequently its aggregation with other

**FIGURE 21.30** Evolution of the apparent viscosity as a function of pH and shear rate of (a) 10% and (b) 20% BiPRO solutions. (Adapted from Bazinet, L., Ippersiel, D., and Mahdavi, B., *J. Agric. Food Chem.*, 52, 1980, 2004.)

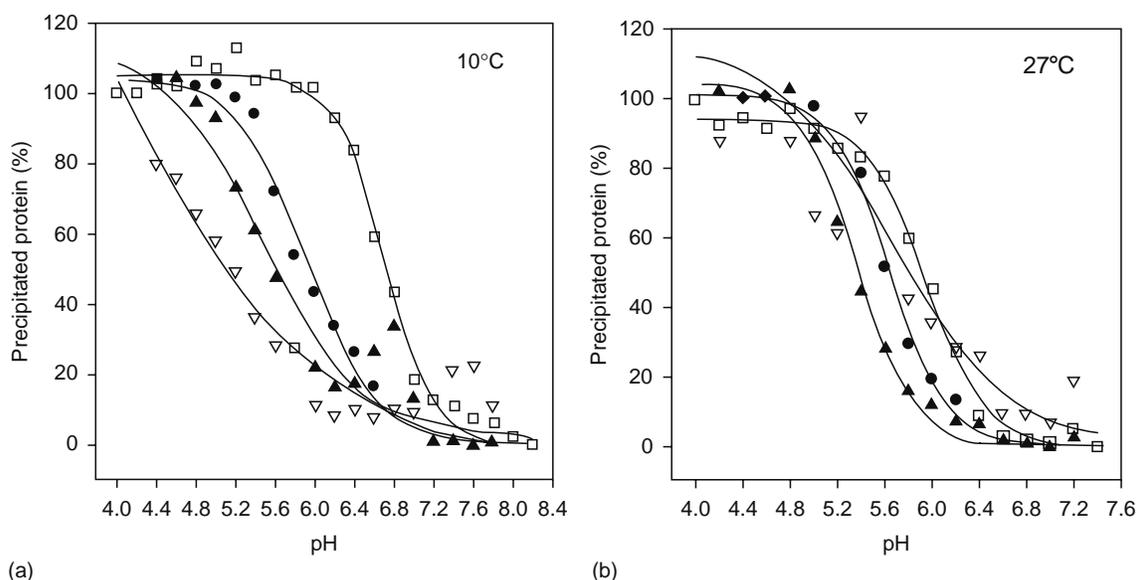

monomer or dimer. Moreover, the increase of viscosity should have a direct consequence on the intern hydrodynamic design of the EDBM cell.

EDBM has numerous advantages in comparison with alternative methods for protein fractionation. The process can be precisely controlled, as electroacidification rate is regulated by the effective current density in the cell. The in situ generation and reuse of dangerous chemicals for the environment (acids and bases) suppress the drawbacks and the risks linked to the handling, transportation, use, and elimination of these products. Moreover, by the use of an electroalytic system, which is well known in industry, EDBM technology can easily be transferred to the industrial scale and installation would not need a complete change of the production process, but only some modifications [2]. However, the main advantages of this technology are the high-protein recovery yield, up to 53% in comparison with 33% and 17%, respectively, from acid whey and sweet whey proteins [21,22], and the lower ash content of the isolates.

#### 21.4.7 FRACTIONATION OF MAJOR SOYBEAN PROTEIN FRACTION

Soybean proteins are composed of four protein fractions: 2 S, 7 S, 11 S, and 15 S according to their respective Svedberg units. The two major reserve soybean proteins are the globulins 7 S or  $\beta$ -conglycinin (37% to 39% of total protein) and 11 S or glycinin (31%–44% of total protein). They have different intrinsic properties leading to different functional properties. Saio and Watanabe [158] reported that the 11 S and 7 S have distinct functional properties: 11 S globulin makes much harder tofu gels than 7 S globulin, precipitates faster, and forms larger aggregates relative to 7 S gels. Ning and Villota [159] found that after extrusion the 11 S globulin fraction appeared to favor expansion and water-holding capacity of the finished product. Numerous processes have been patented to separate these proteins based on their different isoelectric points and the capability of the 11 S fraction to precipitate at low temperatures [160].

Adjusting the temperature to 10°C during EDBM allowed a selective fractionation of soybean protein fractions (Figure 21.31a and 21.31b) [43]. In practice, if a sample of precipitated protein was taken at pH 6.2, the protein composition will be composed of 33.8%, 92.9%, 16.2%, and 8.7% of the original content of the 15 S, 11 S, 7 S, and 2 S fractions, respectively. This leads to a solution enriched in the 11 S fraction in the precipitate (71.8% of 11 S and 10.8% of 7 S) and to a solution enriched in the 7 S fraction in the supernatant (46.6% of 7 S and 4.6% of 11 S) [43]. The selective fractionation at low temperature is explained by the fact that proteins which have a high proportion of hydrophobic to polar amino acids, and therefore have structures which depend on hydrophobic interactions, are particularly sensitive to denaturation at the freezing point [87]. According to Chefel et al. [87], soy fractions 11 S and 7 S have relatively high average hydrophobicity values as calculated using Bigelow's equation [161]. Consequently, the combination of the differences in low-temperature sensitivity and in the isoelectric point of both the 11 S and 7 S fractions, the main protein soybean fractions, would allow their selective separation by BPM electroacidification.

**FIGURE 21.31** Evolution of percent precipitated proteins of the different protein fractions 15 S (●), 11 S (□), 7 S (▲), and 2 S (▽), in a 30 g/L SPC solution with 0.06 M added KCl, during pH decrease by BPM electroacidification at (a) 10°C and (b) 27°C. ### 21.4.8 RECOVERY OF PROTEIN AND COAGULANT AGENT FROM SOY TOFU WHEY

In the tofu-making process, coagulant is added to soy milk at a concentration of 2%–4% (w/w) of the soybeans used in the batch [162,163]. The coagulating agent can be calcium sulfate or magnesium chloride. The coagulant causes the protein to aggregate through calcium or magnesium bridging and eventually to precipitate [163]. The combination of coagulant and subsequent heat processing promotes the aggregation and coagulation of the tofu [163], which is then separated from the residual soy tofu whey (STW) and further processed. Disposal of STW, which contains substantial concentrations of pentose and hexose sugars, minerals, proteins, and excess coagulant, is an expensive process that adds significantly to the cost of tofu manufacturing. Now, the whey is discharged to the municipal sewerage system. By rejecting this waste, an important part of the protein (about 20%) and the coagulant is lost; furthermore, these salted effluents pollute the environment. Then, recovering the Mg from STW would decrease the direct cost associated with tofu production while recovering the protein would increase the production yield.

Electrodialysis (ED), EDBM, and a combined configuration of ED followed by EDBM (ED+EDBM) were evaluated for the recovery of magnesium ( $Mg^{2+}$ ) and protein from STW, where magnesium chloride was used as a coagulant [164] (Figure 21.32). ED alone was performed in batch process using a constant current of 1 A for 30 min. EDBM alone was performed in batch process using a constant current of 1 A during the first 40 min, and a constant current of 3 A during the last 20 min of processing, to accelerate the process of electroacidification. In the combined configuration (ED+EDBM), the STW was first treated in the electrodialysis configuration for 60 min, at 1 A constant current, and then in the electroacidification configuration for another 60 min, at 1 A. The configurations were compared on the basis of changes in electrical conductivity,  $Mg^{2+}$  recovery, percent protein precipitation, and energy consumption.

During electrodialysis treatment, total  $Mg^{2+}$  concentration in the STW diminished from 980 to 800 ppm in 30 min: a 18.4% decrease from the initial concentration. This decrease in  $Mg^{2+}$  concentration is due to  $Mg^{2+}$  migration, from the STW solution to the concentrate compartment where its concentration increases proportionally. For cheese whey and skimmed milk, Hiraoka et al. [165] showed that at the early period of demineralization  $K^+$  and  $Cl^-$  are initially removed followed by calcium, magnesium, and phosphorus. However, deashing rate of about 60% and 30% for cheese whey and skimmed milk, respectively, had to be reached before Mg started to migrate. In our case, about 22% of demineralization was reached at the end of the ED configuration.

During EDBM processing, the pH of STW decreased from 5.5 to 3.4 in 60 min. Changing the current from 1 to 3 A allowed a better migration of ions in the solutions and resulted in a faster reduction in pH. The soluble protein concentration decreased

**FIGURE 21.32** (a) Electrodialysis (ED) and (b) electrodialysis with bipolar membrane (EDBM) configurations tested for recovery of magnesium or protein recovery from STW. BPM, bipolar membrane; CEM, cation-exchange membrane; AEM, anion-exchange membrane.

Note: N/A = not applicable.

from 660 to 510 mg equiv BSA/L: a 22.7% decrease in 60 min. Moreover, this configuration allowed a 14.3% decrease in STW Mg<sup>2+</sup> concentration (decrease from 700 to 600 ppm).

During the ED phase of the combined configuration, the STW pH increased slightly, as previously noted in the ED configuration alone, from 5.6 to 5.9 in 60 min. During the EDBM phase, the pH decreased to 4.0; the pH decreases in the same way in the EDBM configuration and the EDBM step in the combined configuration. The recovery of Mg<sup>2+</sup> from STW was 60.5% during the ED phase in 60 min: the demineralization was performed in a linear fashion during this period (Table 21.10). During the EDBM step, an additional 5% recovery of Mg<sup>2+</sup> was achieved. For the soluble protein concentration, 34.7% of total protein was precipitated during the EDBM configuration step. The combination of the ED and EDBM configurations allowed the recovery of 65% of the Mg<sup>2+</sup> and 34.7% of the proteins from the STW. A demineralization step highly improved the protein precipitation efficiency of EDBM; the efficiency of EDBM increased by a factor of 2 between EDBM configuration and the EDBM step in the combined configuration.

Energy consumption, calculated on a 30 min basis, was about 0.69 kW h/kg Mg<sup>2+</sup> recovered from STW in the ED configuration compared to 0.08 kW h/kg Mg<sup>2+</sup> for the ED step in the combined ED + EDBM configuration (Table 21.10). This could result from the higher temperature of 39°C for the ED+EDBM configuration compared to only 12°C for the ED configuration. Boer and Robbertsen [166] observed that a 10°C change in temperature corresponded to an increase in conductivity and a higher demineralization rate, which had a positive effect on power efficiency. For the EDBM step, values of 1.7 and 3.76 kW h/kg Mg<sup>2+</sup> recovered were obtained, respectively, for the EDBM and the ED + EDBM configurations. The higher initial concentration of Mg<sup>2+</sup> could also be responsible for the higher electrical efficiency for the ED configuration compared to the EDBM configuration [164]. The energy consumption for protein precipitation was lower by a factor of 2 when the STW was partially demineralized by ED before electroacidification by EDBM processing. This confirmed the previous results obtained for protein precipitation slopes.

The combination of demineralization/protein precipitation is an efficient configuration to recover salts and proteins from an STW. Electrodialysis is the most efficient configuration for recovering salts. However for protein recovery, the electroacidification needs a demineralization step to improve its efficiency. Further work is needed to optimize the combined ED + EDBM configuration. Recovery of Mg<sup>2+</sup> and protein from an STW using a two-step process would decrease the cost associated with tofu production. The recovered Mg<sup>2+</sup> could be reused as coagulant thus decreasing the lost of excess coagulant in the effluents. Furthermore, the protein recovered could be reused in the tofu production to increase the protein content of tofu.

## 21.5 OTHER APPLICATIONS: BIOTECHNOLOGY, NUTRACEUTIC, COSMECEUTIC, AND BIOPHARMACEUTIC

BPMs offer a solution to the cation elimination problem accompanying most organic acids: They allow a salt to be split into the corresponding alkali and acid solutions. Consequently, BPMs are used in water-splitting processes and offer possibilities for organic acid recovery from fermentative production. In addition, the decrease in ionic strength induced by cation demineralization coupled with acidification of the solution was also used for the production of phospholipids.

### 21.5.1 FERMENTATIVE PRODUCTION AND ISOLATION OF LACTIC ACID

Lactic acid is one of the organic acids having a wide use in a numerous fields such as food industry, beverage production, pharmaceutical industry, chemical industry, and medicine [167]. Today, more than half of the world production of lactic acid is produced in industrial scale traditionally in simple batch fermentations with low productivities [140]. The conventional fermentation process produces calcium lactate precipitate, which must be concentrated by evaporation and reacidified by a strong acid [168]. The disadvantages of the conventional fermentation processes are a low reaction rate, an elaborate product recovery, a large amount of by-products, and thereby negative impact on the environment. There are other possibilities for lactic acid recovery, but solvent extraction, direct distillation, adsorption, and other relatively simple methods have certain limitations, which obstruct their wider use [169,170]. Electrodialysis is one of the very promising and perspective methods provided by the rapid development of membrane processes.

Bipolar membrane ED was used by Norddahl [171] and Norddahl et al. [172] for fermentative production and isolation of lactic acid (Figure 21.33). A sterilized growth medium as whey permeate from production of whey protein concentrate (WPC) with an admixture of protein-hydrolyzing enzymes was subjected to continuous fermentation in a fermenter by *Lactobacillus* sp. bacteria, which produces lactic acid. The fermentation liquid was ultrafiltered (cutoff 5000 Da, 7.3 m<sup>2</sup> total membrane area) to retain the retentate containing bacteria culture and nonhydrolyzed whey protein, and allowed dissolved matter to pass, including lactic acid formed in the fermentation process. Since ammonia was used to control pH fermentation, the lactic acid was in the form of ammonium lactate. The permeate from the UF process was treated on a chelating resin to bind divalent ions thus preventing precipitation of calcium salts that might otherwise lead to a slow irreversible scaling of the membrane in a subsequent electro dialysis treatment of the permeate. The eluate from the ion-exchange resin was concentrated in a two-step ED process, in which the first step uses conventional ED membranes. In the second step, BPMs separate the salts formed into lactic acid, inorganic acids, and ammonium hydroxide solution (Figure 21.27). Ammonium lactate was thereby converted to ammonium hydroxide and lactic acid in two separate streams. The overall recovery rate of lactic acid was quite high, about 85%–90% based on the amount of sugar added to the fermenter [171].

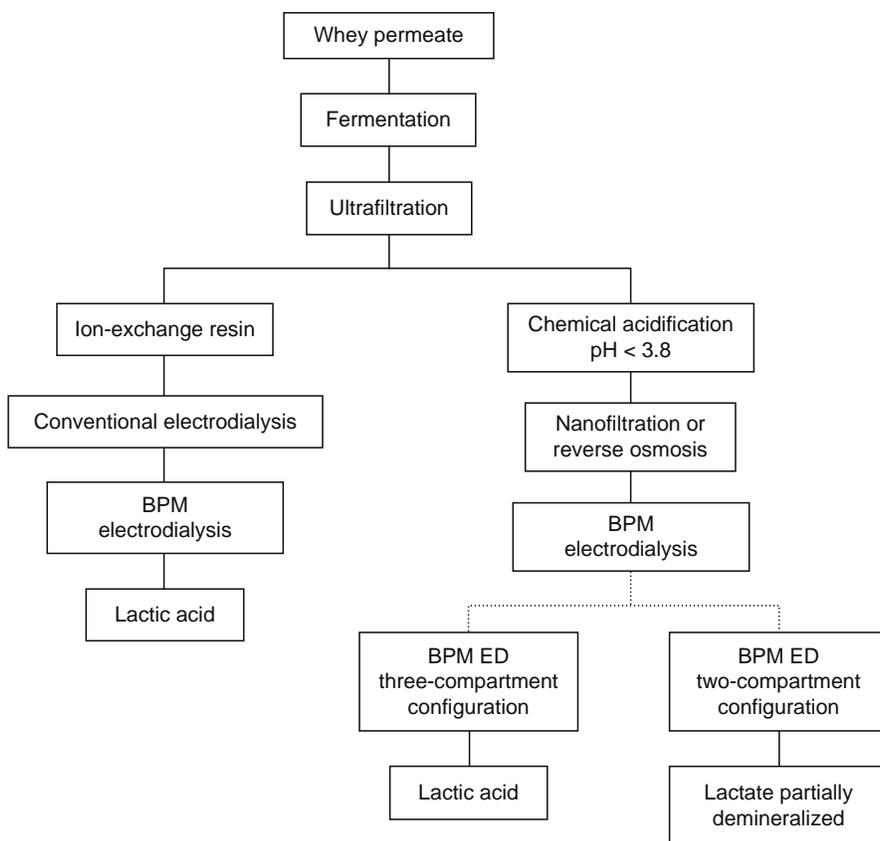

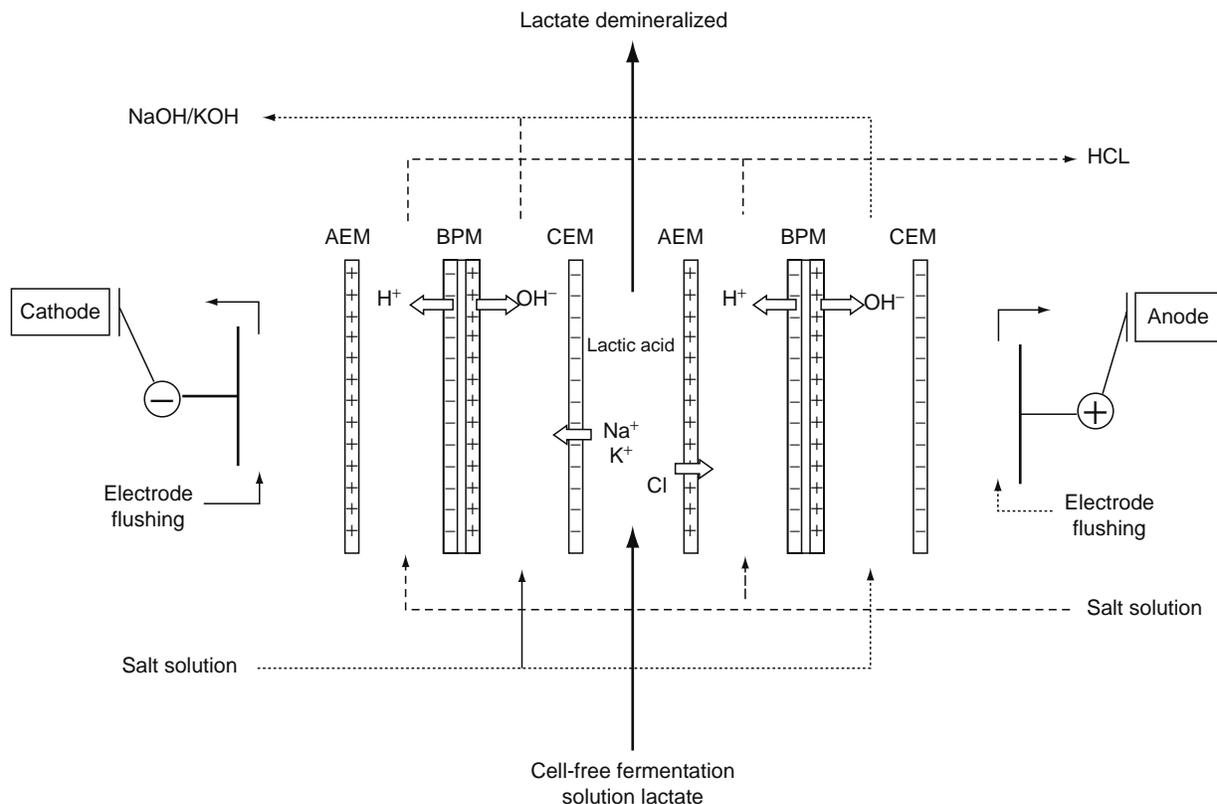

FIGURE 21.33 Process for fermentative and isolation of lactic acid. (From Bazinet, L., *Crit. Rev. Food Sci. Nutr.*, 45, 307, 2005.)

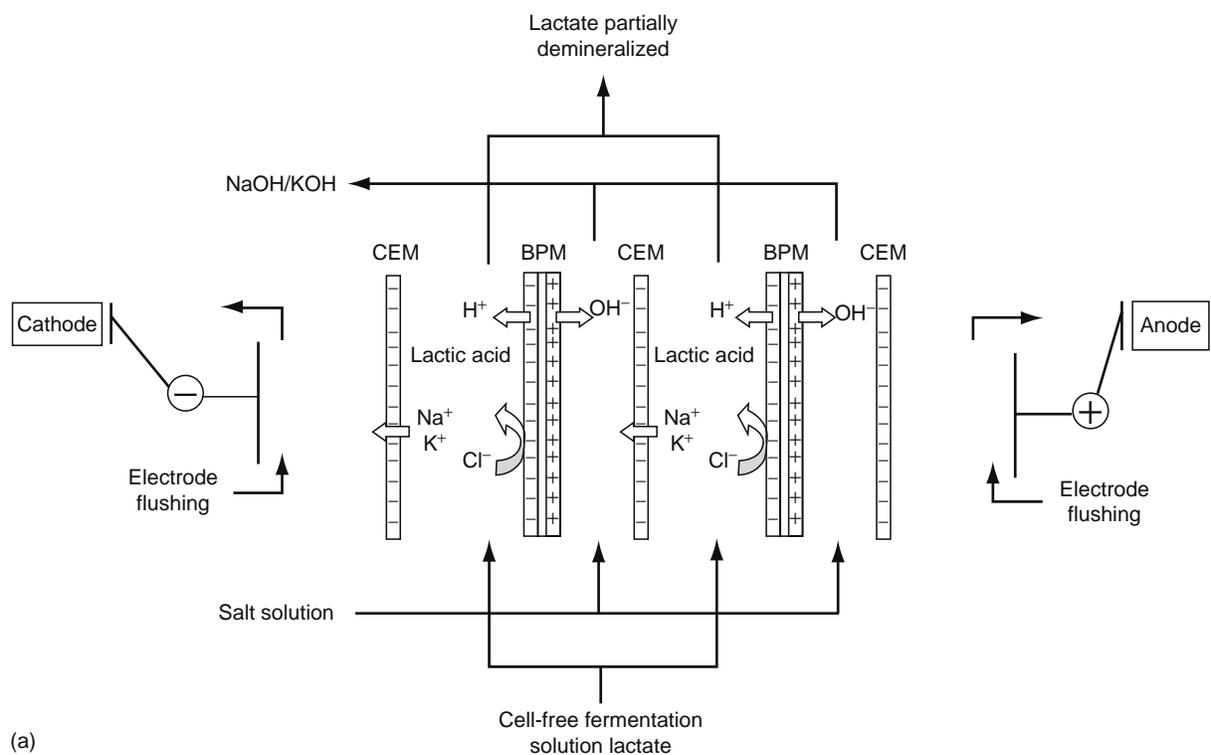

This process was simplified from the general process proposed by Van Nispen and Jonker [142], since the feed stream contained no organic matter that could foul the BPM. Finally, the lactic acid could be purified and concentrated to the desired concentration using a falling film multistage vacuum evaporator or compression evaporator. Recently, a further development based on this process provided a novel purification procedure for isolation [172]. After ultrafiltration of the fermentation liquid, the permeate was acidified (Figure 21.33). The acidification comprises adjustment of the pH to a value of below 3.8, preferably between 2.5 and 3.0, to below the  $pK_a$ -value of lactic acid (3.86). As a result, the free lactate ions combine with hydrogen ions to form lactic acid having no net electrical charge. The resulting acidic solution was then subjected to a nanofiltration or reverse osmosis process to retain divalently charged ions and molecules larger than 180 g/mol. The permeate, free of calcium and magnesium was treated by ED in which ion-selective membrane and BPM separate the inorganic salts from the lactic acid (Figure 21.33). Lactic acid was thus recovered in the feed stream, which was deionized during ED.

Various arrangements are possible for this ED process. Bipolar membrane ED can be operated using a three-compartment configuration, with separate compartments for brine-, base-, and acid-containing streams [142,171,172] (Figure 21.34). The brine compartment, to which the lactate is fed, is passed through the membrane stack in the space between the monopolar and anionic membranes. The base stream is led between the monopolar cationic membrane and the anionic side of the BPM, where the hydroxide ions are generated. The acid stream is led between the monopolar anionic membrane and the cationic side of the BPM, where acid is generated. Thus, the anions (mainly chloride) are transported from the brine compartment, through the monopolar anionic membrane, to the acid compartment, where they combine with protons generated by the BPM to form the corresponding acid. Similarly, cations (Na, K, etc.) are transported from the brine compartment, through the monopolar cationic membrane, to the base compartment, where they combine with hydroxide ions generated by the BPM to form bases. In this way, hydrochloric acid and Na/K hydroxide can be recovered in the acid and base compartments, respectively.

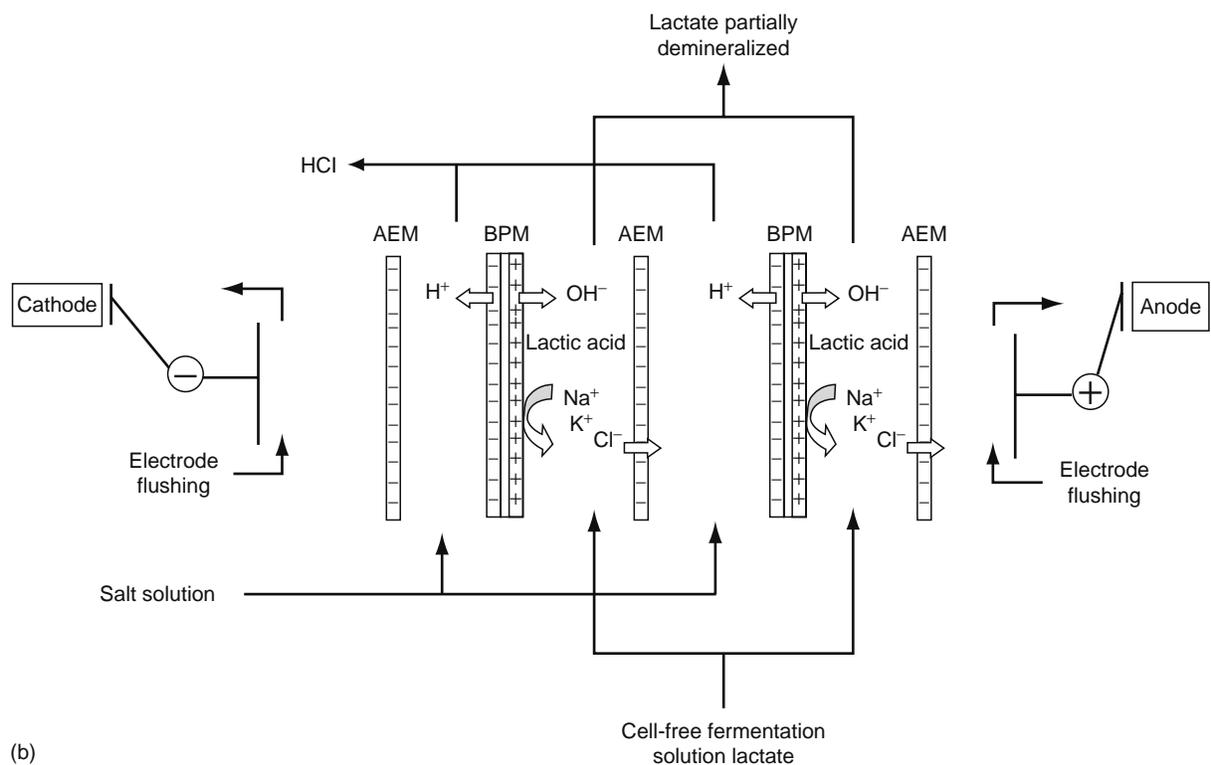

Alternatively, the bipolar membrane ED can be operated using a two-compartment configuration, where either the anionic (Figure 21.35a) or the cationic (Figure 21.35b) monopolar membranes are omitted. In this mode of operation, only cations or anions are removed from the feed compartment and replaced with either protons or hydroxide ions. A brine compartment is

**FIGURE 21.34** Operation of BPM ED using a three-compartment configuration without lactate migration. (From Bazinet, L., *Crit. Rev. Food Sci. Nutr.*, 45, 307, 2005.)

(a)

(b)

**FIGURE 21.35** Operation of BPM ED using a two-compartment configuration coupling. (a) Cation-exchange membrane (CEM) and (b) anion-exchange membrane (AEM). (From Bazinet L., *Crit. Rev. Food Sci. Nutr.*, 45, 307, 2005.)

therefore not present in this configuration. A disadvantage of this configuration, however, is that the lactic acid-containing stream is only partly deionized, since only cations or anions are removed.

This improved process for lactic acid production has the advantage of being simple and inexpensive and resulting in a high-lactic acid recovery rate requiring fewer steps. According to Norddahl et al. [172], it is possible to reach an overall recovery rate of about 90%–95% or more than 98% based on the amount of sugar added to the fermenter. Further, several additional advantages are obtained by the invention, including

1. No need to use chemicals to regenerate ion-exchange materials.
2. Higher operating efficiency, since in contrast to a process using ion exchange, there is no risk of calcium or magnesium ions passing through the ion-exchange resin; therefore, the process is also easier to control.
3. All the effluent streams are recycled, the acids and bases generated in the optional bipolar ED step being returned to the process.
4. A reduction in the amount of waste products, since the only waste generated is in the concentrate from nanofiltration, which contains  $\text{Ca}^{2+}/\text{Mg}^{2+}$  ions and colored compounds.

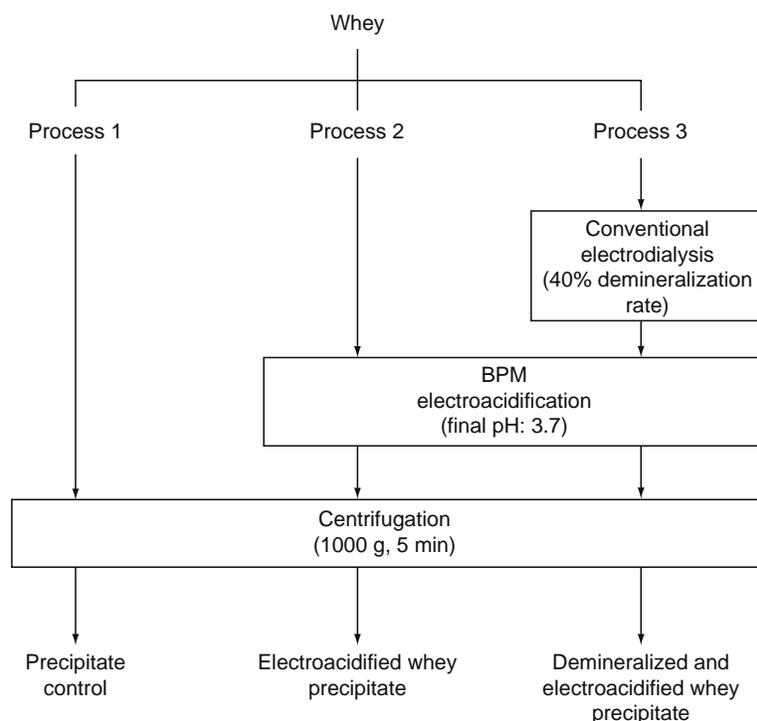

### 21.5.2 PRODUCTION OF PHOSPHOLIPIDS

Dairy whey is a by-product of cheese and casein manufacture. Cheese whey contains 7–10 g/L of proteins with a high content of  $\beta$ -lactoglobulin (3 g/L) [173] and about 2–8 g/L of lipids [174]. Whey lipids are composed of almost 66% of nonpolar lipids and 33% of polar lipids. Polar lipids are mainly phospholipids with 34% phosphatidylethanolamine, 31% phosphatidylcholine, 15% sphingomyelins, 12% phosphatidylinositol, and 8% phosphatidylserine [175]. In comparison with other sources of phospholipids available in the market (soybean essentially), the dairy phospholipids are original due to the presence of a high concentration in sphingomyelins and a low proportion of polyunsaturated fatty acids [175]. Hence, the presence of a high concentration of sphingomyelins in the lipids of the skin suggests a possible use of whey phospholipids in cosmeceutic. Furthermore, the fact that the fatty acids presented a low rate of polyinsaturation would have a main impact on the susceptibility to oxidation of these lipids.

Whey is generally concentrated by evaporation and spray dried to obtain WPCs. Over the past several years, WPCs have been largely used in the food industry as nutritional and functional ingredients. Typically, conventional WPCs are composed of more than 35% of protein and have a fat content higher than 4% [176]. However, the presence of lipid in these products affects their functional properties [177] and promotes the development of oxidation reactions, which could impart off flavors [178]. For these reasons, methods to decrease fat content in the final product have been developed. Among those methods, the thermocalcic precipitation can be cited. It consisted of the addition of divalent calcium ions to the solution the pH of which was adjusted to 7.3. This solution was then heated to allow aggregation and precipitation of phospholipoprotein complexes [174,179,180]. These complexes were then eliminated by, for example, microfiltration. With this method, it is possible to produce a WPC containing less than 0.5% of lipids [181]. However, this microfiltration process have to be optimized to obtain a satisfactory membrane flow and protein permeation. De Wit and Klarenbeek [182] have found that the decrease of the ionic strength of whey solutions combined with chemical acidification at pH 4.6 allowed the precipitation of lipoproteins, which could be separated by decantation. Ionic strength reduction was carried out by demineralization with ion-exchange resins, electro dialysis, or diafiltration. Another method consisted of an acid precipitation of lipids in a medium with a low-ionic strength. Phillips et al. [183] and Boswell and Hutchinson [176] have proposed a process consisting of a preliminary concentration of the whey by ultrafiltration until a solid value of nearly 23% was reached. This intermediate WPC was then diluted to decrease the ionic strength and was chemically acidified to reach a pH of 4.3. Separation of the fat compounds by flocculation was then obtained. The clarified product was concentrated by ultrafiltration and dried by an atomization process. The final product was then composed of less than 1% of lipids [176]. However, the chemical products used for the WPC acidification present the disadvantage of adding organic or mineral salts which increase the ionic strength of the solution.

Recently, Lin et al. [184] used EDBM technology for acidification and decreasing the ionic strength of a fresh cheddar cheese whey. In this study, EDBM process was carried out with or without preliminary decrease of whey mineral salts content by conventional electro dialysis to obtain precipitates with high level of lipids (Figure 21.36). After centrifugation of the treated whey, composition of flocs and precipitation yields was determined.

Whey centrifugation at 1000 g during 5 min (process 1) allowed a 20.8% recovery of cheddar cheese whey initial lipids (Table 21.10). The other components, proteins and lactose were precipitated at a lower rate (1.1% and 0.6%, respectively). A 32.1% whey lipid precipitation was obtained in process 2 consisting of an electroacidification to reach a pH value of 3.7 before the centrifugation step. This represents a 54% increase of precipitation rate in comparison with process 1, with proteins and lactose precipitation levels quite similar (1.9% and 0.9%, respectively). Demineralization step before electroacidification had only small effect on the precipitation level: Similar precipitation levels for lipids and lactose were obtained in comparison with process 2 values except for proteins. Conventional electro dialysis allowed an increase of protein precipitation from 1.9% to 3.3% (Table 21.11).

**FIGURE 21.36** Cheddar cheese whey treatment by conventional electro dialysis and EDBM before final centrifugation.

Phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (PS) have a nitrogen atom in their structure; then it was possible to estimate the nitrogen content of precipitates from their lipid contents. The calculated nitrogen content from the phospholipids was close to the total nitrogen values detected in the precipitates (except for the process 3), which suggests that precipitates were composed mainly of phospholipids. Other constituents should be proteins, lactose, and mineral salts but at a low level. These latter two compounds could be washed by water.

Lipids recuperation by centrifugation in process 1 was due to residual fat particles. The increase of lipids precipitation levels in processes 2 and 3 may be explained by the formation of lipids/proteins complexes during electroacidification precipitates [182]. The protein–lipid interactions that exist in food systems involve hydrophobic interactions between apolar aliphatic chains of the lipid and the apolar regions of the protein. In model systems, the energy of the protein–lipid interaction reaches a maximum in the neighborhood of the isoelectric point of the protein [87]. The associations between lipids and proteins are probably electrostatic interactions involving the phospholipids. The isoelectric point of the  $\beta$ -lactoglobulin, the main whey protein, is at pH 5.5. So at pH 3.7, the protein carries a positive electric charge [185]. However, some phospholipids have a negative charge at acid pH like the phosphatidylserine which have, at pH 3.7, two negatively charged groups: the phosphoric acid group and the carboxylic acid group [186]. An equation, including calcium ion level that represents the mechanism of protein/lipid complex formation, was reported by Cornell and Patterson [187]:

**TABLE 21.11**  
**Whey Components Precipitation Yields**

	Process 1 (%)	Process 2 (%)	Process 3 (%)
Lipids	20.8 ± 3.5	32.1 ± 4.7	29.7 ± 2.3
Proteins	1.1 ± 0.7	1.9 ± 0.5	3.3 ± 0.4
Lactose	0.6 ± 0.4	0.9 ± 0.2	1.1 ± 0.1
Total solids	1.5 ± 0.6	2.3 ± 0.4	2.6 ± 0.2

where

P denotes protein with a charge  $z$

Ca denotes calcium ion

L denotes phospholipid carrying a negative charge

$n$  denotes number of phospholipids bound per protein group

Lau et al. [188] have shown that calcium ions are linked to phospholipids. The binding of calcium with lipids inhibits the formation of lipid/protein complexes. The decrease in mineral salts, particularly in magnesium and calcium ions, during processes 2 and 3 promotes the lipid/protein complexes formation. This phenomenon was confirmed by higher precipitation levels for lipids and proteins in process 3 in comparison with process 1 (Table 21.11). Equation 21.1 also means that an increase of  $P^{z+}$  components should improve the lipid/protein complexes formation. This increase of  $P^{z+}$  may be obtained by a concentration step of whey solutions by ultrafiltration.

On the basis of these observations, further works were carried out by Bazinet et al. [189] to evaluate the effect of protein concentration on the lipid precipitation. In this second study, a WPC with 55% of protein on dry basis was used. WPC electroacidification was carried out with or without preliminary demineralization by conventional electro dialysis. The effect of the ionic strength on precipitation rates of fats was also evaluated by water dilution of the WPC samples.

Products  $A_1$ ,  $B_1$ , and  $C_1$  which were the supernatants coming from the centrifugation of products A, B, and C (Figure 21.36) presented similar levels of total solids and proteins (Table 21.12). However, the fat contents are significantly lower in products  $B_1$  and  $C_1$ : lipid levels in supernatants  $A_1$ ,  $B_1$ , and  $C_1$  were 0.63%, 0.55%, and 0.47%, respectively. Then, the EDBM process resulted in an increase in the rate of lipid precipitation (35% yield) in comparison with a single-step centrifugation. The demineralization process carried out under the given conditions did not induce a destabilization of the lipids matter which could have resulted in a higher lipid precipitation. However, a more important decrease of the ionic strength can have significant effect on lipids precipitation. This was the object of the second part of this study on the decrease of the ionic strength of solutions by dilution of the acidified WPC.

Hence, in products from D to I, which were the supernatants obtained after dilution, decantation, and centrifugation of previous products, respectively, significant drops in protein and lipid levels were observed in comparison with the initial product composition (Table 21.12). Only samples H and I had a protein level different from the other samples (Table 21.12). The decrease of protein content was of 9% and 8%, respectively, for these products. This suggests that a part of the protein in the supernatants has precipitated. This could be explained by their lower ionic strength (conductivity of 0.4–0.8 mS/cm). Products D, E, F, and G had similar protein contents. In a general manner, the acidification by EDBM followed by a dilution resulted in the preservation of more than 90% of the protein present initially. For the fat content, the more important decrease was observed for products E and F with a respective reduction of their lipid contents of 73% and 66%. In second position are products H and I with 49% and 45% respective reduction of lipids levels (Table 21.12). These different precipitation levels might be explained by the initial fat contents of the products. Effectively, products E and F obtained from samples B and C contained between 0.72% and 0.78% of fat while products H and I obtained from products  $B_1$  and  $C_1$  have fat levels between 0.47% and 0.55%. Samples dilution following the EDBM step resulted in a reduction of lipids from 0.78% to 0.21%, a decrease of nearly 73% of initial content in WPC lipids. It also resulted in clarified supernatants with a low level in lipids and with the majority of the proteins present initially.

This new process would have two advantages, the production of a phospholipid-enriched fraction, which could be used in cosmeceuticals and nutraceuticals and a purified (demineralized and delipided) and more valuable protein fraction after concentration of the whey. EDBM process could be a part of the first step of WPC treatment for the valorization of the whey in the form of lipid fractions of different nature. In comparison with the chemical acidification, EDBM process has the

**TABLE 21.12**  
**Protein and Lipid Contents of Initial Samples (A, B, C,  $A_1$ ,  $B_1$ , and  $C_1$ )**  
**and of the Diluted Samples Supernatants (D to I)**

Products	Protein Content (%)	Fat Content (%)	Products	Protein Content (%) Multiplied by Dilution Factor	Fat content (%) Multiplied by Dilution Factor
A	9.27	0.76	D	9.25	0.54
B	9.72	0.78	E	9.57	0.21
C	8.89	0.72	F	8.04	0.24
$A_1$	9.01	0.63	G	9.00	0.50
$B_1$	9.63	0.55	H	8.80	0.28
$C_1$	8.84	0.47	I	8.17	0.26

advantage of offering continuous acidification without the addition of salt. This could allow, in an industrial process, (1) to maintain a low-ionic strength of the solution, for example, before or after WPC dilution and (2) to produce a purified WPC (with a low ash level).

## 21.6 SUCCESSFUL EDBM INDUSTRIAL PLANTS

Authors are grateful to Eurodia Company (Wissous, France) for its contribution to this part.

### 21.6.1 HISTORY OF ELECTRODIALYSIS WITH BIPOLAR MEMBRANES

Over the past 15 years, more than a dozen known commercial plants totaling about 2500 m<sup>2</sup> of BPMs have been installed throughout the world. These membranes came from two suppliers: Aqualytics Corporation (Warren, New Jersey) and Tokuyama Corporation (Tokyo, Japan) (Neosepta).

Table 21.13 reviews the (known) different plants installed worldwide with above membranes and the corresponding estimated membrane area. The first bipolar system was delivered in 1986 to Washington Steel in Pennsylvania for the recovery of hydrofluoric and nitric acids from stainless steel pickling liquor and the most recent one has been installed in China for the production of an organic acid. In the last few years, some of the plants in operation in the United States have been closed due mainly to overall plant shutdowns, product line changes, or other economical reasons.

Therefore, we know of about 1850 m<sup>2</sup> of BPM currently (or soon) in operation, mainly for the production of specialty and fine chemicals, such as amino and organic acids. The limited number of EDBM plants in operation is the result of many factors, mainly industry concerns over reliability and cost. The relatively high investment of EDBM systems limits its use so far to higher value products. However, improvement in stack and plant design, as well as overall process design, allows its use for the production of a growing number of products. Already, four new plants have been installed in the last 2 years.

## 21.6.2 EDBM: A COST-EFFECTIVE SOLUTION FOR THE PRODUCTION OF SPECIALTY AND FINE CHEMICALS

### 21.6.2.1 Criteria for the Application of EDBM

The effective utilization of EDBM requires the following conditions:

- Total multivalent cations content in the treated fluid was in the range less than 1–5 ppm. Indeed, the multivalent cations may precipitate by association with  $\text{OH}^-$  ions in the stack. This precipitation may occur in the CEM during the ionic transfer from the acid to the base compartment, thus destroying this membrane. It is to be noted that the BPM is not affected by this problem.
- Feed concentration in organic acid salt greater than 1 equiv/L: this specification allows a reduction of the membrane area required for the conversion because the current density can remain high enough during most of the conversion. This leads to a decrease of both the investment and operating costs.
- Operating temperature lesser than 40°C.
- No oxidizing compounds. These requirements are related to the materials used to manufacture the membranes.

### 21.6.2.2 Organic Acid Production in France

Eurodia Industry delivered an EDBM plant in 1997 in France for the production of an organic acid from its sodium salt (Figure 21.37). The acid, produced by fermentation, must remain confidential as well as the name of the customer. The plant was initially designed to produce 2600 mton/year of acid (100%) over 8000 h of operation. Two EUR20-240 stacks with 81 m<sup>2</sup> of effective cell area were initially installed in the two-compartment configuration (see Figure 21.37) with Neosepta CMB cation-exchange and BP1 BPM. The acid conversion rate (purity) is 98% with a concentration of 390 g/L: this is equivalent to a final conductivity of 3 mS/cm. The NaOH was initially produced at a concentration of 6 wt% to be reused in the fermentation (most microorganisms do not like acidic conditions). The plant initially operated in a batch mode to consistently meet the customer requirements. The initial battery-limit investment was £1,050,000.

After several years of operation, a membrane life of 20,000 h was reached for the BPMs, while the CEMs have been replaced after 18,000 h. The electrodes have not been changed until now. The customer has increased the capacity in several steps by adding several EUR20 and EUR40 stacks and an additional capacity expansion is being considered. By changing the operation from batch mode to feed and bleed, the base concentration could be increased from 6 to 8 wt% with the same current efficiency (for a new plant, the NaOH could be produced at 10 wt%). The main operating costs are power at 0.88 kW h/kg of produced acid and membrane (electrodes) replacement at 0.077 £/kg.

### 21.6.2.3 Acetic Acid Production in Germany

In 2002, Eurodia has supplied chelating resins and bipolar ED plant for 1700 ton/year acetic acid production, which represents 450 m<sup>2</sup> as total membrane area (Figure 21.38). The purpose of this application is to recover acetic acid from sodium acetate waste effluent and to reuse it in the process. The feed flow of sodium acetate concentration at 210 g/L is 1.5 m<sup>3</sup>/h and 91.5% is converted in acid. Acetic acid is recovered at 3 N and sodium hydroxide at 1.5 N. This plant was built according to pharmaceutical standards.

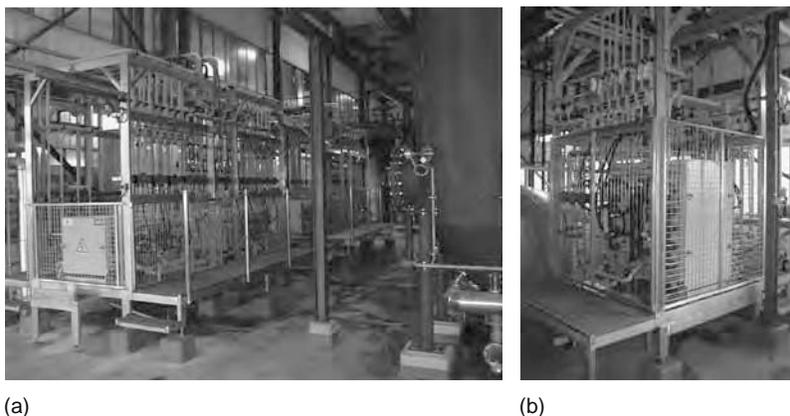

FIGURE 21.37 (See color insert following page 588.) Organic acid production in France. (From Eurodia Co.)

**FIGURE 21.38** (See color insert following page 588.) Acetic acid production in Germany. (From Eurodia Co.)

#### 21.6.2.4 pH Adjustment of Wine

After the development of wine stabilization by conventional ED, INRA Pech-Rouge with Eurodia has developed a new application of EDBM for wine. In many regions, the pH of wine is quite high. To improve the quality, the pH of wine must be increased from 0.3 to 1 pH unit. The EDBP allows this pH decrease in continuous treatment with a high efficiency and without any addition of chemicals (Figure 21.39). The official European Community approval is under progressing for this technology since 2005. This application is allowed in United States after getting Food and Drug Administration approval in 2004.

#### 21.6.2.5 EDBM Included in Complete Processes

As previously mentioned, the efficiency of EDBM, as a single-unit operation, has been demonstrated for the recovery/production of specialty chemicals. However, to propose overall cost-effective solutions, EDBM has frequently to be considered as one step of a complete process. As an example, the process reported in Figure 21.40 could be proposed for the production of an

**FIGURE 21.39** EDBMs for the stabilization of the wine pH. (From Eurodia Co.)

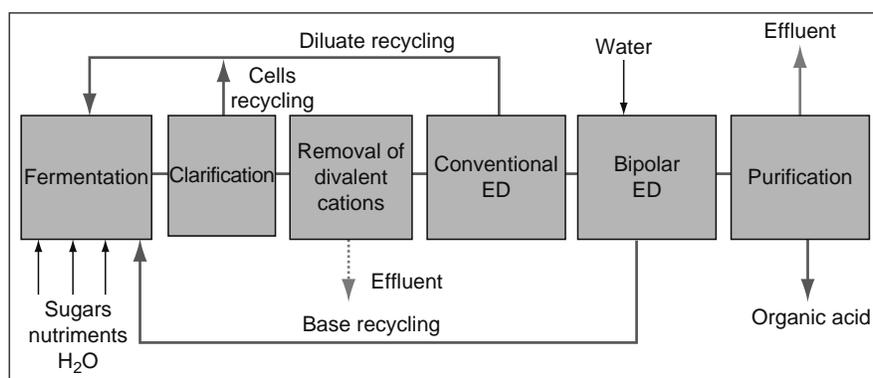

FIGURE 21.40 Organic acid production from a fermentation step. (From Eurodia Co.)

organic acid, such as lactic acid starting from sodium lactate produced by fermentation. The heart of the process is the conversion step performed by EDBM. To meet the feed requirements of EDBM (see above), the fermentation broth is first clarified by microfiltration. Then, the divalent cations content is lowered to a range of 1–5 ppm. The target species, i.e., sodium lactate, are concentrated and purified by conventional electro dialysis. After the conversion of sodium lactate into lactic acid, the product is purified by ion-exchange resins.

It is to be noted that the environmental impact is greatly reduced compared to traditional precipitation processes. Indeed, recycling can be optimized to the extent that the only environmental discharge is due to the use of ion-exchange resins. Furthermore, the effluent generated by the divalent cation removal step can be reduced by coupling both ion-exchange and membrane techniques. In 2002, Eurodia sold an equipment for a 2500 ton/year of lactic acid production in China. It consisted in three conventional ED stacks EUR40 and two EUR40 bipolar stacks, which represent a total membrane area of 2310 m<sup>2</sup> (Figure 21.41). An ultrafiltration skid with organic membranes was installed to clarify the fermentation broth.

## 21.7 CONCLUDING REMARKS AND PERSPECTIVES

EDBM is a recent technology, which appeared only in the 1980s, with the first commercial BPMs. Twenty years later of commercialization, lots of commercial plants are in operation and the demand for this technology grows up due to improved economics resulting from better design for ED stack and operating conditions.

EDBM has numerous advantages. Among others, (1) it uses electricity to generate the desired ionic species to acidify or alkalize the treated solutions, (2) water dissociation at the BPM interface is continuous and the process can be precisely controlled by the effective current density in the cell, (3) the in situ generation and reuse of dangerous chemicals for the environment (acids and bases) suppress the risks linked to their handling, transportation, and elimination, (4) the water consumption is lower by reuse of a part of the effluents generated and a low-energy consumption, and (5) the duration life of BM is more than 10,000 h, and reaches 20,000 h for specific applications.

However, some disadvantages of EDBM still exist: (1) the cost of equipment, which limits its use to high value products, (2) the permselectivity of the associated AEMs, decreasing the effectiveness of the BPM. In addition, presently, the development of EDBM is always limited by the number of applications, which are mainly focused on acid/base production. But, the selectivity and the lifetime of associated homopolar membrane are continuously increasing owing to researches in polymer science, along with the quality of new BPM. Food, nutraceuticals, biotechnology, and pharmaceutical are and will be in the future very interesting fields of application for combining all the advantages of BPM technology in a more competitive market. Promising applications for the production or recovery of organic and amino acids, as well as other specialty/fine chemicals and biomolecules are under study. The development of the technology, and its application in the agri-food and bio-industries, will surely help to minimize the cost of the BPMs equipment. In the future, EDBM would have to be considered as a step of a complete process and not as a single-unit operation, to discover its multiple potential uses not only in the chemical industry.

## 22.1 INTRODUCTION

### 22.1.1 GENERAL OVERVIEW

Microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) are the four major membrane processes that have become standard unit operations in the dairy industry. They often offer cheap capital and utility costs and have displaced conventional separation techniques that require phase change, such as the energy-intensive distillation, evaporation, or freeze concentration. Membrane processes require only small amounts of electrical energy for pumps and small amounts of steam for heating cleaning solutions, so that even RO, which is the most energy intensive of membrane processes, offers economic advantage. Also, unlike most separation processes, which require tall and hence more expensive buildings, membrane systems are relatively compact and they may often be accommodated in existing buildings [1–3].

Since their introduction in the 1960s, membrane technologies have been utilized in food industries because they provide a unique opportunity for accomplishing both the fractionation and the concentration of components in liquid systems without phase change, while retaining desirable physical and chemical characteristics of key food components. Two of such food commodities with various components of desirable functional properties and health-enhancing effects, especially when utilized in purified form, are milk and whey [4–6].

### 22.1.2 CURRENT AND NEW APPLICATIONS

Both retentate and permeate from membrane separation techniques have become important starting materials in producing novel products and ingredients from milk of unique functional properties and organoleptic quality. Henning et al. [7] enumerated the current and new applications of membrane technologies in the dairy industry, which include

- Microfiltration processing for clarification and defatting of cheese whey, for selective separation and concentration of micellar caseins from milk for various purposes, for fractionation of caseins and their peptides, for recovery of native whey proteins from milk, for gentle sterilization of milk to produce extended shelf life liquid milk and cheese milk, for fractionation of globular milk fat and its components, for the reduction of microorganisms in cheese brine, and for the removal of colloidal particles in membrane cleaning solutions.
- Ultrafiltration processing for whey proteins concentration and fractionation, for recovery of lactose from milk and whey, for total milk protein concentration for the production of milk protein concentrate (MPC) or milk protein isolate (MPI), for milk standardization for continuous mechanized manufacture of cheese and other fermented products, and for production of high-solids milk base for dried milk production.
- Application of RO in the partial demineralization or pre-concentration of whey, and the treatment of dairy effluents.
- Application of NF in the simultaneous demineralization and concentration of whey, concentration of lactose from the permeate of the UF whey, and the purification of membrane cleaning solutions.

## 22.2 MEMBRANE-BASED PROCESSES AND THEIR USES

### 22.2.1 MICROFILTRATION

Microfiltration is a technique that allows the differential concentration in the retentate of the feed components that are larger than the average pore diameter of the membrane [8]. Developed as early as 1929 by Sartorius-Werke, in Germany, microfiltration is one of the oldest filtration technologies whose main use was for water and beverage sterilization [9,10]. MF membranes have pore diameter ranging 0.1–10  $\mu\text{m}$ , which can selectively separate particles with molecular weights >200 kDa based on sieve effect [8,11,12].

The advent of ceramic membranes that can withstand pH range from 0.5 to 13.5, or from 0 to 14 for some membranes, such as Membranlox, and temperatures over 100°C provided significant advantages in terms of chemical, thermal, and mechanical stability over the more available polymeric membranes [13]. This and the invention of crossflow microfiltration (CFMF), which is an economic and efficient method for purification of fine particle or proteins, increased the utilization of MF in the dairy industry [14]. Today, CFMF is utilized in the dairy industry in three major applications: (1) removal of bacteria, (2) whey defatting, and (3) micellar casein enrichment of milk for cheesemaking and other applications [10]. A fourth and relatively new application of MF in dairy processing, which is based on the pioneering work of Goudéranche et al. [15], is the recovery and fractionation of native milk fat globule from milk, or even from mixed milk, and whey cream [16,17].

### 22.2.2 ULTRAFILTRATION

Ultrafiltration involves the separation of molecules in solution predominantly according to their sizes and shapes as well as charges and affinity for the membrane [18–20]. It involves the use of membranes with a molecular weight cut-off (MWCO) in

the range of 1–300 kDa and a pore size of  $\sim 0.01 \mu\text{m}$ , which operate at a pressure of  $< 10 \text{ bar}$  (1000 kPa) [11,21]. The nominal MWCO of UF membranes makes them appropriate for processing colloidal suspensions to filter particles or dissolved macromolecules that are  $< 1 \mu\text{m}$  in size [11]. For this reason, crossflow UF is used in a wide range of applications other than those in the food industry, such as biotechnology, pharmaceutical industry, and water and wastewater treatments [21]. When used in milk processing, UF results in a retentate containing proteins, fat, and colloidal minerals at higher proportions than that found in untreated milk, and permeate consisting water, minerals, lactose, nonprotein nitrogen (NPN) compounds, and water-soluble vitamins [11].

The application of UF in the dairy industry started, in the early 1970s, with the separation and concentration of whey proteins from cheese whey to protein-rich retentate and lactose-containing permeate [22–24]. Later, it was introduced as a cheese manufacturing technology, also in the early 1970s, for its potential in increasing cheese yield by the incorporation of whey proteins and other milk constituents in the cheese matrix while allowing a greater degree of control over cheese composition [3,25–28]. Cheesemakers recognize UF technology as more flexible than traditional processing methods and give unique opportunities to meet the demand for large product diversity [29]. The introduction of the thermal and pH resistant polysulfone membranes in the market in the mid 1970s, and the development of ceramic membranes and improved polysulfone membranes in the 1980s contributed to the advancement of UF technology, which was followed by explorations of different applications of UF in the dairy industry [26,29]. Among such applications are the potential of UF as a method for standardizing milk composition and clot-forming properties, and as a technique for developing new cheese varieties with different textural and functional characteristics [27,30–32]. Presently, concentration and purification of milk proteins to produce MPCs and MPis are two of the important applications of UF in milk processing [33].

The purification process for UF retentates is optimized by including a diafiltration (DF) step [3,34]. Compared with conventional processes, UF with DF has the advantage of allowing high product purity and process yield such as the removal of lactose from milk to the desired degree [3,35]. This process commonly includes three basic steps: (1) a pre-concentration stage, (2) a DF stage to purify the retentate and permeate, and (3) a final concentration stage to maximize the concentration of high-molecular weight solute in the retentate [35].

### 22.2.3 REVERSE OSMOSIS

Reverse osmosis membranes are characterized by an MWCO of  $\sim 100 \text{ Da}$ , and the process involves transmembrane pressures (TMP) of 10–50 bar (1000–5000 kPa), which are 5–10 times higher than those used in UF [11,36]. Unlike UF, the separation by RO is achieved not by the size of the solute but due to a pressure-driven solution–diffusion process [36]. Like UF membranes, RO membranes are uniquely structured films from synthetic organic polymers and consist of an ultrathin skin layer superimposed on a coarsely porous matrix [3]. The skin layer of the RO membrane is nonporous, which may be treated as a water-swollen gel, and water is transported across membrane by dissolving in this gel and diffusing to the low-pressure side [3]. In the dairy industry, RO is used to concentrate milk or whey by removal of water and ionized minerals [11].

### 22.2.4 NANOFILTRATION

Nanofiltration separates particles with molecular weights in the range of 100–500 Da and allows the rejection of ions based on their diffusion characteristics and charge [11,24]. NF separation is governed by mass transfer phenomena, which comprises diffusion and flow through pores and involves the use of membranes that are tight enough to retain lactose when utilized for dairy applications [11,24]. Due to the tightness of the membrane, Jelen [37] suggested that the NF process can be considered as an ultratight UF or as a loose RO. Somewhat similar to UF, NF is able to perform simultaneous separation and concentration functions and is commonly used in the dairy industry to process UF and MF permeates [24,36]. NF is often utilized in the concentration and partial demineralization of the UF permeates in whey processing [37].

## 22.3 INDUSTRIAL APPLICATIONS

### 22.3.1 CONCENTRATION AND FRACTIONATION OF WHEY PROTEINS BY ULTRAFILTRATION

To date, the fractionation and concentration of whey proteins from cheese whey remain to be one of the more successful industrial applications of UF [22–24]. Due to flux decline during operation, however, Mulvihill and Ennis [38] reported that the practical limit for whey concentration by UF in modern plants is around 24% total solids, with a protein:total solids ratio limit of  $\sim 0.72:1$ . DF is used to achieve a higher ratio of protein to total solids,  $\sim 0.80:1$ , and a total solids content of about 28% [38].

The efficiency of UF in whey processing is limited by a few factors, the most significant of which are concentration polarization and membrane fouling [6,39–41]. While both factors, which adversely affect permeate flux, may be aggravated by protein–protein and membrane–protein interactions [23,40,42–44], they may also be minimized by choosing suitable membrane material and configuration as well as the appropriate process conditions such as TMP, feed velocity or recirculation rate, temperature, and the chemical environment of whey [42,45,46].

The membrane material and the molecular conformation of the whey proteins are of considerable influence on flux decline [40,41,47]. Opposite charges on the whey proteins and the membrane induce protein–membrane electrostatic attractions that initiate protein adsorption on the membrane surface [23,40,46]. This may result in the undesirable denaturation and aggregation of the adsorbed proteins, especially at high-shear operations [48,49]. To date, the polymeric polysulfone membrane remains to be the most widely used membrane in whey UF primarily because of its low cost, good thermal stability, and mechanical properties [6,50]. It is commonly believed that compared with ceramic membranes and hydrophilic polymeric membranes, the hydrophobic polysulfone membrane gives low fluxes and more severe fouling [40]. However, Doyen et al. [43] showed that in the UF of whey, practically the same flux/concentration factor and whey permeability coefficient are obtained using polysulfone and ceramic membranes. The minimization of the hydrophobic and electrostatically induced interactions between polysulfone membrane and whey proteins, especially denatured whey proteins, which lead to massive fouling is still a challenge to date [40,42,51,52].

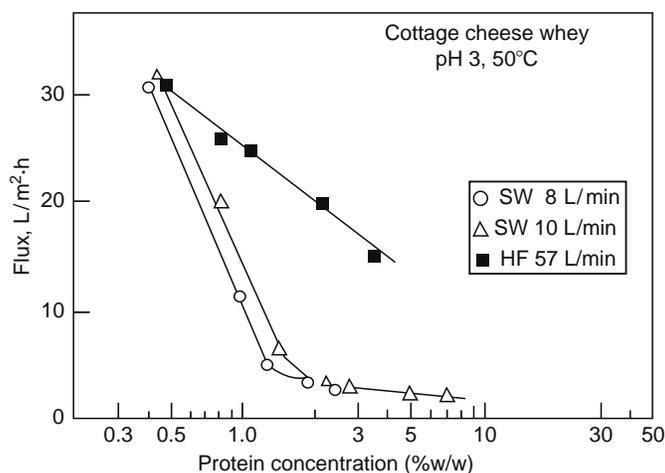

While  $\alpha$ -lactalbumin ( $\alpha$ -La) was found to have the greatest gel-forming tendency in UF of whey using polysulfone membranes and is the cause of immediate loss of initial flux,  $\beta$ -lactoglobulin ( $\beta$ -Lg) has great effect on long-term fouling [23,47]. Although whey proteins themselves are the major foulants, calcium and phosphates have been directly implicated with membrane fouling as possible catalysts or bridging agents between the proteins and the membrane or the proteins themselves, and the formation of insoluble calcium salts [23,41,47,53,54]. Rao [41] observed that for both sweet whey and acid whey, flux was controlled by fouling through gradual adsorption of whey proteins to the membrane surface and pore plugging by precipitated calcium phosphate. Hanemaaijer et al. [23] found that the UF membrane characteristics do not influence the deposition of calcium phosphate as strongly as pH and temperature. They observed membrane rejection of Ca at higher pH and temperature because its solubility decreases at these conditions [55]. Their findings were consistent with those of Kuo and Cheryan [45]. Labbé et al. [54] found that phosphates, either calcium phosphate, apatite and hydroxyapatite at pH 6.9, or sodium hydrogen phosphate at pH 5.6, were the main mineral foulants in the UF of raw and clarified whey using ceramic membranes. The same authors suggested the formation and adsorption of calcium–phosphate–protein complexes on the membrane surface at high pH. This explains the gelatin-like and firmly compacted fouling layer at high pH and the loose fouling layer at low pH observed by Kuo and Cheryan [45]. Using sweet whey, data by Hanemaaijer et al. [23] showed that calcium permeates satisfactorily through an acrylic copolymer membrane (30 kDa MWCO) at pH 6.0 and 45°C at a permeate to initial feed calcium content ratio of about 0.9 after 2 h of process time. Marshall and Daufin [56] pointed out that around pH 6, calcium changes to a more soluble form and that phosphate is in the soluble sodium hydrogen phosphate.

Using tubular ceramic membrane, Aimar et al. [19] showed that in the UF of sweet whey at pH 6.3, there was no considerable difference in flux plateau values at crossflow velocities from 1.8 to 4.0 m·s<sup>-1</sup> at 50°C and TMP of 3 bar (300 kPa). This seems to indicate that the critical TMP in UF of whey is ~3 bar (300 kPa), although the absolute flux plateau values might be affected by pH and the membrane material and configuration. Kuo and Cheryan [45] found that the critical TMP in the UF of pre-filtered cottage cheese whey, acidified to pH 3, at 50°C using 20 kDa MWCO polysulfone membrane in spiral wound configuration, was between 3.1 and 3.5 bar (310 and 350 kPa). At higher pressures, these authors pointed out that, even at high flow rates, flux declined rapidly due to extensive fouling and deposit layer compaction, reiterating that higher flow rates are beneficial only at pressures below some critical pressure [40,49]. Brans et al. [6] suggested that concentration of whey should be carried out just above the critical pressure where flux is equal to the limiting flux, to achieve optimal operation. Kuo and Cheryan [45], however, did not observe the critical TMP for hollow fiber module because of the limited pressure rating of the module.

Although flux decline may be minimized through appropriate process variables, energy consumption is a function of these variables [22]. While TMP–flux relationships (for pressure-controlled systems) and fluid velocity–flux relationships (for mass transfer-controlled systems) are relatively independent of module design [22,40,43], the pressure drop–fluid velocity relationship, and thus energy consumption, is a characteristic of the particular module design [22]. Polysulfone membranes are usually in the spiral wound or hollow fiber configurations. The available hollow fiber modules in the industry are limited by their low TMP ratings. The spiral wound modules, which can withstand higher pressures and are able to minimize the occurrence of concentration polarization, involve the lowest in capital and operating cost compared with other configurations [57–59].

Depending on process objective, UF can be carried out below, above, or at the critical TMP in which the flux ceases to increase linearly with increase in TMP, and therefore, referred to as the limiting flux [6,49]. When the feed solute concentration is low, higher TMP is required to achieve the limiting flux [60]. Therefore, using the spiral wound configuration to concentrate large volume of low solute-concentration feed, such as whey, is practical. On the other hand, the hollow fiber configuration has the advantage of giving higher flux than the spiral wound due to higher shear rates developed in the module for the same pressure drop [22,58]. This would be of advantage for high solute-concentration systems, such as pre-concentrated whey, where permeation is more likely to be mass transfer controlled and a high crossflow velocity is needed to maintain reasonable flux [6,22].

In concentrating whey proteins, DF is employed, in which water or buffer is continually added to the retentate while lactose and minerals are simultaneously removed in the filtrate, to increase whey protein purity [4,52,61]. This is commonly done in constant-volume mode where water or buffer is added to the retentate at the same rate as permeation. There is an optimum

**FIGURE 22.1** Variation of flux with protein concentration during UF of cottage cheese whey. (From Cheryan, M. and Kuo, K.P., *J. Dairy Sci.*, 67, 1406, 1984. With permission.)

protein concentration in the retentate at which DF can be commenced where the trade-off between permeate flux and the number of diaivolutes are balanced, and only the minimum membrane area or process time is necessary [62,63]. Using 20 kDa MWCO polysulfone membrane sheets, Nilsson [18] found that, in the UF of reconstituted WPC-80, the relative flux reduction increased with protein concentration and then plateaued up to about 3.2% protein concentration in the retentate. Above this concentration, the relative flux reduction increased sharply. Cheryan and Kuo [22] showed that at 3.35 bar (335 kPa) TMP and 50°C, the flux approached a minimum when the retentate reached about 3% protein concentration using polysulfone spiral wound membrane while the flux in the polysulfone hollow fiber is four times higher (Figure 22.1). This suggests that DF may be effectively carried out after 3% protein concentration in the retentate has been reached.

### 22.3.2 PRETREATMENT OF CHEESE WHEY BY MICROFILTRATION

Most commercial whey protein concentrate (WPC) and whey protein isolate (WPI) are produced from classic cheese whey. To remove cheesemaking remnants, such as starter culture bacteria, enzymes, glycomacropptide, and fat, the whey is clarified, pasteurized and, in the case of acid whey, decalcified before WPC or WPI manufacture [58,61,64]. Although clarification processes, such as pH adjustment or salt addition followed by gravity settling or centrifugation, are useful in removing colloidal calcium phosphate and protein–mineral complexes, they do not remove phospholipoprotein complexes and the smallest milk fat globules [65]. A number of authors have demonstrated the detrimental effects of fat on the functional and keeping quality of whey concentrates [61,66,67]. Centrifugation reduces the fat content of whey down to only 0.05%, which is predominantly small fat globules between 1 and 2  $\mu\text{m}$  in diameter, and increases up to 3% when whey is concentrated by UF [68].

Pretreatment of cheese whey by MF has emerged as a necessary step in producing WPI and WPC of varying whey protein content [69]. The MF of cheese whey has two specific applications: (1) defatting of whey and (2) removal of bacteria, or cold pasteurization, to produce high-quality WPC or WPI of valuable functional and health or medical properties [70].

Tanny et al. [71] proposed CFMF as a potential solution to the fat removal problem in whey. Using 1.2  $\mu\text{m}$  pore size MF membrane to clarify sweet cheese whey, Merin et al. [68] observed a permeate that was totally free of fat, while containing all the other whey components. Compared to the centrifuge-separated and nontreated whey, Merin et al. [68] reported 30% increase in permeation flux when the MF permeate was used as a feed stream in UF to produce WPC. They explained that this is probably due to the absence of small fat globules and casein fines in the MF permeate, which were suggested as major contributors to permeation resistance in the UF of sweet whey. The same group observed reduction of bacteria in the MF permeate by 1 to 2 orders of magnitude.

Rather than the thermo-calcic aggregation of lipoproteins and subsequent MF, Pearce et al. [72] showed the efficacy of CFMF in the direct removal of residual lipids from separated and pasteurized cheddar cheese whey. Results of their study indicated improvement in the foaming ability of the defatted whey products. Using 0.22  $\mu\text{m}$  cellulosic membrane, Hawks et al. [67] showed that MF is more effective in reducing the fat content of both acid whey and sweet whey compared with centrifugation. However, while MF is effective in removing PLPC, it also partially retains whey proteins, specifically bovine serum albumin (BSA) and immunoglobulin-G (Ig-G) [65]. The extent of retention depends on physicochemical and hydrodynamic conditions during the MF process.

### 22.3.3 CHEESE MANUFACTURING

#### 22.3.3.1 Ultrafiltration of Milk

The French government's dairy research laboratory, the Hungarian Dairy Research Institute, and the Australian Commonwealth Scientific and Industrial Research Organization can be given credit for propelling the UF of milk forward [70]. Since the pioneering work of Professor Maubois and colleagues in France in the 1970s, the concentration of total milk proteins by UF has been utilized extensively in the dairy industry to create a liquid pre-cheese for the production of soft cheese such as feta and Camembert [70,73,74]. In this process, the appropriate amount of water, lactose, and minerals are removed by UF from the milk, to make the pre-cheese, before coagulation and fermentation [25,28,70]. Using the UF pre-cheese, rennet coagulation could take place with the incorporation of whey proteins in the cheese matrix, which substantially increases the yield per liter of milk by 16%–20% while enabling the attainment of a more uniform product [25,28,70].

Ultrafiltration may be integrated into the cheesemaking process either for partial milk concentration or full milk concentration (Table 22.1), in which cutting and whey drainage are entirely eliminated and 100% of the whey proteins of milk are retained in the cheese matrix [28,75,76]. The reduced volume of the liquid pre-cheese and the absence of whey drainage from the curd when UF pre-cheese is used lead to the reduction of rennet requirement by ~80% compared to what is usually needed in conventional manufacture of cheese [25,77].

Pedersen and Ottosen [29] calculated ~13%–14% reduction in skim milk requirement in the German quarg cheese production if UF is employed rather than the conventional thermo-separator technique to recover acid whey after fermentation. They further estimated that the raw material savings for other UF fresh acid cheeses production including cream cheese are in the order of 4%–6% and 0.5%–1.5% fat. In the UF process described by Pedersen and Ottosen [29], the UF is carried out following heat treatment of milk (95°C for 5 min) and fermentation (pH 4.4–4.6), recovering acid whey from the UF step by the end of the process. Schkoda and Kessler [75] suggested the reduction of acid whey drainage by modifying this conventional UF process. They suggested the inclusion of twofold pre-concentration of skim milk by UF before heat treatment (UF–UF process). However, pre-concentration of skim milk by UF was reported to cause bitterness in quarg cheese and other fresh cheeses due to the higher buffering capacity of retentates compared with normal milk, the increased starter growth and possibly the high concentration of calcium in the UF milk [78]. Schkoda and Kessler [75] proposed the use of mesophilic starters of sufficient activity to ensure adequate acid and flavor production in the UF milk and lactose concentration of up to 9% in the retentate. The authors showed that the fresh cheese produced from the UF–UF process had the same quality attributes as those produced from

<sup>b</sup> — = not reported.

the conventional UF process. They also noted increased firmness and about 50% increase in calcium content in the cheese made from the UF–UF process compared to that made from the conventional UF process, suggesting that high calcium concentration was an unlikely cause of bitterness in fresh acid cheeses from UF milk. They reported at least 50% reduction of acid whey amount from the process compared to the conventional UF process.

Aside from improved yield, the use of UF pre-cheese results in the improvement of product taste and texture compared to cheese produced by conventional methods because of the reduction of lactose content, controlled acidification rate, and increase in the water-holding capacity of the product due to the incorporation of whey, which makes for softer product [25,73,79]. Lucisano et al. [77] noted an enhanced rennet-induced clotting time of UF-concentrated milk as pH is lowered from its natural pH level.

Using hollow fiber membrane with 30 kDa MWCO at 50°C and 0.8 bar (80 kPa) longitudinal pressure drop, Waungana et al. [80] reported that concentration of skim milk by UF to protein levels of ~6% (concentration factor of 2) and ~9% (concentration factor of 3) had no effect on gelation time in rennet coagulation at the natural milk pH. They also noted that an increase in UF milk concentration led to an increase in the curd firming rates and storage modulus, which is a measure of solid-like behavior. This is because reducing the aqueous volume in the retentate decreases the mean path between casein micelles. Since the aggregation rate depends on the number of effective collisions between casein micelles, a gel will form at a lower extent of  $\kappa$ -casein hydrolysis [81–83]. However, Waungana et al. [80] reported that lowering the pH to 6.5 before renneting resulted in shorter gelation time values, which increased with protein concentration, and increased curd firming rates for the UF milk.

Although UF technology has been successfully utilized in the production of soft cheeses, problems were encountered in the production of hard and semi-hard cheeses from UF-concentrated milks. These products tend to be very hard and crumbly in texture, which may be associated with the difference in coagulation properties of UF milk because of high protein and calcium concentration [80]. The coagulation time of UF milk is too short and curd firmness is high which renders cutting of the curd in conventional cheesemaking equipment impossible [82].

Using a UF retentate obtained at low concentration factor [79] is an alternative method for producing hard and semi-hard cheeses with characteristics similar to those produced by the conventional method. Kosikowski [84], for instance, suggested that 1.8x is the limit for making good-quality cheddar cheese. In a related work on raw milk, Hinrichs [76] reported a transition from Newtonian to non-Newtonian flow behavior above a concentration factor of 2 in the UF, which corresponds to more than 8% fat and 3.33% protein in the retentate. Similarly, Erdem [83,85] found that because of concentration by UF to twofold and threefold using 10 kDa MWCO polysulfone membrane, the protein system in skim milk becomes more agglomerated via hydrophobic bonds, which results to reorganization of the protein system into a more compact micellar structure.

Aside from further increasing cheese yield due to enhanced incorporation of whey proteins, heat treatment of UF milk was suggested as appropriate in controlling the rate of curd formation and curd firmness, because the heat-induced interaction between  $\beta$ -Lg and  $\kappa$ -casein prolongs coagulation time and lowers curd firmness [82]. Because rennet-induced gelation of cheese milk is hindered by whey protein denaturation, it has been suggested that high heat treatment (HHT) of milk should be ruled out as a possible application for the production of semi-hard and hard cheeses using normal milk [32]. However, the increase in casein concentration through UF concentration of milk counteracts the reduction in gel strength caused by denatured whey proteins because more caseins for network formation are available [25,86]. Therefore, if UF pre-cheese were used, high heating and denaturation of whey proteins would be permissible to integrate them into the cheese [32].

In 1973, Maubois et al. noted a surprising property of ultrafiltered ultra-high temperature-treated (UHT) milk—its rennet coagulum forming an ability suitable for cheesemaking, which is ordinarily lost as a result of the heat treatment, is restored [87]. Furthermore, Maubois et al. [25] observed that UF retentates containing twice the normal amount of proteins than milk that were easily transformed into cheese, regardless of whether application of UHT treatment was before or after UF. This finding was confirmed by later studies of Sharma et al. [82], who reported that the heat-treated UF milk, concentrated up to 4x, retains its coagulation and curd firming ability despite a slight decrease in the rate of  $\kappa$ -casein hydrolysis. The same group also noted that the initial rate of  $\kappa$ -casein hydrolysis in the heated UF milk was not statistically different from that in unheated milk. Similarly, Guinee et al. [27] observed that concentration of milk by UF helps to restore the gelation properties of HHT milk.

Guinee et al. [27] observed that HHT of skim milk, which brings about whey protein denaturation and reduces cheese curd firming rate, had little influence on the gelation time of high-protein (15%–19%) UF retentates. They reported that the gelation time of HHT milk approached that of normal-pasteurized milk (72°C, 15 s) at protein concentrations greater than ~12%–16%, depending on the level of whey protein denaturation. The authors attributed this whey protein denaturation effect on gelation time to the closer proximity of rennet-altered micelles in the high-protein retentates, which in turn increases the probability of collision and aggregation. Steffl (cited in Ref. [32]) reported that rennet-induced gelation was hindered when more than 60% whey proteins of cheese milk were denatured, prolonging gelation time. Similarly, Waungana et al. [80] reported that gelation time is not affected up to 60% denaturation level of  $\beta$ -Lg in normal skim milk but the storage modulus of rennet gels decreased gradually with increase in the extent in  $\beta$ -Lg denaturation and its association with casein micelles.

When UF milk of 6%–9% protein concentration was heated at 140°C for 4 s, Waungana et al. [80] observed increased gelation time, decreased curd firming rates, and decreased storage modulus values compared with unheated milk of the same protein concentration. The authors noted that these effects were more pronounced when the UHT treatment was done before UF of skim milk. They speculated that the nature of the  $\beta$ -Lg/ $\kappa$ -casein complexes and the way in which these associate with casein micelles upon heating of UF concentrates is different when normal milk is heat treated before UF. In a related study, El-Shibiny et al. [88] reported a reduction of calcium to dry matter ratio during DF of whole milk with distilled water after UF to concentration factor of 5 at 50°C, which they supposed to be the partial dissociation of the colloidal calcium phosphate and its subsequent removal in the permeate during DF. The same group observed an increase in the size and weight of the micelles during DF, which they interpreted as the aggregation of micelles following the partial removal of colloidal calcium. The findings of Pignon et al. [89] are in agreement with these. They found that while the internal structure of globular casein micelles remains significantly unperturbed, they tend to agglomerate when temperature is increased from 20°C to 70°C, or when pH is lowered from 6.6 to 6.0, during UF due to slight loss of calcium phosphate and  $\kappa$ -caseins from the stabilizing layer.

Aside from increased protein concentration, Guinee et al. [27] and Waungana et al. [80] noted that the total effects of heat treatment on rennet coagulation of UF-concentrated skim milk are influenced by changes in mineral equilibria. In relation to this, Hinrichs [76] reported increased resistance from coagulation and gelation during storage of UF-concentrated whole milk compared with NF and RO-concentrated milk. This is due to the UF milk's low ash content and the fact that the initial aggregation reaction in milk is controlled by the salt concentration [76].

Premaratne and Cousin [78] studied the changes in the chemical composition of skim milk during UF (30 kDa MWCO) at 50°C and average TMP of 1.2 bar (120 kPa) to approximate concentration factors of 2, 4, and 5. They noted that milk proteins membrane retention was about 99%. They reported an increase in the protein concentration from an average of 3.42% in skim milk to 6.85%, 13.51%, and 17.10% at concentration factor values of 2, 4, and 5, respectively, while fat was also proportionately concentrated with increase in concentration factor from 0.11% in skim milk to 0.24%, 0.45%, and 0.60%. Because lactose is present in the free state in milk and has a molecular weight lower than the MWCO of the UF membrane used, its concentration decreased progressively during UF from an initial 5.06% to 4.76%, 4.29%, and 4.06% at concentration factor values of 2, 4, and 5, respectively. Bastian et al. [20] reported 100% retention and recovery of fat and rennet clottable N and 1%–3% recovery of lactose in the UF of pasteurized (72.2°C for 16 s) skim milk (pH 6.7) to concentration factor of 5 using spiral wound membrane (10 kDa MWCO) at 54°C and 1.4 bar (140 kPa) TMP.

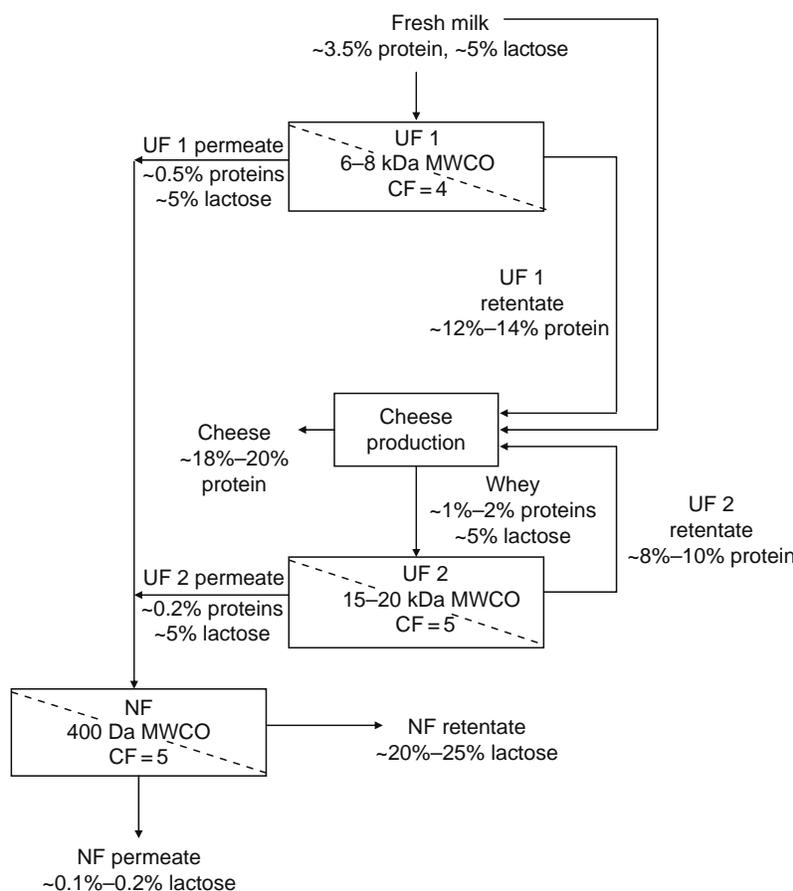

The concentration of minerals such as  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , which are associated with milk proteins and fats gradually increased with concentration factor while the free amino acids and the B vitamins (except riboflavin), which are mostly free and not bound to proteins were extensively lost to the permeate in the work of Premaratne and Cousin [78]. The authors commented that the increase in the mineral concentration in the retentate, which increases the buffering capacity of milk, can result in adverse effects such as longer fermentation time and higher than normal final pH of cheese, while the B vitamins could affect the growth of the lactic acid bacteria during cheesemaking. Similarly, Rajagopalan and Cheryan [90] observed that during UF of reconstituted nonfat dry milk (NDM), with composition similar to that of skim milk, the ash decreases initially but becomes constant, indicating that the minerals were being rejected by the membrane. They noted that this led to incomplete removal of the ash components, giving a limiting ash to protein ratio of 0.08, even after exhaustive DF. They surmised that this was because the minerals are insoluble or associated with the proteins. Bastian et al. [20] found that the acidification of milk resulted in loss of Ca, Na, and P from the retentate due to the solubilization of colloidal calcium phosphate. They noted that this result was more pronounced when the retentate was diafiltered.

Cunha et al. [79] noted an increase in the titratable acidity with increasing concentration factor (from 1.2 to 1.8) in the UF of semi-skimmed milk (1.33% fat) using 10 kDa MWCO Romicon polysulfone hollow fiber membrane at 50°C. They explained that this result is mostly due to the protein concentration, which increased the apparent acidity of the retentates and promoted an increase in its buffering capacity. When the UF retentates were made into reduced-fat Minas Frescal cheese, they noted a decrease in yield with increasing concentration factor, due to the decrease in moisture content.

Recently, Atra et al. [24] proposed the integration of two-stage UF in milk and whey proteins concentration for cheesemaking and NF to concentrate lactose from the UF permeate for a cleaner and more economic cheese production (Figure 22.2). The processes incorporate whey proteins into the cheese curd by pre-cheese milk production using first-stage UF to a concentration factor of 4. The whey proteins drained from the curd are recovered and concentrated by a second-stage UF before being added back to the cheese curd. Lactose is recovered from the two UF stages and concentrated by NF.

### 22.3.3.2 Microfiltration of Milk and Recovery of Native Whey Proteins

A major emphasis in the utilization of MF in the dairy industry that is of relevance to cheesemaking is changing the casein to whey protein ratio or the casein to fat ratio in milk fractions [91]. MF of whole or skim milk produces a retentate that is rich in native micellar casein, which improves the cheesemaking process, and a crystal clear and sterile permeate with composition close to that of sweet whey but with greater amount of native whey proteins that is suitable for direct manufacture of whey protein isolate [8,52,92–95]. In processing skim milk using MF membranes of 0.2  $\mu\text{m}$  pore size or smaller, the permeation of

**FIGURE 22.2** Schematic diagram of the proposed combined UF and NF process for more economical cheese production. (From Atra, et al., *J. Food Eng.*, 67, 325, 2005. With permission.)

lactose and minerals is very similar to that observed in the UF of skim milk as the casein to whey protein ratio gradually increases [96].

Le Berre and Daufin [97] reported that >99.6% of casein micelles, 100–300 nm in size, and >30% of whey proteins were retained in the MF of skim milk using 0.1  $\mu\text{m}$  composite membrane consisting of a  $\text{ZrO}_2$  filtering layer on an  $\alpha$ -alumina support at 50°C. The process was carried out at a TMP range of 0.05–0.2 bar (5–20 kPa) until the volume reduction ratio (VRR) of 2 was reached and was then continued in a feed and bleed mode at a TMP of 3.00 bar (300 kPa). On the other hand, Samuelsson et al. [98] reported 12% retention of whey proteins in the MF of skim milk at 55°C, TMP range of 0.1–1.9 bar (10–190 kPa) and 8  $\text{m}\cdot\text{s}^{-1}$  crossflow velocity using 0.14  $\mu\text{m}$   $\text{ZrO}_2$  ceramic membrane in tubular configuration until a VRR of 1.15 was reached. Pierre et al. (cited in Ref. [99]) obtained native phosphocaseinate (PPCN) with casein to total protein ratio of 0.93 by MF of skim milk using 0.14  $\mu\text{m}$  multichannel ceramic membrane under high tangential velocity of  $>6 \text{ m}\cdot\text{s}^{-1}$  and very low uniform TMP along the hydraulic path of 0.1–0.2 bar (10–20 kPa). On the other hand, while flux declined by 50% at concentration factor of 3, Pouliot et al. [99] reported that with conventional CFMF at 50°C, average TMP of 1.9 bar (190 kPa) and 6.9  $\text{m}\cdot\text{s}^{-1}$  crossflow velocity using 0.22  $\mu\text{m}$  pore size membranes, native PPCN may also be produced at a casein to total protein ratio of 0.91. Jost et al. [93] showed that after threefold concentration of milk by MF, the casein-nitrogen (CN) of the retentate increased to 83% of the total nitrogen (TN) in the retentate and after DF using six initial retentate volumes of demineralized water, the casein purity was ~95%.

Casein enrichment of cheese milk significantly improves the rennet coagulability and the productivity of cheese plants, especially those producing hard cheeses [100]. For instance, the rennet coagulation time of a 3% native PPCN solution is reduced by 53% compared to that of raw milk, and the gel firmness after 30 min is increased by more than 50% (Pierre et al., 1992, cited in Ref. [100]).

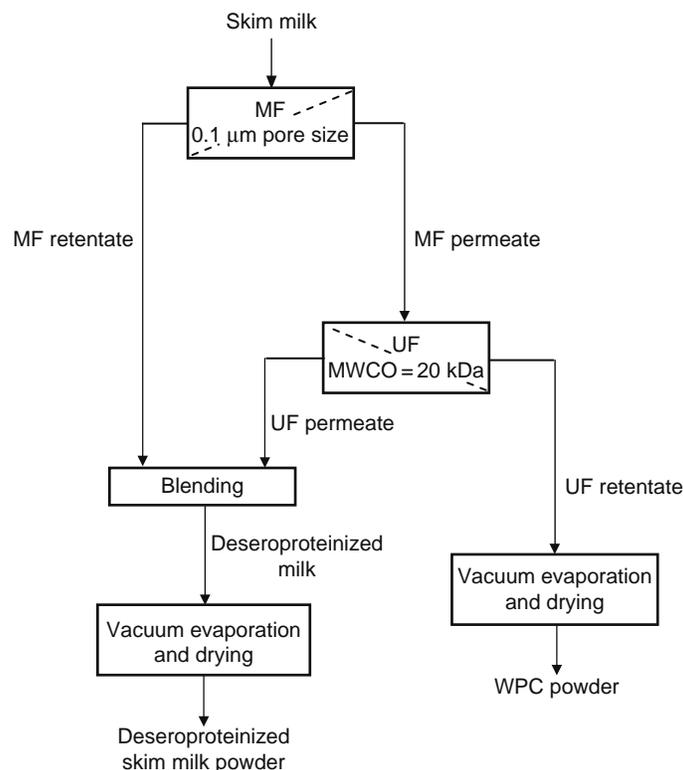

Milk coagulation depends on a number of factors, such as the kinetics of the enzyme reaction, the concentration, and the state of the proteins, especially casein, the balance of minerals, especially calcium, and pH [101]. Most of these factors are directly influenced by UF or MF processing. Caron et al. [101] compared the rennet coagulation properties of milk enriched with a regular ultrafiltered retentate powder (RUF) to milk enriched with a diafiltered MF (DMF) retentate powder. RUF was prepared by concentrating skim milk to concentration factor of 5 by UF, while DMF was prepared from skim milk concentrated

by MF to concentration factor of 3, diafiltered with deionized water and then concentrated by UF (50 kDa MWCO) to concentration factor of 2 to increase the caseins to whey proteins ratio. They observed that the DMF-enriched milk coagulated faster than the RUF-enriched milk. MF and DF increased the casein content, while reducing whey protein and lactose concentrations in the retentate compared with just UF. Compared with that of control milk (with 3.5% total protein content), they reported an overall improved gel firmness but longer coagulation time for milk enriched to 4.5% and 5.0% total protein, regardless of retentate powder used. The authors reasoned that this may have been due to enzyme diffusion retardation in the casein-enriched milk.

Reduction of microorganisms in milk before cheese production must be achieved in such a way that the functionality of the milk proteins is not affected. Heat-resistant spores, such as *Clostridium tyrobutyricum* and *C. sporogenes* can cause severe spoilage of the cheese by late fermentation that can result in the production of H<sub>2</sub> and CO<sub>2</sub> gases, and unpleasant smelling fermentation products [102]. Although heat sterilization reduces these spores, because of the heat-induced complexation between  $\beta$ -Lg and  $\kappa$ -casein, UHT milk normally does not form a rennet gel and consequently could not be used efficiently for cheesemaking [87].

The partial removal of whey proteins by MF reduces the detrimental effects of heat treatment on the rennet coagulability of milk [100]. The use of MF followed by UF produces micellar casein-rich powder that increases cheese yield. The removal of  $\beta$ -Lg during MF eliminates the heat-induced  $\beta$ -Lg/ $\kappa$ -casein complex typically found in NDM used in cheesemaking [101,103]. The extent of formation of the  $\beta$ -Lg/ $\kappa$ -casein complex decreases and the increase in the electronegativity of casein micelles is not high enough to prevent their aggregation when caseinomacropепptide is cleaved even if the milk is UHT-treated [100]. The MF of raw, pasteurized, UHT, and sterilized whole milks (3.5% fat) using 0.45  $\mu$ m pore size membrane allowed the recovery and quantification of whey proteins and whey protein/ $\kappa$ -casein macroaggregates in the milk, which Carbonaro et al. [104] stressed may lead to finding the mechanisms by which these aggregates are formed during heat treatment of milk. This will be useful for process modeling and in understanding how such aggregates affect the nutritional quality of milk proteins.

To address the adverse effects of heat treatment on the rennet coagulability of milk during cheesemaking, Quiblier et al. (cited in Ref. [105]) developed a process that involves the partial removal of whey proteins, especially  $\beta$ -Lg, from skim milk followed by mild to moderate heat treatment. The process was adapted by Garem et al. [105] to produce milk powder for cheesemaking that is partially depleted of whey proteins to avoid the formation of  $\beta$ -Lg/ $\kappa$ -casein complex during thermal processing. The steps involved in the process are as follows (Figure 22.3): (1) partial or total removal of whey proteins of the milk by 0.1–0.2  $\mu$ m pore size MF membrane, (2) UF of the MF permeate using membranes with MWCO  $\leq$ 20 kDa,

**FIGURE 22.3** Schematic description of the process of preparation of the whey protein-depleted skim milk powder. (From Garem, A., Schuck, P., and Maubois, J.-L., *Lait*, 80, 25, 2000. With permission.)

(3) blending of the MF retentate with the UF permeate, and (4) vacuum evaporation and spray drying of the blend at moderate heat application to produce the recombined milk powder for mozzarella cheese manufacture [105]. They reported about 31% depletion of whey protein from the fresh milk, which resulted in a firmer gel during rennet coagulation and in a significant cheese yield increase of 7.3%. Their data also showed important decrease in stretch water losses without having to modify the cheesemaking process as with common recombined milk. Moreover, since the MF–UF recombined milk does not require the addition of chemical additives, they suggested that its utilization might be of economic advantage over common recombined milk of higher casein to whey protein ratio.

Terré et al. [106] showed that MF membrane of 0.2  $\mu\text{m}$  pore size also allows separation of  $\beta$ -casein when this component, by physicochemical means, is solubilized from the casein micelles [92]. Moreover, at high recirculation velocity of the retentate of at least  $6\text{ m}\cdot\text{s}^{-1}$ , efficiency of separation is strongly related to the maintenance of low temperatures ( $2^\circ\text{C}$ – $6^\circ\text{C}$ ) in the MF equipment and adjustment of ionic strength in the caseinate solution. Products obtained on both sides of the MF membrane are suitable for modifying the  $\beta$ -casein to  $\alpha_s$ -casein ratio of cheese milks and consequently, the texture and flavor of resulting cheeses, which may result to new cheese varieties [92]. van Hekken and Holsinger [91] reported that the cold MF ( $4^\circ\text{C}$ ) of skim milk using either 0.2 or 0.1  $\mu\text{m}$  pore size ceramic membrane gave a permeate, which when ultrafiltered enabled the production of  $\beta$ -casein-enriched retentates with  $\beta$ -casein to  $\alpha_s$ -casein and  $\beta$ -casein to  $\kappa$ -casein ratios that were twofold to fourfold and threefold greater than those of skim milk, respectively. The retentates formed softer gels with greater syneresis and hydration, and lower holding capacities than skim milk gels. They suggested that such gels may be used as starting materials in the production of novel soft cheeses.

### 22.3.3.3 Vatless Manufacture of Cheese

Caron et al. [101] studied the effect of acidification of milk in the MF and UF processes on the rennet coagulability of milk. Diafiltered MF retentate powder from acidified milk (ADMF) was prepared by acidifying milk to pH 6 using lactic acid solution, concentrating the milk by MF 3x with DF, and then concentrating the MF retentate by UF (50 kDa MWCO) 2x. They observed that ADMF contained ~90% protein, while RUF and DMF retentate contained ~69% and ~83%, respectively. They also noted that ADMF had reduced concentrations of mineral, noncasein nitrogen (NCN) and NPN, and whey proteins. This is because acidification of milk increases soluble minerals and during DF of acidified MF milk more lactose and minerals are removed from the retentate while further reducing whey proteins content. This led to decreased gel firmness for milk enriched with ADMF.

In a related study, Brandsma and Rizvi [94] gradually acidified pasteurized skim milk to pH 6.0 using 1.6 g of glucono-delta-lactone (GDL) per kilogram of skim milk to promote solubilization of micelle-bound colloidal minerals into the serum phase of milk. GDL was used in the acidification process for its ability to hydrolyze and form gluconic acid in a temperature-dependent manner that allows highly predictable and controlled method of lowering the MF retentate pH. Using 0.2  $\mu\text{m}$  pore size MF ceramic membrane operated at a TMP of 2.6 bar (260 kPa),  $50^\circ\text{C}$ , and  $7.5\text{ m}\cdot\text{s}^{-1}$  crossflow velocity, they concentrated the acidified skim milk to concentration factor of 8. They observed an effective change in mineral balances, specifically Ca, while maintaining 87.4% nominal whey protein permeation. They reported 20.1% decrease in Ca concentration and 12.6% increase in whey protein concentration in the MF retentate compared to milk at its natural pH of 6.6. The whey protein content of the MF retentate they observed is about 55% lower than typical UF retentates [94].

The process was utilized to produce MF milk for the manufacture of mozzarella cheese using 80–100  $\mu\text{L}$  rennet per kilogram of MF cheese milk at  $32^\circ\text{C}$ – $36^\circ\text{C}$  to give post-coagulation cutting time of 15–20 min. When the same MF retentate and butter oil were utilized in the manufacture of low-moisture part-skim (LMPS) mozzarella cheese, Brandsma and Rizvi [107] observed delay in the rheological and functional development of MF retentate LMPS, which occurred between 30 and 60 days as opposed to 7 and 30 days for commercial LMPS mozzarella. They noted an improvement in rheological and functional behavior in the MF retentate LMPS using starter culture. These indicate that the MF of skim milk with in-process acidification to pH 6 can be potentially developed into a novel cheesemaking process to manufacture cheese of improved textural and functional qualities, along with the recovery of highly functional native whey proteins in the MF permeate, or virgin whey [95].

The virgin whey harvested from the MF, which does not contain cheesemaking remnants, fats, or spores, contained ~5.3% total solids (TS), ~6% of which is whey proteins. Brandsma and Rizvi [94], Punidadas and Rizvi [108], Solanki and Rizvi [109], and Ardisson-Korat and Rizvi [110] showed that the virgin whey's composition is consistent at mass concentration factor of 8. Brandsma and Rizvi [107] suggested uniform transmembrane pressure (UTMP) operation to improve permeate flux and achieve a calcium to total protein ratio in the MF retentate suitable for cheesemaking. Similarly, Vadi and Rizvi [111] suggested that to achieve practical permeate flux values at concentration factor higher than 6 in the MF of skim milk at pH 6 and  $50^\circ\text{C}$  using 0.2  $\mu\text{m}$  pore size membrane, operation in the UTMP mode is necessary. Table 22.2 gives the permeate flux achieved at different concentration factor values in the MF of skim milk.

Using 0.1  $\mu\text{m}$  pore size MF ceramic membranes in a Tetra Alcross M-38 system operated at UTMP of 1 bar (100 kPa),  $50^\circ\text{C}$ , and crossflow velocity of  $5\text{ m}\cdot\text{s}^{-1}$ , Ardisson-Korat and Rizvi [110] showed that at mass concentration factor of 8, the MF retentate contains up to 30% total solids that can be used for semi-continuous vatless manufacture of LMPS mozzarella cheese.

They reported 66%–71% whey proteins depletion and calcium to casein ratio in the MF retentate suitable for LMPS mozzarella cheese with properties comparable to those of commercial products.

In a related study, Maubois et al. [112] noted high-protein purity of WPI produced from milk microfiltrate, or ideal whey harvested before cheesemaking, by MF of milk at low concentration factor of 2. The same group suggested the suitability of milk microfiltrate as starting material in obtaining native whey protein fractions. Bacher and K nigsfeldt [113] showed that because of the absence of glycomacropeptide and the relatively large amount of native whey protein in milk microfiltrate WPI (MWPI), it showed vastly improved functionality compared with WPC-80 from cheese whey. However, with the exception of gelation property, MWPI's functionality is similar to cheese whey WPI. They reasoned that this was probably due to a pretreatment that removes denatured WP from the cheese whey before WPI manufacture.

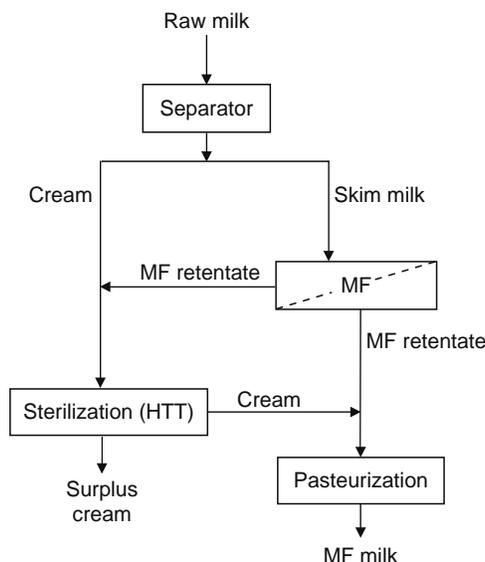

With the objective of increasing calcium and lactose content of MF retentate in addition to micellar casein while maximizing whey protein depletion, Nelson and Barbano [114] developed a multistage MF process that removed ~95% of whey protein from skim milk. They reported that the MF retentate produced from this process contained soluble minerals, NPN, and lactose similar to the original milk. This was accomplished by using the permeate from the UF of the MF permeate to diafilter the MF retentate after achieving a concentration factor of 3 in the MF. Aside from the recovery of native micellar caseins, they showed that the process enabled the production of whey protein stream (UF retentate) with protein content similar to that of commercial WPC.

#### 22.3.4 REMOVAL OF MICROORGANISMS

Since the 1980s, MF has been investigated as an alternative technology to centrifugation for clarification and bacteria removal of milk and whey and is often referred to as a gentle sterilization method [8,68,115,116]. Due to bacterial spoilage, high-temperature, short-time (HTST)-processed milk can last up to 14 days only [117]. Although ultrapasteurization can extend refrigerated fluid milk shelf life to 45 days, it imparts distinct cooked flavor to milk, which may be undesirable to some people [52,118,119]. Unlike UHT pasteurization, MF can reduce the amount of bacteria and spores without affecting the taste of the milk, and provides longer shelf life than pasteurization [6,52,87].

Spore-forming bacteria, which represent the main surviving species after pasteurization, are better retained by MF membrane because of their large cellular volume, giving a decimal reduction of ~4.5 (cited in Ref. [8]). For instance, due to the high retention of *Bacillus cereus* in MF, which is between 99.95% and 99.98%, the shelf life of milk is improved from 6–8 days by conventional pasteurization to 16–21 days by MF [87,120]. Also, decimal reduction factors for MF are higher than that for bactofugation, which is the continuous reduction of bacteria and spores from milk and skim milk by centrifugal force that results to about 98% reduction in spores [6,87].

The work of Holm et al. [121] and that of Piot et al. (cited in Ref. [8]) led to the development of one of the most important applications of MF in the dairy industry, the Bactocatch process with a patent owned by Tetra Pak [8,121]. In this process, cream is removed from whole milk by centrifugation [119]. Skim milk is then passed through 1.4  $\mu\text{m}$  pore size MF membrane where up to 99.99% bacteria reduction at 50°C, UTMP of 0.5 bar, and a high crossflow velocity of 7.2  $\text{m}\cdot\text{s}^{-1}$  is accomplished at a volumetric reduction factor of 20, or 200 in larger membrane modules where the retentate, which represents 5% of the total starting volume, is concentrated 10 times more (Figure 22.4) [6,8,13,87,120]. The MF retentate and cream undergo ultrapasteurization treatment (115°C–130°C for 4–6 s) and are then combined with the nearly bacteria-free MF skim milk [11,119]. Common permeate fluxes obtained in the industry are between 500 and 800  $\text{L}\cdot\text{h}^{-1}\cdot\text{m}^{-2}$ , usually up to 10 h operation, giving average decimal reduction of bacteria above 3.5 while proteins and total solids transmissions are about 99% and 99.5%, respectively [8,52]. Trouv e et al. (cited in Ref. [122]) examined the retention of 7 species of bacteria that typically occur in raw milk using the Bactocatch process and reported 2.6 log reductions during the MF of milk contaminated with initial bacterial levels

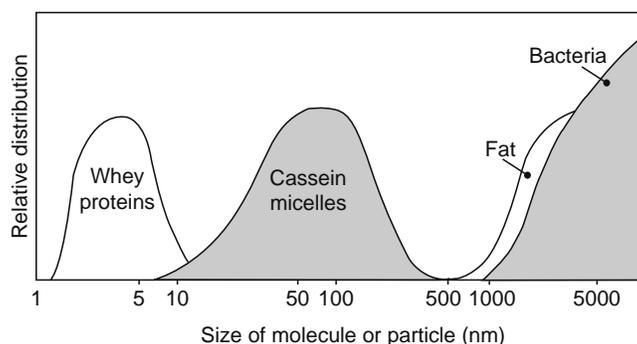

**FIGURE 22.4** MF process used by Olesen and Jensen in collaboration with Alfa-Laval and Ceraver in the integration of CFMF in a milk processing line for the production of milk with low bacteria content. (From Olesen, N. and Jensen, F., *Milchwissenschaft*, 44, 476, 1989. With permission.)

of  $10^2$ – $10^7$  cfu·mL<sup>-1</sup>, where bacterial retention rates were 99.93%–99.99%. While the efficiency of the process in removing bacteria and spores is widely accepted, it does not guarantee the complete removal of pathogenic bacteria in milk as required in milk pasteurization [11].

As the size distribution of bacteria in milk (0.4–2.0  $\mu\text{m}$ ) partly overlaps with that of fat globules (Figure 22.5), MF can be used as a pretreatment of skim milk for the production of raw milk cheeses and reduction of spores in acid cheese milk [6,123]. In 1987, Piot et al. (cited in Ref. [9]) showed that MF process using an inorganic alumina membrane of 1.8  $\mu\text{m}$  pore size could skim 98% of the fat and reduce bacterial counts by 2 orders of magnitude, with no apparent rejection of proteins. Using 1.4  $\mu\text{m}$  ceramic membranes, Pafylas et al. [124] compared the reduction in microbial population in nonfat and 1% fat milk in conventional CFMF operation and UTMP MF operation, which were both run at 50°C, TMP of 1.0 bar, and a crossflow velocity of 5.0 m·s<sup>-1</sup>. They found that, except for fat and bacteria, the distribution of major milk components in the MF milk did not change in either operation modes. While both MF operation modes gave a microfiltered milk with an average fat content of 0.05%, and a bacterial reduction of 4–5 log cycles, the average flux over a concentration factor of 10 was higher with the UTMP mode. The group, however, cautioned that over long-term (8–16 h per day) continuous operation, a gradual increase in fouling or concentration polarization may lead to undesirable changes in milk composition.

Eckner and Zottola (cited in Ref. [124]) reported that sterilizing microfilters, such as the 0.2  $\mu\text{m}$  membranes commonly used in the pharmaceutical industry, would foul too rapidly when operated in the conventional crossflow manner, resulting in low flux and permeates with an undesirable solids profile, making them of little practical value in the dairy industry. Guerra et al. [102] employed the combined benefits of reverse asymmetric 0.87  $\mu\text{m}$  pore size polymeric membranes and backshock technique to control the adverse effects of concentration polarization and fouling in the removal of bacterial spores in skim milk

**FIGURE 22.5** Size distribution of major milk components. (From James, B.J., Jing, Y., and Chen, X.D., *J. Food Eng.*, 60, 431, 2003. With permission.)

at low linear velocities and, therefore, low-energy consumption. Reverse asymmetric membranes are those whose porous layer, rather than the skin layer, faces the retentate side, making the fouling layer more loose and consequently result in lower cake resistance as long as the porous layer is not completely filled up [125,126]. The backshock technique involves temporarily forcing the permeate stream backwards through the membrane and into the retentate stream by pressurization of the MF permeate side at short time interval of  $<1$  s at around  $0.2\text{--}1$  s $^{-1}$  frequency to prevent the formation of fouling layer. Guerra et al. [102] reported spores reduction factors of 104–105 at high and stable fluxes of about  $500\%$  L·h $^{-1}$ ·m $^{-2}$  and 100% casein transmission at low-linear velocities of  $0.5\text{--}1.0$  m·s $^{-1}$ .

Elwell and Barbano [119] determined the efficacy of MF, using  $1.4$   $\mu\text{m}$  Membralox ceramic membranes at  $50^\circ\text{C}$  and an average TMP of 39 kPa, followed by pasteurization ( $72^\circ\text{C}$  for 16 s) in reducing the total number of bacteria, spores, and coliforms in skim milk and in extending the shelf life of skim milk at  $0.1^\circ\text{C}$ ,  $2.0^\circ\text{C}$ ,  $4.2^\circ\text{C}$ , and  $6.1^\circ\text{C}$  storage temperatures. They reported an average of 3.79 log reduction in bacterial count by MF and an average of 1.84 log reduction by pasteurization of the MF skim milk, giving an average of 5.6 log reduction from the raw count due to the MF-pasteurization process. They observed that both coliforms and spores in the skim milk were reduced by MF to an undetectable level and that fat was reduced from 0.1% to 0.03%. Bacterial count in the MF pasteurized skim milk did not exceed  $20,000$  cfu·mL $^{-1}$  after 92 days at  $0.1^\circ\text{C}$ – $6.1^\circ\text{C}$  storage temperatures. However, the microbial shelf life is limited by the shelf life due to proteolysis to 78 days for  $2^\circ\text{C}$  storage temperature or 32 days for  $6.1^\circ\text{C}$  storage temperature.

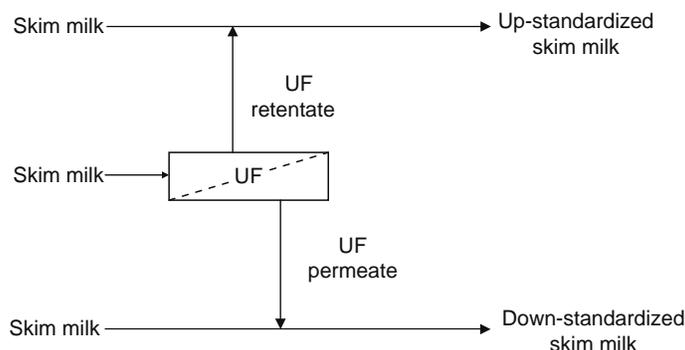

### 22.3.5 STANDARDIZATION OF MILK AND MILK PROTEIN CONCENTRATION

Before the 1990s, there were few options to standardize milk: remove or add fat as cream, add casein as NDM, evaporated milk, or condensed milk [127]. Although to a lesser extent than fat content, the protein content of fluid milk also exhibits considerable natural variability worldwide. This variability is significantly magnified in dairy products that are manufactured by water removal, such as skim milk powder [128]. The International Dairy Federation (IDF) interprets protein standardization to imply relatively small changes in protein content, within the limit of natural variability, that are achieved by the addition or removal of natural milk constituents without altering the natural ratio of whey protein to casein [128].

By UF it is possible to adjust the mass ratios of different milk constituents, including proteins, without adversely affecting their physicochemical properties [11]. The development of more efficient membranes in the 1990s made UF an economically and technologically feasible option to standardize milk proteins and to improve the nutritional uniformity of milk and other dairy products (Figure 22.6) [31,127,128]. Percent total solids as high as 43.3 may be achieved by concentrating whole milk by UF and DF [63], while a volume reduction as high as 85%, with a retentate containing 78% protein (dry basis), may be achieved in the UF of skim milk [129]. This high concentration of solids in the retentate leads to increased viscosity. The viscosity of skim milk UF retentates increases with its dry matter content as follows: 2 cP at 10% dry matter content, 4 cP at 15%, 10 cP at 20%, 33 cP at 25%, and 70 cP at 28% [130], while a drastic increase in the retentate viscosity is observed when the protein concentration exceeds 14% [131].

In the United States, ultrafiltered whole milk is concentrated to approximately 30% total solids and ultrafiltered skim milk to approximately 18% total solids and shipped to cheesemakers for use in standardizing milk or supplementing existing milk supplies to increase manufacturing productivity [127].

Using the appropriate membrane and operating conditions, UF is especially useful in the production of MPI containing low amount of lactose and high amount of native proteins with the same casein to whey proteins ratio as in milk [90]. High milk protein powders (HMPP), or MPC from ultrafiltered milk have become increasingly important over the past years because of their wide range of compositions and hence functionality and applicability [103].

**FIGURE 22.6** Schematic illustration of the use of UF for the production of up-standardized or down-standardized skim milk. (Adapted from Rattray, W. and Jelen, P., *Trends Food Sci. Technol.*, 7, 227, 1996. With permission.)

Alvarez et al. [132] found that UF/DF using polysulfone UF membrane with MWCO of 20 kDa, operated at 5 bar (500 kPa) TMP at recirculation rate of  $6 \text{ m}^3 \cdot \text{h}^{-1}$ , could achieve a protein to lactose ratio ranging from 1.7 to 9.5, 7.9%–12.3% defatted dry matter, 4.7%–8.9% protein, and 2.7%–0.8% lactose. Novák [33] reported a 90% true protein recovery after UF of skim milk and 98.4% recovery after DF using deionized water using spiral wound membrane of 5 kDa MWCO at 50°C and neutral pH. He noted that the process enabled the production of MPC with 90% true protein content after UF, and MPI with maximum total solids of 38% and true protein and lactose contents of 98.4% and 0.7%, respectively, after DF. Using 20 kDa MWCO polysulfone UF membrane operated at 50°C and TMP of 2 bar (200 kPa), El-Shibiny et al. [88] reported 18.5% total solids concentration of MPI with 89.1 total protein to dry matter ratio after UF of whole milk to a concentration factor of 5 and DF using four diavolumes of distilled water. Mistry and Hassan [133] reported 99.7% removal of lactose from pasteurized skim milk after UF to concentration factor of 5 and 3 DF cycles, each time using 4 diavolumes (based on retentate volume at concentration factor of 5) of water, using spiral wound module at 38°C. The final retentate was spray dried to produce delactosed, HMPP, which maintained its white color and bland flavor for 1 year of storage at room temperature. They suggested at least two DF to achieve the lactose reduction they obtained in the UF retentate, which contained total solids of 21.6% and 18.9% protein. The HMPP, which had an average composition of 5.3% moisture, 83.9% total protein, 2.3% fat, 0.7% lactose, and 7.1% ash, was of high-protein content—with caseins to whey proteins ratio similar to skim milk—and low mineral and lactose content [103,133,134]. Mistry [103] reported that because of the low lactose content of HMPP, its microstructure is more similar to that of caseinates but considerably different from NDM. It has a lower foaming capacity compared with commercial protein concentrates because of its relatively high fat content (2.3%) [103].

Milk of UF-standardized protein and total solids content enables the production of fermented dairy products of improved quality and characteristics compared with those produced from milk fortified with milk powder or evaporated milk [11]. Due to the similarity of the protein fractions in HMPP and those of skim milk and the virtual absence of lactose, Mistry and Hassan [134] suggested its utilization for the development of new dairy products and the improvement of existing ones. When these authors used HMPP to produce nonfat yogurt, they found that fortification level up to 5.6% protein can produce acceptable yogurt with smooth texture and firm body that did not exhibit whey separation even without the addition of stabilizers. They noted, however, that  $>5.6\%$  protein concentration, the yogurt becomes excessively firm and has a grainy texture and flat flavor.

Ozer et al. [135] compared the gelation properties of unconcentrated reconstituted milk ( $\sim 16\%$  TS) and milk concentrated by UF, RO, and direct concentration on reconstitution ( $\sim 23\%$  TS) for yogurt making. They found that yogurt from the UF milk contained the highest amount of protein ( $\sim 9\%$ ) and fat ( $\sim 8\%$ ), and the least amount of lactose ( $\sim 0.8\%$ ). They reported that unlike the other milk systems, the complex modulus ( $G^*$ ) of the UF milk did not reach a plateau within the experimental time frame, but continued to increase over the entire period of incubation. Due to the similarity in the loss tangent ( $\tan \delta$ ) values for the UF milk and those of other samples, the authors surmised that although the same interactive forces were involved in the gel formation of the milk samples, the flocculation kinetics for the high-protein UF milk may have changed. The system may have entered into a metastable state, in which the strength of the gel can continue to increase.

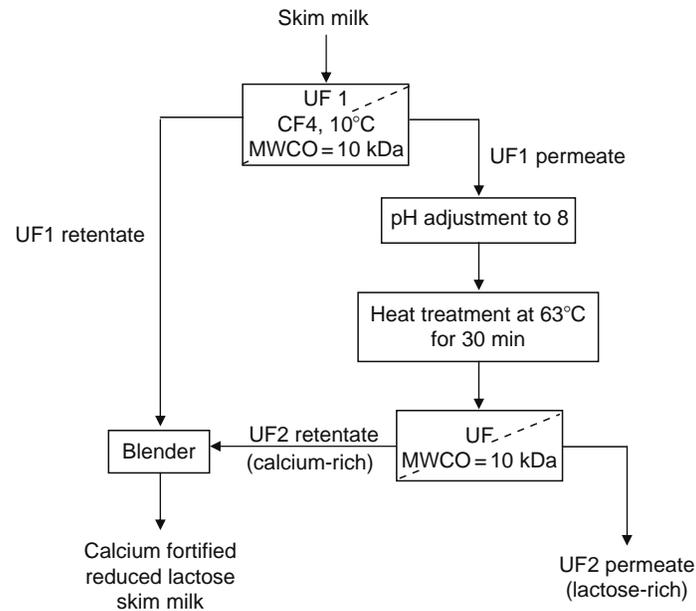

Aside from applications to fermented products, UF-standardized milk may also be used for the manufacture of several other dairy products. For instance, Lee and White [136] reported an increase in the protein value of ice cream when UF retentate rather than NDM was used for solids-not-fat (SNF) source in the formulation at substitution levels of 25%–75%. They also reported that because of the high level of casein in the ice cream made from UF retentate, its water-binding capacity increased, which resulted to an improvement in flavor and stability of body and texture.

### 22.3.6 RECOVERY OF LACTOSE AND MINERALS

Vyas and Tong [137] developed a method for calcium fortified reduced lactose skim milk production, which involves two UF steps (Figure 22.7). The process aimed to maximize calcium recovery without adversely affecting the native state of the milk proteins, while effectively removing lactose from the skim milk. In the first UF step (UF1), skim milk was ultrafiltered using a spiral wound module (10 kDa MWCO) at 2 bar (200 kPa) TMP and 10°C to concentration factor of 4. The permeate from UF1 was adjusted to pH 8, heated at 63°C for 30 min, to cause the formation of calcium complex or precipitates, and was then ultrafiltered (UF2) at the same condition as UF1. The retentate from UF2, which contained the concentrated calcium was mixed with the retentate from UF1 to produce the calcium fortified reduced lactose skim milk. They reported 70% recovery of the calcium from UF1 permeate during UF2 while enabling the recovery of high-purity lactose in the UF2 permeate.

### 22.3.7 FRACTIONATION OF MILK FAT AND ITS COMPONENTS

Milk fat globules are composed of triglyceride core and are surrounded by a natural biological membrane, the milk fat globule membrane (MFGM), which contains proteins, glycoproteins, enzymes, phospholipids, triacylglycerols, glycolipids, and other minor compounds, renders them compatible with the aqueous environment [138–140]. Because of its origin and amphiphilic nature, MFGM isolates were found to show good emulsifying properties and nutritional advantages such as modulation of cholesterol uptake, protection against bacterial infections in the gut, and inhibitory effect on colon cancer [141]. Although the

**FIGURE 22.7** Production of calcium fortified reduced lactose skim milk. (From Vyas, H.K. and Tong, P.S., *J. Dairy Sci.*, 86, 2761, 2003. With permission.)

MFGM proteins account for only 0.03%–0.04% of the total proteins in whole milk [139,142], many properties of dairy products are influenced by the responses of the MFGM components to various treatments [139,143]. For instance, it is supposed that a large part of the microstructure and consistency of dairy products, such as cheese, is largely affected by interactions between the casein matrix and fat globule, so that if the number of fat globules in the milk were to be modified without altering its total fat content, it may be possible to manipulate these interactions [144]. Since it is thought that fat globule size, which ranges between 0.2 and 15  $\mu\text{m}$ , could be a much better separation criterion between small and large globules than fat globule density, MF is the preferred technology over centrifugation to separate fat globules according to size rather than density without damaging the MFGM [140,144,145].

Goudéranche et al. [15] developed a CFMF process, which permits the selection of native small fat globules (SFG, 1–3  $\mu\text{m}$ ) and large fat globules (LFG, >5  $\mu\text{m}$ ) in raw milk. Using this process, Goudéranche et al. [144] confirmed that increasing or decreasing the number of native fat globules in milk leads to significant changes in the texture of liquid milk, yogurt, fresh cheese, sour cream, Camembert cheese, and mini Swiss cheese. They reported that products with greater amount of SFG gave creamier, smoother, and finer texture. They suggested the possible differences in triglyceride composition of SFG and LFG to be responsible for their observations. Briard et al. [146] reported that small and large native milk fat globules extracted from the same milk using the MF process developed by Goudéranche et al. [15] exhibited small variations in their total fatty acids. On the other hand, using the same system, Michalski et al. [17] found no major differences in triglyceride structures between native milk SFG and LFG after eliminating thermal history and the influence of cooling rates.

Using the milk fat globule MF fractionation process of Goudéranche et al. [144], Michalski et al. [140] observed pronounced difference in physicochemical and functional properties of Emmental cheeses made using native SFG and LFG. They reported lower flexibility and firmness in SFG cheeses, which had greater moisture and underwent greater proteolysis compared to LFG cheeses, 52 days after manufacture. However, lipolysis was threefold lower in SFG cheeses. Results of these studies confirm that the use of native milk fat globules with different sizes, separated using MF, can lead to a range of new dairy products with different physicochemical and functional properties [140]. Even interactions between milk serum proteins and MFGM proteins at different physicochemical conditions can now be characterized to elucidate their influence on dairy products quality because native milk fat globules can now be recovered by MF [139].

In the manufacture of butter, cream undergoes churning, a mechanical process which involves agitation in the presence of air that disrupts the phospholipid-protein membranes of the fat globules as they aggregate, releasing the water-soluble material, along with most of the proteins, lactose, and minerals, into the aqueous phase, or buttermilk [147–149]. Aside from the proteins in the buttermilk, which are mainly caseins and whey proteins, phospholipids render buttermilk as a potential source of ingredients of functional and nutraceutical applications [147–149]. Although native MFGM have been isolated from cream and purified by repeated washing-off of casein and whey proteins using simulated milk ultrafiltrate (SMUF) for characterization such as those done by Ye et al. [139,143], a commercial isolation and fractionation methods for MFGM components from buttermilk are yet to be developed [147].

Sachedva and Buchheim (cited in Ref. [147]) removed caseins from reconstituted buttermilk by precipitation of the caseins followed by MF of the phospholipids-rich buttermilk serum phase using 0.2  $\mu\text{m}$  pore size ceramic membranes. The authors reported a recovery of 67% of the total phospholipids, giving a final buttermilk extract containing about 1.5% phospholipids and 9% protein (dry basis) but the yields varied depending on coagulation conditions. Corredig et al. [147] observed retention of skim milk-derived peptides, especially caseins, in the UF (250 and 500 kDa MWCO) of reconstituted commercial buttermilk (8% w/v in deionized water) to a concentration factor of 2 and subsequent DF. When a 0.1  $\mu\text{m}$  pore size hydrophilic polysulfone Supor 100 membrane (Pall Gelman, Ann Arbor, Michigan) was used, greater permeation of the whey proteins was observed, although caseins were retained with the MFGM components, allowing the production of buttermilk concentrate. The addition of sodium citrate to buttermilk before MF disrupted the casein micelles, allowing their improved removal from the retentate to produce the MFGM isolate. However, the retention of whey proteins, especially  $\beta$ -Lg, and to a lesser extent,  $\alpha$ -La, by the membrane was still considerable, even at repeated DF. The authors surmised that the retained proteins are probably whey protein aggregates or complexes with caseins or the MFGM components, the amounts of which depend on the heat treatment history of the buttermilk, which is commonly very severe to render the cream sterile before butter manufacture. Nevertheless, the proposed process enabled the production of MFGM isolate with 35% (w/w) lipid and 60% (w/w) protein, which comprised 70% MFGM proteins, 6% caseins, and 24% whey proteins. Roesch et al. [148] showed that emulsions containing MFGM isolates produced from the process, developed by Corredig et al. [147], had small particle distribution with droplets of higher surface coverage showed good stability to creaming compared to buttermilk concentrate.

Morin et al. [149] compared the permeate flux through a 0.45  $\mu\text{m}$  pore size ceramic MF membrane during volumetric concentration to 2x and two-diavolume DF of regular buttermilk and whey buttermilk at 8–10°C and 0.8–0.95 bar (80–95 kPa) TMP. They reported that due to the lower amount of total solids, especially caseins and minerals, in the whey buttermilk, the permeate flux was significantly higher compared with that for regular buttermilk. They suggested that whey buttermilk has the potential of being a suitable starting material in producing MFGM isolate. However, they also recommended the standardization of whey cream before butter making as they noted variability in its lipid and phospholipids content.

## 22.4 MEMBRANE PERFORMANCE

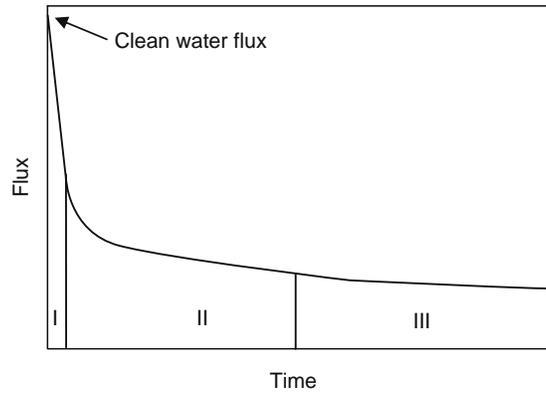

### 22.4.1 FOULING AND FLUX PREDICTION

Concentration polarization and fouling are the main phenomena that limit the practical applications of membrane filtration. Both result in the unfavorable time-dependent flux decline and alteration of the membrane rejection behavior that compromise process efficiency [19,150–153]. Concentration polarization occurs at the beginning of the filtration process when a concentration gradient of the retained components is formed on or near the membrane surface [19]. The underlying mechanism behind this practically reversible phenomenon is the unbalanced transport of dissolved components between the bulk phase and the membrane surface. Fouling, on the other hand, is the largely irreversible deposition of solid materials on the membrane surface or within its pores [154]. Both occurrences limit the permeation rate by increasing hydraulic resistance to permeate flow. The osmotic back-pressure developed due to solids accumulation on the membrane surface also reduces driving force to permeation [49].

The hydrodynamic conditions employed in the process, and the physicochemical properties of the membrane and the feed solution are the main factors that influence the extent of concentration polarization and the occurrence of fouling [150]. For instance, in dairy processing applications where milk proteins are involved, protein–protein interactions can contribute to fouling of membranes in a variety of ways, such as inducing aggregation in solution, adding to the adsorbed protein layer, or altering the effective sieving coefficient of the constituent proteins [155]. Protein–membrane interactions, on the other hand, may lead to pore plugging, pore narrowing, and solids deposition that give rise to cake formation on the membrane surface [46]. On the other hand, the hydrodynamic conditions in crossflow filtration may alleviate fouling because, while the permeate flux drags particles toward the membrane, the crossflow induces particle back transport into the bulk phase [156].

One important finding in membrane fouling during dairy processing is that at a pH equal to the isoelectric point of the proteins, a minimum flux caused by severe fouling is observed. Huisman et al. [150] summarized the possible explanations to this observation that has been put forward by many authors as follows: (1) Hydrophobic interactions between hydrophobic membranes and the proteins are enhanced at the isoelectric point of the proteins where they become hydrophobic. (2) At their isoelectric point, proteins tend to aggregate more readily due to reduced electrostatic repulsion and this causes severe fouling. (3) Aside from enhanced transmission through the membrane, the small sizes of proteins at their isoelectric point cause them to form a densely packed fouling layer of low permeability. (4) Adsorption of more proteins through protein–protein interactions on the protein monolayer, which is usually hindered by electrostatic repulsion at all pH values, is enhanced at the isoelectric point of the proteins. This absence of electrostatic repulsion also leads to increased protein transmission through the membrane.

Mineral precipitation and complexation with proteins also contribute to fouling considerably. Adsorbed minerals may serve as salt bridges between the protein and the membrane, which aggravates fouling. In physicochemical conditions that promote calcium phosphate precipitation or calcium–protein complexation, membrane fouling in the filtration of milk or whey is severe,

**FIGURE 22.8** Conceptual stages of flux decline in UF at constant-pressure operation: stage I, concentration polarization; stage II, membrane fouling (usually due to protein deposition); stage III, further particle deposition or consolidation of the fouling layer. (Adapted from Marshall, A.D., Munro, P.A., and Trägårdh, G., *Desalination*, 91, 65, 1993. With permission.)

although owing to the stabilizing influence of the casein micelles, the severity of fouling in milk filtration is less compared to that in whey [56]. Away from the isoelectric point of the proteins, added salts that alter the ionic strength tend to reduce the electrostatic repulsion by shielding charges, causing molecular contraction, thereby decreasing permeability [56].

Fat or lipid materials and calcium–lipid complexes also contribute to fouling and flux decline in membrane processing of milk or whey. The transport properties of the feed stream and the changes they undergo as the concentration process proceeds also affect the rate of permeation. At high concentrations, the increased fluid viscosity near the membrane surface limits back-diffusion of solids from the polarized layer to the bulk phase, thereby, depressing flux rate [46].

Huisman et al. [150] observed two fouling regimes in the UF of BSA using flat-sheet module of polysulfone membranes with MWCO of 30, 100, and 300 kDa: (1) the low-fouling regime at the initial stages of filtration and (2) the high-fouling regime at the later stages of filtration. They found that for the more retentive membrane, such as 30 kDa MWCO membranes, the hydrophobic protein–membrane interactions determine the fouling behavior at the low-fouling regime, while in the high-fouling regime, protein–protein interactions determine the overall performance. These were not definitively observed for the less retentive membranes, such as 100 and 300 kDa MWCO membranes, for which they found that the structure of the fouling layer seemed to have a more important influence on the final fouling.

Although permeate flux may decline far below the theoretical capacity of membranes, the typical variation of flux with time is that of an initial rapid decrease followed by a long and gradual flux decline (Figure 22.8) [157]. Modeling this flux decline caused by fouling during filtration provides better understanding of membrane fouling and provides predictive tools for successful scale up or scale down of filtration systems [153].

#### 22.4.1.1 Mechanistic Models for Flux Decline

To understand the flux decline in pressure-driven membrane operations, a number of models were developed. Two of the most widely studied models are the resistance model and the concentration polarization model. The resistance model is the oldest and is based on the cake filtration theory, where it is assumed that a cake layer of rejected particles, which are too large to enter the membrane pores, is formed. The frictional drag due to permeation through these immobile particles leads to additional hydraulic resistance [21]. The cake layer and the membrane are considered as two resistances in series, and the permeate flux is described by Darcy's Law as

$$J \equiv \frac{1}{A_m} \frac{dV}{dt} = \frac{\text{TMP}}{\mu(R_m + R_c)} \quad (22.1)$$

where

$J$  is the permeate flux

$A_m$  is the membrane filtration area

$V$  is the total volume of permeate

$t$  is the filtration time

TMP is the transmembrane pressure

$\mu$  is the viscosity of the permeate

$R_m$  is the intrinsic membrane resistance

$R_c$  is the cake resistance

This model has been successful in describing flux decline during dead-end filtration of particulate suspensions, but is not appropriate for application to crossflow filtration where the feed solution continuously recirculates [158]. Also, neither the occurrence of macromolecules and colloidal particles diffusion nor the influence of solute–solute and solute–membrane interactions on flux decline is considered in this model [42,59,159].

Aimar et al. [19] noted that in the UF of complex liquids, such as cheese whey, which contains proteins, salts and casein fragments, concentration polarization, and adsorption and cake formation play a role in flux behavior during crossflow filtration. They may induce osmotic pressure in the retentate side since the chemical potential of the solute-rich polarized layer is lower than that of the permeate, and therefore at equilibrium, a positive osmotic pressure develops in the retentate to equal that of the permeate. The smaller the solute, the greater is its contribution to the osmotic pressure of the liquid, so that in milk, lactose and the minerals have the biggest contribution to osmotic pressure. In skim milk or whey, the osmotic pressure is around 7 bar (700 kPa) and this must be exceeded in RO to commence permeation; in UF, only the proteins contribute to the osmotic pressure, which increases exponentially with protein concentration [56]. In any case, a TMP greater than the osmotic pressure is required for solvent to flow from the retentate side to the permeate side. This leads to the reduction in the effectiveness of applied TMP as driving force to permeation.

Concentration polarization caused by macromolecules, which may induce a reversible osmotic pressure that disappears after the filtration pressure is released, and the adsorption on the membrane pores of solid materials or inside the membrane pores of solid materials, which are rid of by rinsing the membrane after the filtration process, are occurrences that both contribute to the reversible resistance to permeation,  $R_{rev}$ . On the other hand, the solids that are deposited on the membrane surface or inside the pores, which are removed only by chemical cleaning of the membrane, constitute the irreversible fouling,  $R_{irrev}$ .

When both  $R_{rev}$  and  $R_{irrev}$  are considerable, Equation 22.1 may be written as

$$J = \frac{\text{TMP}_{\text{eff}}}{\mu(R_m + R_{rev} + R_{irrev})} \quad (22.2)$$

where  $\text{TMP}_{\text{eff}}$  is the effective transmembrane pressure which is equal to  $\text{TMP}_{\text{appl}} - \Delta\Pi$ , wherein  $\text{TMP}_{\text{appl}}$  is the applied transmembrane pressure and  $\Delta\Pi$  is the osmotic pressure [19,21].

In systems that involve solutes <100 kDa in size, such as most of the whey proteins, this model is found to be appropriate [56]. In the UF of WPI solutions using dead-end MF with disc-type ceramic membranes of 0.8  $\mu\text{m}$  nominal pore size, Mourouzidis-Mourouzidis and Karabelas [160] observed that irreversible fouling effectively develops during the first cycle. In the UF of sweet whey, Aimar et al. [19] commented that for low levels of  $\text{TMP}_{\text{appl}}$ , the effective pressure is not a function of crossflow velocity while at higher  $\text{TMP}_{\text{appl}}$ , where the extensive occurrence of concentration polarization is more likely, the effective pressure increases with increasing crossflow velocity. On the other hand, the irreversible fouling, which results to the modification of the transport properties of the membrane, is responsible for the variations in time of permeate flux. The rate of tangential flow, which determines the wall shear stress ( $\tau_w$ ), plays a critical role in alleviating this phenomenon in that it helps erode the adsorbed solid materials during the filtration process, limiting the thickness of deposited layer on the membrane surface. In the UF of reconstituted skim milk using tubular polyvinyl difluoride (PVDF) membranes (200 kDa MWCO), Grandison et al. [161] reported that increasing the  $\tau_w$  at constant TMP led to an increase in both the initial flux and subsequent flux decline, and to a decrease in  $R_{irrev}$ .

Where proteins and other dairy components are involved, aside from cake filtration, the occurrence of pore blocking (complete and intermediate pore blockage phenomena) and pore constriction adversely impacts permeation flux [21,112,153,162,163]. For instance, in the MF of skim milk, as the membrane pore size increases, the contribution of irreversible fouling to overall fouling also increases, indicating greater fouling within the membrane structure [151]. The effects of these various fouling occurrences can be estimated using the appropriate equations given in Table 22.3. An alternative approach is to use the general differential equation

$$\frac{d^2t}{dV^2} = k \left( \frac{dt}{dV} \right)^n \quad (22.3)$$

which may also be written as

$$\frac{dJ}{dt} = -kJ(JA_0)^{2-n} \quad (22.4)$$

where the value of the exponent  $n$  specifies the filtration model considered:

$n = 0$  for cake filtration

$n = 1$  for intermediate blocking

$n = 3/2$  for pore constriction

$n = 2$  for complete pore blocking [164]

**TABLE 22.3**  
**Classical Fouling Models**

Model	Governing Equations	Normalized Flow Rate
Complete pore blockage	$\frac{dA_u}{dt} = -\alpha Q_u C_b$	$\frac{Q}{Q_0} = \exp\left(-\alpha \frac{\text{TMP}}{\mu R_m} C_b t\right)$
Intermediate pore blockage	$\frac{dA_u}{dt} = -\alpha' Q_u C_b \frac{A_u}{A_0}$	$\frac{Q}{Q_0} = \left(1 + \alpha' \frac{\text{TMP}}{\mu R_m} C_b t\right)^{-1}$
Cake filtration	$\frac{dR_p}{dt} = f' R' J_b C_b$	$\frac{Q}{Q_0} = \left(1 + f' R' \frac{2\text{TMP}}{\mu R_m^2} C_b t\right)^{-1/2}$
Pore constriction	$\frac{d(N_0 \pi r_p^2 \delta_m)}{dt} = \alpha_{in} Q_u C_b$	$\frac{Q}{Q_0} = \left(1 + \alpha_{in} \frac{Q_0}{\pi r_0^2 \delta_m} C_b t\right)^{-2}$

Note:  $A_u$ , area of unblocked membrane ( $\text{m}^2$ );  $A_0$ , initial area of unblocked membrane ( $\text{m}^2$ );  $C_b$ , bulk concentration ( $\text{g}\cdot\text{L}^{-1}$ );  $f'$ , fractional amount of total foulant contributing to deposit growth;  $J_b$ , filtrate flux within the blocked area ( $\text{m}\cdot\text{s}^{-1}$ );  $Q$ , volumetric flow rate ( $\text{m}^3\cdot\text{s}^{-1}$ );  $r_p$ , radius of membrane pore (m);  $R_m$ , resistance of the clean membrane ( $\text{m}^{-1}$ );  $R_p$ , resistance of the deposit ( $\text{m}^{-1}$ );  $R'$ , specific protein layer resistance ( $\text{m}\cdot\text{kg}^{-1}$ );  $t$ , filtration time (s). Greek letters:  $\alpha$ , pore blockage parameter ( $\text{m}^2\cdot\text{kg}^{-1}$ );  $\beta$ , pore constriction parameter (kg);  $\delta_m$ , membrane thickness (m).

The concentration polarization model, which is based on the stagnant film theory, was developed to describe the back-diffusion phenomenon during filtration of macromolecules. In this model, the rejection of particles gives rise to a thin fouling layer on the membrane surface, overlaid by a concentration polarization layer in which particles diffuse away from the membrane surface, where solute concentration is high, to the bulk phase, where the solute concentration is low [158]. At steady state, convection of particles toward the membrane surface is balanced by diffusion away from the membrane. Thus, integrating the one-dimensional convective–diffusion equation across the concentration polarization layer gives

$$J_v = \frac{D}{\delta} \ln \frac{\phi_w}{\phi_b} = k \ln \frac{\phi_w}{\phi_b} \quad (22.5)$$

where

$D$  is the diffusion coefficient

$\delta$  is the thickness of the concentration boundary layer

$\phi_w$  is the solids volume fraction on the wall

$\phi_b$  is the solids volume fraction in the bulk solution

$k$  is the mass transfer coefficient equal to  $D/\delta$

For the UF of proteins, the concentration polarization model has been found to predict the filtration performance reasonably well [56]. However, this model is inherently weak in describing the two-dimensional mass transport mechanism during crossflow filtration and does not take into account the solute–solute interactions on mass transport that occur extensively in colloids, especially during MF [21,44,158,159]. The diffusion coefficient, which is inversely proportional to the particle radius, is low and underestimates the movement of particles away from the membrane [56]. This results to the well-known flux paradox problem where the predicted permeate flux is as much as two orders of magnitude lower than the observed flux during MF of colloidal suspensions [56,58,158]. This problem has then been underlined by the experimental finding of a critical flux for colloids, which demonstrates the specificity of colloidal suspension filtration wherein just a small variation in physico-chemical or hydrodynamic conditions induces important changes in the way the process has to be operated [21].

Modifications of the resistance and the concentration polarization models, which involve inclusion of suitable parameters depending on membrane system and the feed chemistry, were introduced achieving some success in explaining the influence of process conditions on flux decline. Saksena and Zydney [44] extended the stagnant film model to account for the effects of both hydrodynamic and thermodynamic solute–solute interactions on bulk diffusion in binary protein system (BSA-IgG) by making appropriate changes on the diffusion coefficient in the model. The modified model sufficiently explained the flux-pressure dependence during UF of binary protein system in a stirred cell UF. Using the model, the authors deduced that BSA transmission is reduced by the concentration gradient in IgG, which increased BSA's diffusive flux. Bacchin et al. [21] unified the resistance and the concentration polarization models to theoretically describe the crossflow filtration of

colloidal particles and molecules and, by numerical simulations, showed that the unified model can identify the crossover from the occurrence of concentration polarization to irreversible fouling, which is useful in membrane system design. Their findings, however, were not verified by experimental results on real systems.

Using experimental results on ovalbumin, Nyström [165] deduced that the charge on the protein rather than the difference in charge between the membrane and the protein, determines the degree of protein deposition on membrane surface. When the protein is charged, the solubility (protein stability) increases and the affinity for the membrane material decreases. Where the membrane charge is opposite to that of the protein, initial adsorption may result in a thin modified layer of charged proteins on the membrane surface that then repels further deposition as quasi-steady flux is attained [165].

### 22.4.1.2 Empirical Fouling Models

Assuming that the amount of flux decline is a function of cumulative permeate volume, Merin and Cheryan [47] suggested that initial flux decline in the UF of whey be defined by

$$J = J_0 V^{-b} \quad (22.6)$$

where

$J$  is the instantaneous flux at any time,  $t$

$V$  is the volume permeated

$J_0$  is the initial flux at  $t=0$ , which is an indication of the resistance to solvent transport by the membrane as well as the concentration polarization layer formed on the membrane by the proteins

$b$  is the indicator of the rate of fouling during long-term operation, or the true fouling effects, due to specific membrane–solute interactions

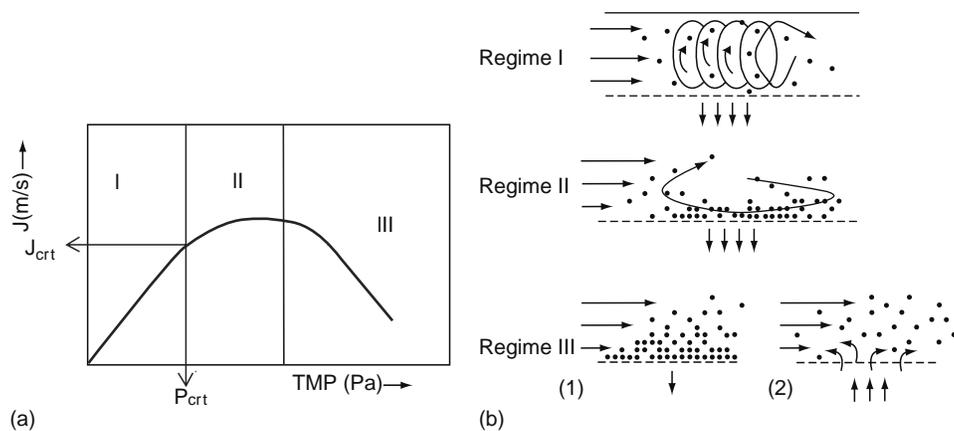

Using individual whey and cottage cheese whey as feed streams, the authors used the model to speculate how each protein influences flux decline and how their interactions in whey under certain physicochemical conditions affect flux decline in polysulfone membrane. Although their findings provided useful insights, they were limited to the initial flux decline in the UF. Kuo and Cheryan [45] utilized the same model to investigate long-term fouling of cottage cheese whey on polysulfone membrane in spiral wound configuration. The model proved useful in identifying critical process settings but insufficient in providing basic understanding on membrane–solute interactions, which the authors suggested, have the biggest influence on initial flux decline before attaining quasi-steady flux. The model is limited by its inability to identify the point at which concentration polarization and gel-layer is formed on the membrane surface. Despite this, it is by far, one of the most utilized models in understanding fouling in the UF of whey.

### 22.4.1.3 Limiting Flux versus Critical Flux

In membrane processes, permeate flux generally increases with TMP, although the increase in flux for solutions is lower than that of pure water flux. At high TMP values, the permeate flux is not significantly affected by increases in pressure and it levels off to almost a constant value before dropping at higher TMP values. This constant flux is called the limiting flux, which increases with increasing crossflow velocity. Michaels [166] used the film theory to explain the observed maximum stationary flux when increasing the TMP of a filtration system. Materials deposited on the membrane by mass transport are removed by the wall shear force and diffuse back into the bulk flow. Beyond the limiting flux, operation at sustained permeability and selectivity is not possible due to the accumulation and compaction of the fouling layer on the membrane [167].

Field et al. [157] introduced the concept of critical flux in membrane filtration. They proposed that upon start-up, there exists a flux below which a decline of flux with time does not occur. Although a concentration polarization layer is present, solid deposition on the membrane that gives rise to cake layer formation does not take place, so that a nonfouling or cake-free operation is achieved. This flux is the critical flux and it may either be in “strong” form, in which flux is identical to the clean water flux at the same TMP, or in “weak” form, in which flux varies linearly with TMP but the slope of the line differs from that of clean water [6,157,161].

Figure 22.9 shows the three regimes that are manifested in membrane filtration in accordance to the critical flux theory [6]. Regime I is the subcritical regime where flux varies linearly and reversibly with TMP. Because the operation capacity is small due to low flux values, processing in this regime requires large membrane area otherwise a high crossflow velocity is employed to increase capacity [6]. Due to the effective prevention of fouling or cake formation, the membrane selectivity in this regime is optimal. Processes where high product purity is required, such as the fractionation of whey proteins, are carried out in this regime. The flux in regime II is independent of TMP. It is equal to the limiting flux, which can be described by the cake filtration or back transport model where the transport of particles toward the membrane is balanced by the back-transport toward the bulk flow. Therefore, high crossflow velocity can promote high flux in this regime. For instance, the reduction of

**FIGURE 22.9** (a) Critical flux regimes: (I) Subcritical operation where flux is linear with TMP and no flux-dependent fouling, (II) TMP above the critical pressure and flux is described by gel filtration or back transport model, and (III) TMP is far above critical pressure, time-dependent flux decline occurs. (b) Graphical representation of fouling in the critical flux regimes: (I) Subcritical operation, fouling is prevented by mechanical action such as turbulent mixing, (II) filtration with a dynamic cake layer, showing particle back transport into the crossflow, and (III) time-dependent flux decline with severe cake formation (1), which could be remedied by backpulsing (2). (From Brans et al., *J. Membr. Sci.*, 243, 263, 2004. With permission.)

bacteria and spores, and concentration of casein micelles by MF are carried out just above the critical pressure, or the lower part of regime II, usually utilizing a combination of high crossflow velocity and low UTMP for optimal flux. Although selectivity is not optimal in this regime, it can lead to optimal capacity, which is particularly advantageous when expensive membranes are used. Optimum capacity in the concentration of whey proteins can also be achieved in regime II. The high TMP, which is way above the critical TMP, in regime III results in time-dependent flux decline that is mostly attributed to cake compaction. Therefore, periodic mechanical removal of fouling, such as by backshock or backpulse, is necessary for stable extended operation.

The critical flux value depends largely on the hydrodynamic conditions in the process, the membrane pore size, and the feed physicochemical condition [161,168]. Appropriate manipulation of these parameters, specifically the hydrodynamic condition, may lead to the reduction or even the elimination of both reversible and irreversible fouling of the membrane. Youravong et al. [152] estimated the critical flux in the UF of skimmed milk to lie between 55 and 60  $\text{kg}\cdot\text{h}^{-1}\cdot\text{m}^{-2}$  and that the average critical TMP was 0.22 bar (22 kPa) at 50°C using PVDF membranes with MWCO of 200 kDa. In the UF of WPC and sodium caseinate suspension, Youravong et al. [168] reported that both gave the weak form of critical flux, which increases with increase in crossflow velocity.

Although in many cases, the critical flux is equal to the limiting flux, in other cases operating at the limiting flux causes more fouling [161]. Therefore, it is useful to determine the operating conditions that will sustain satisfactory performance, in terms of selectivity and permeability, around the critical zone especially for an extended period of operation. A pseudo steady-state operation, described by the cake filtration model, is desirable in long-time operations. Since the permeation flux,  $J$ , governs convective mass transport to the membrane and that the efficient wall shear stress,  $\tau_{\text{weff}}$ , governs particle and molecule back-transport from the membrane toward the bulk flow, and that these transport phenomena are necessary for sustained operation, then a critical ratio,  $(J/\tau_{\text{weff}})_{\text{crit}}$ , may also exist for satisfactory long-time membrane operation [96,169]. Le Berre and Daufin [97] as well as Gésan-Guiziou and Daufin [169] determined the value of the critical ratio in the MF of skim milk as 0.95 and 1.00  $\text{L}\cdot\text{h}^{-1}\cdot\text{m}^{-2}$ , respectively. Exceeding these values led to the accumulation of milk components on the membrane surface. This suggests that the critical ratio pertains to the transition to irreversible material deposition on the membrane. Furthermore, the similarity of the critical ratio values that the two groups obtained even when they used different membrane modules and adapted different approach suggests that the critical zone in the MF of skim milk is mainly related to the characteristic of the deposit. These indicate the usefulness of the critical ratio in determining critical operating conditions.

Despite the numerous efforts in understanding the fouling mechanisms and the influence of operating parameters involved that lead to flux decline in filtration systems, there remain significant gaps in the present knowledge on this phenomenon. To date, none of the theoretical models, and their numerous modified forms, and empirical models sufficiently explain the influence of membrane–solute interactions and solute–solute interactions on real dairy systems.

## 22.4.2 ENERGY CONSUMPTION

Aside from mild operating conditions suitable for processing dairy systems, membrane technology involves smaller energy consumption and higher rate of return of investment that punctuates the technology's economic advantages over conventional

**TABLE 22.4**  
**Comparison of Energy Consumption and Average Flux for Various UF Systems Used in Whey Processing**

Module Design	Type of Whey	Membrane Material	Average Flux (L·h <sup>-1</sup> ·m <sup>-2</sup> )	TMP (kPa)	Energy Use (kJ) Per Cubicmeter of Permeate
Spiral wound	Acid whey	Polysulfone	38	480	5.2 × 10 <sup>3</sup>
Spiral wound	Cottage cheese whey	Polysulfone	12	335	3.0 × 10 <sup>3</sup>
Hollow fibers	Cottage cheese whey	Polysulfone	28	155	5.9 × 10 <sup>3</sup>
Plate and frame	Gouda whey	Ceramic	51	300	8.8 × 10 <sup>3</sup>
Tubular	Gouda whey (decalcified)	Ceramic	74	500	1.4 × 10 <sup>4</sup>
Tubular	Cottage cheese whey	Ceramic	24	225	4.5 × 10 <sup>5</sup>

Source: From Cheryan, M. and Kuo, K.P., *J. Dairy Sci.*, 67, 1406, 1984. With permission.

separation techniques [170,171]. For instance, Marshall [1] reported that a single-effect evaporation system and a quadruple-effect evaporation system consume as much as 626 and 126 kWh per ton of water removed, respectively, and that five- to seven-effect evaporation systems and mechanical vapor compression consume 37–53 kWh per ton of water removed. On the other hand, RO system used for water removal of milk consumes only 9–19 kWh per ton of water removed [1]. In the United States, the cost of concentrating skim milk from 8.8% to 45% total solids by plate-and-frame RO plant with a capacity of 9,000 kg·h<sup>-1</sup> was estimated to be 50% cheaper compared to the cost of water removal by evaporation [63,172]. If evaporation and RO were combined to achieve the same total solids concentration, the total energy consumption is less than one-third of that when evaporation alone is employed [63,172].

Although the smaller energy consumption involved in membrane operations is very well known, the membrane type and configuration must be carefully chosen to further optimize energy cost in specific applications. For the same purpose and set of operating parameters, one membrane type or module design might be advantageous over another as far as energy consumption is involved. Cheryan and Kuo [22] compared the amount of energy used in the UF of whey using different membrane types in various configurations (Table 22.4) and found that polysulfone membrane in spiral wound configuration consumed the least amount of energy (kJ) per cubicmeter of permeate collected compared with polysulfone in hollow fiber configuration and ceramic membranes, both in tubular and plate-and-frame configurations.

## 22.5 CLEANING AND SANITATION

Effective cleaning and sanitation are necessary strategies to restore membrane performance after processing and to sustain hygienic operation [170]. It is generally acknowledged that a major cost associated with membrane maintenance in the dairy industry is that incurred from cleaning and sanitizing the membranes after processing. The cost of water and wastewater generated during cleaning alone was estimated to comprise 20% of the total cleaning cost [173]. The fact that cleaning and sanitation protocols affect the membrane lifetime and efficiency is also a concern [55,174]. Therefore, the cleaning process must be optimized to lessen the adverse effects of cleaning agents on membrane life, the cost of purchasing and disposing of cleaning chemicals, as well as the volume of water consumed and wastewater produced [175].

Optimization of membrane cleaning and sanitation processes involves the understanding of: (1) the complex interactions between the foulants and the membrane and (2) the economic impact of the cleaning and sanitation processes [174]. In dairy applications, the usual soil consists of proteins, fat, carbohydrates, and minerals, with fat and protein residues being the most difficult to remove [173]. Interactions between these dairy foulants and the different membrane materials have been the subject of many studies to date.

### 22.5.1 CLEANING

Membrane cleaning involves the removal of a substance that is not an integral part of the membrane material [176]. The process must remove fouling deposits and must restore the normal capacity and separation characteristics of the equipment [175]. The cleaning process is usually divided into two main steps: rinsing and chemical cleaning.

The membrane is rinsed with softened water immediately after processing to remove reversible fouling from the membrane surface by mechanical actions, such as mixing, turbulence, and shear. Marked increase in flux can be achieved by rinsing because of the removal of soluble material or desorption of foulants or additives [175]. In dairy applications, the rinsing water should have a fouling index lower than 1.5 and be of acceptable bacteriological quality [177]. Specifically for MF and UF plants, Krack [173] reiterated that the salt density index of the rinsing water should be <3, otherwise problems may occur.

As a guideline for the water quality, the following may be used: total hardness should be maximum of 3.57 mmol (357 ppm  $\text{CaCO}_3$ ), total amount of bacteria 1000 per mL, total amount of coliform bacteria  $<1$  per mL [173].

After water rinsing, chemical cleaning is carried out to remove tightly bound materials on the membrane surface and pores. Appropriate chemical cleaners are chosen to remove specific foulants, such as nonionic detergents (0.1%) to remove fat deposits, acids to remove inorganic precipitates or oxide films, and alkaline detergents (0.1%–0.5%) to remove protein deposits [3,175]. Nitric and phosphoric acids are the most frequently used acids for cleaning membranes. However, citric acid is also used and favored by some due to its mildness compared with nitric acid [175]. Hydroxide solutions, either sodium hydroxide or a mixture of sodium hydroxide and potassium hydroxide of pH 11–12, added with sodium hypochlorite for improved cleaning and disinfecting power, are usually recommended for the alkali cleaning [175].

Aside from detergent cleaning, enzymatic cleaning is also considered for membranes soiled with dairy foulants. Enzymatic cleaners are usually employed if the membrane pH limitation is at or below 10 or if a high level of contaminants is present [173]. Enzymes are advantageous over traditional chemical cleaners in that they are biodegradable, less aggressive to the membranes, and they can improve cleaning efficiency by reducing energy costs and the amount of chemicals needed [175].

Other than the type and composition of the cleaning agent, the order and duration of the cleaning steps, and the physical operating parameters are key components of an effective cleaning strategy [175]. To obtain good mechanical cleaning effects, it is recommended that the circulation flow rate is to be higher and the pressure lower than those used during the normal operation [178]. Another factor to be considered is the amount of cleaning solution in comparison to the membrane surface, which in process plants today ranges between 4 and 5  $\text{L m}^{-2}$  membrane surface [173].

### 22.5.1.1 Water Rinsing

The first stage of rinsing is usually carried out with the permeate side of the membrane module closed, or TMP values close to zero, to limit convective transport of permeate particles toward the membrane. This prevents adsorbed materials on the membrane surface from migrating to the membrane pores, maximizing the rate of erosion of fouling on the membrane surface. At this stage, the crossflow velocity is a major operation parameter. Later, when permeate convective transport is allowed by opening the permeate side valve, the pore foulants are removed more efficiently [177]. This strategy improves rinsing efficiency, which is measured in terms of hydraulic resistance reduction during rinsing, and helps minimize the consumption of cleaning agents during the chemical cleaning step.

The feeding mode of rinsing water also influences rinsing efficiency. Some membrane modules allow backflushing, where the rinse water is made to flow from the permeate side to the retentate side. This is carried out at the beginning of the rinsing step, or periodically during the rinsing step, to remove internal fouling and to dislodge hard deposits on the membrane surface rather than compressing the fouling layer that renders rinsing inefficient. Whether the rinsing water is recycled or not, especially during the first stage of the rinsing step, also impacts rinsing efficiency. Cabero et al. [177] observed that 15 min rinsing of ceramic membrane, which was previously fouled with whey, without recycling the rinsing water removed larger part of hydraulic resistance compared to when rinsing water was recycled. The same authors also reported that prolonging the rinsing time does not improve the rinsing efficiency when water is recycled.

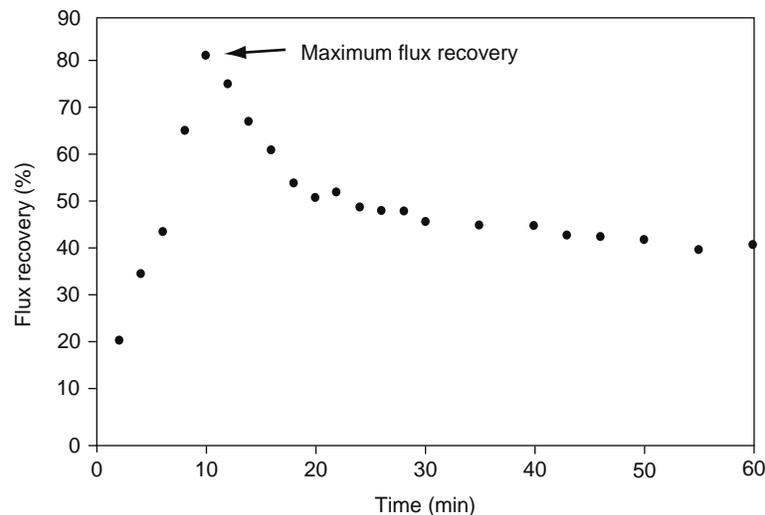

The temperature at which water rinsing, including intermediate rinsing, is carried out is also a major consideration. Warm water rinsing rather than cold water is preferred to avoid temperature stress on the membrane and to avoid break-up of well-emulsified soil that may lead to redeposition of dairy foulants on the membrane [173]. The duration of rinsing time varies with the size of the membrane plant, and usually ranges between 5 and 20 min.

### 22.5.1.2 Chemical Cleaning

Most chemical cleaning protocols consist of an alkali detergent step followed by an acid step, with appropriate rinses in between. However, for polymeric membranes, it is also common to follow the acid cleaning step with a second alkali cleaning step supplemented with chlorine as this further improves flux [176,179]. In some cases, acid cleaning has been recommended as the first step, especially for whey applications, where mineral fouling maybe more important than protein fouling [176].

Many researchers consider the restoration of clean water flux as a measure of the degree of membrane cleanliness [3,180]. However, it is insufficient to characterize cleaning efficiency by either flux recovery or resistance removal alone because large resistance removal values are often easily obtained even when considerable amounts of foulants are still deposited on the membrane [181]. For instance, Bohner and Bradley [180] utilized a cleaning procedure at 43°C where after processing and flushing with water, acid solution, a 1:1 blend of nitric and phosphoric acids at pH 1.8, was recirculated for 1 h. After another water flush, sodium hydroxide solution with 0.1% surfactant (w/v) at pH 11.8 was then recirculated also for 1 h to clean spiral wound polysulfone UF membranes (10–15 kDa MWCO) soiled with cheddar cheese whey. Results of scanning electron microscopy of the membranes after cleaning indicated that protein deposits and bacteria still contaminated the membrane surface even after reducing the hydraulic resistance and restoring the permeate flux to its value before processing.

To improve the removal of deposits on the membrane surface, Bohner and Bradley [179] modified the cleaning procedure described previously. The modified procedure, which was carried out at 54°C, consisted of a 2 min initial rinsing of the

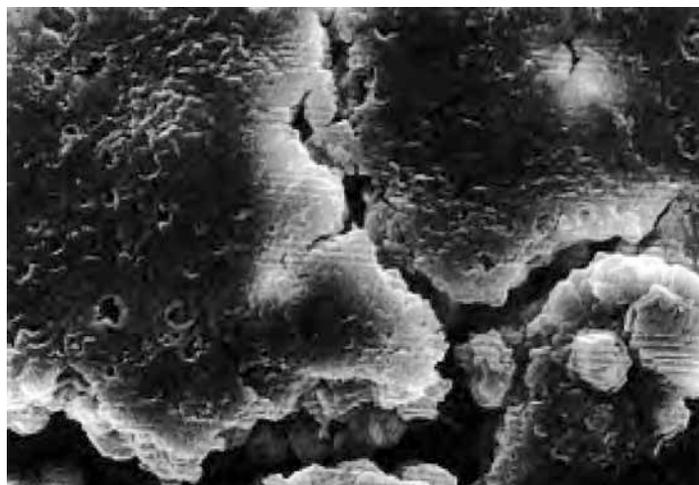

**FIGURE 22.10** Dynamics profile of the flux recovery in cleaning WPC-fouled PVDF MF membranes using NaOH solution at pH 13 and 30°C, and at crossflow velocity of  $0.45 \text{ m}\cdot\text{s}^{-1}$  and 350 kPa TMP. (From Mercadé-Prieto, R. and Chen, X.D., *J. Membr. Sci.*, 254, 157, 2005. With permission.)

membrane system with water. Sodium hydroxide at pH 11.0, with 0.1% of nonionic surfactant added, was circulated for 20 min. After a 2 min rinse with water, a 1:1 mixture of nitric and phosphoric acids at pH 2 was circulated for 20 min before a final water rinsing. With the scanning electron microscopy images of the cleaned membrane, Bohner and Bradley [179] found that the cleaning procedure rid the membrane surface of whey residues. They also noted that the cleaning procedure did not damage the membranes even when it was used continuously for 300 h. However, when the cleaning temperature was increased from 54°C to 63°C, they observed damage on the membrane after 100 h of cleaning.

Although alkali cleaning of membranes soiled with dairy proteins is generally accepted in the dairy industry, its efficacy and optimal cleaning capacity has been the subject of a number of studies. Caustic concentration, operating temperature during alkali cleaning, and the length of cleaning time impact flux recovery (Bird and Bartlett, 2002). An optimal sodium hydroxide concentration where the flux recovery reaches maximum was found to range between 0.075 and 0.5% (w/w) [182]. The typical dynamic flux recovery profile, expressed as the ratio of flux during cleaning to clean water flux, consists of an initial sharp increase followed by an exponential decay to a steady-state value as that shown in Figure 22.10 [182]. The existence of maximum flux recovery has been the subject of a number of investigations.

Using light microscopy, Bird and Bartlett [170] observed that the deposit on sintered stainless steel MF membrane ( $2.0 \mu\text{m}$ ) fouled with whey consists of a loose sheet-like protein-rich structure which is removed during the first few minutes of chemical cleaning (Figure 22.11). Cleaning with sodium hydroxide removes the loose top proteinaceous layer, which results to the sharp

**FIGURE 22.11** Scanning electron microscopy image of sintered membrane surface fouled with WPC deposits. (From Bird, M.R. and Bartlett, M., *J. Food Eng.*, 53, 143, 2002. With permission.)

increase in flux recovery as in Figure 22.10. Bird and Bartlett [170] found that underneath the proteinaceous top layer are aggregates of calcium phosphate imbedded in a protein sheet. Although the protein sheet is eroded with continuous cleaning, the authors found that calcium phosphate remains on the surface of the membrane. They also found that proteinaceous materials are present within the membrane pores. They hypothesized that the flux decline observed during the caustic cleaning of membrane is caused by these proteinaceous in-pore fouling that swells at high pH.

The physicochemical conditions of the foulants and the cleaning agents are important considerations in designing efficient cleaning procedure. Kim et al. [181] studied the cleaning of UF membranes, fouled with BSA, using acid, bases, and anionic and cationic surfactants. They reported that when membranes were fouled at the isoelectric point of BSA (pH 5), hydraulic resistance removal was highest when hydrochloric acid and sodium hydroxide solutions were used. If the membranes were fouled at pH 7, at which BSA has a net negative charge, they found that the cationic surfactant cetyl-trimethyl-ammonium bromide (CTAB) was more effective due to electrostatic interactions between the protein fouling layer and CTAB. Muñoz-Aguado et al. [174] reported that at pH 7, the protein layer on polysulfone UF membrane (30 kDa MWCO), recirculated with BSA solution or reconstituted WPC, was almost three times thicker than that at pH 5. However, the permeate fluxes were lower at pH 5. This was due to the more compact and less permeable protein layer formed on the membranes at pH 5, which is the isoelectric point of BSA and the mean isoelectric point of whey proteins. On the other hand, the significant net negative charge on the proteins at pH 7 causes expansion of the protein fouling layer that results to thicker but more permeable deposit. Such understanding of protein fouling behavior and possible membrane–protein interactions led to the exploration of other cleaning strategies.

Proteases, lipases, or enzyme detergents, which hydrolyze proteins and fats, are sometimes used to supplement or replace alkaline detergent cleaning, particularly when using less alkali-resistant cellulosic membranes [3]. Muñoz-Aguado et al. [174] studied the efficiency of CTAB, the enzyme  $\alpha$ -chymotrypsin ( $\alpha$ -CT), and the complex mixture of detergents and enzymes Terg-A-Zyme (TAZ) in cleaning polysulfone UF membrane fouled with BSA. All the cleaning agents took about 1 h to reach maximum cleaning efficiency at 40°C. The use of CTAB at 0.2% (w/w) concentration resulted to better flux recovery than the use of  $\alpha$ -CT. They reported that, at pH 5 and 7, the efficiency of CTAB is enhanced by the prior cleaning of the membranes with  $\alpha$ -CT, due to the better accessibility of the proteins in the cake layer that has been disrupted by the prior action of  $\alpha$ -CT at 0.01% (w/w) concentration. The inclusion of water rinsing, also at 40°C, in between the  $\alpha$ -CT and CTAB cleaning cycles further improved flux recovery. They also found that excessive treatment with these cleaning agents exacerbates fouling, with  $\alpha$ -CT reinforcing the membrane–protein binding, or acting as a foulant itself. The group reported the highest flux recovery using TAZ at 0.4% (w/w) concentration. They observed similar trends when cleaning membranes fouled with reconstituted WPC. However, because of the more complex fouling layer formed by reconstituted WPC, higher concentration of TAZ, 0.75% (w/w), was necessary to achieve the maximum flux recovery.

Although the effectiveness of multistep cleaning processes using surfactants, enzymes, or surfactant-enzyme system in flux recovery is well-established, the economic impact of these procedures needs to be evaluated for truly optimized membrane cleaning. Physical methods of cleaning membranes simultaneous to processing are also being investigated. One such method is the use of electric field pulse to dislodge membrane fouling and restore initial flux while processing continues [171].

### 22.5.2 SANITATION

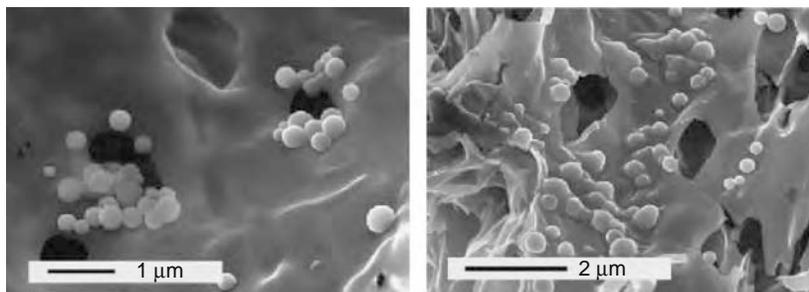

Plants are cleaned, sanitized, and rinsed immediately after processing, and right before processing to ensure satisfactory initial process conditions from microbiological standpoint [3]. Because chlorine is freely permeable to most membranes that it is able to sanitize the permeate side of the system as well as the retentate side, using solutions of sodium hypochlorite containing 100–200 ppm of active chlorine is a common sanitation technique for many membranes, except cellulose acetate reverse osmosis membranes, which can only tolerate brief exposure to chlorine at 10–50 ppm level [3].

Bohner and Bradley [180] evaluated the efficiency of a sanitizer whose composition enabled the release of chlorous acid and chlorine dioxide from sodium chlorite at pH 2.7 in destroying bacterial populations in a polysulfone spiral wound UF membranes soiled for 2.5 h by circulating and concentrating cheddar cheese whey and skim milk. Using results from swabbing, they reported that the sanitizer was effective in controlling microbial populations in UF membrane systems. Bohner and Bradley [180] investigated the use of sanitizing cycle at 54°C after cleaning, which consisted of a 15 min recirculation of sodium hypochlorite solution prepared by diluting commercial household bleach solution diluted to contain 100 ppm of active chlorine in warm, softened tap water, and its pH adjusted to 6.5 using nitric acid. The authors commented that an effective cleaning procedure followed by this low-cost sanitizing procedure is able to satisfy industrial concerns.

## 22.6 CHALLENGES AND EMERGING APPLICATIONS OF MEMBRANES IN THE DAIRY INDUSTRY

### 22.6.1 CHALLENGES

A major factor that remains to be the biggest challenge in optimizing the performance of membrane processes in the dairy industry is biofouling, which is caused by specific interactions between the membrane and various proteins, as well as protein–protein interactions that can lead to pore-narrowing or pore-blocking, during the filtration process [40,153,155].

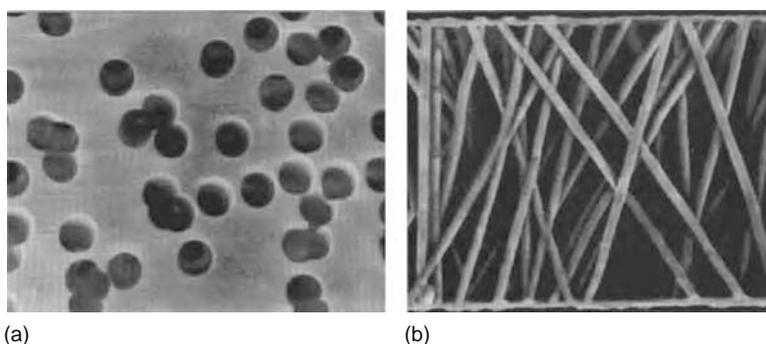

**FIGURE 22.12** Protein fouling of internal pore surfaces of MF membrane following filtration of skimmed milk at 300 psi TMP for 30 min. (From James, B.J., Jing, Y., and Chen, X.D., *J. Food Eng.*, 60, 431, 2003. With permission.)

The irreversible alteration of membrane morphology caused by protein fouling during processing leads to severe flux decline and alteration of membrane rejection properties [153]. Biofouling can adversely impact membrane processing economics because of the loss of filtration efficiency, process down time to clean the membrane, and the decrease in membrane lifespan due to frequent cleaning [183]. Therefore, considerable efforts during the past three decades in the dairy industry were not only concentrated on process innovation, but also in understanding and combating the biofouling phenomenon.

Savello et al. [184] studied the fouling of 0.2  $\mu\text{m}$  pore size MF ceramic membrane by milk proteins in two filtration conditions: (1) static, where the membrane is soaked in skim milk for 5 min to allow the surface adsorption of proteins and (2) dynamic, where the retentate is recirculated continuously until constant permeation rate was achieved. They observed greater reduction in clean water flux under dynamic conditions than static conditions. SEM images of the fouled membrane by static mode showed that the fouling is not only limited to surface deposition of particles, but also by pore-blocking (Figure 22.12). They modified the membrane surface by silanization using glycidoxypolytrimethoxysilane and 3-aminopropyltriethoxysilane to derivatize the membrane surface and block the active sites for protein binding. Washing the surface-modified membrane with protein solvent after static and dynamic fouling tests only partially restored the clean water flux while alkali and acid washes completely restored the flux. This, they deemed, suggests that, aside from milk proteins, minerals play a critical role in the fouling mechanism of ceramic membranes.

James et al. [155] suggested that, in addition to surface chemistry, the surface morphology and internal microstructure of a membrane affect fouling and membrane performance. Klobes et al. [185] suggested the use of capillary pore membranes made from polyester film, which is supported by a nonwoven polypropylene or polyester backing, in the MF of milk systems rather than tortuous path membranes. Such membranes are microporous with cylindrical straight through pores of uniform diameter manufactured by a two-step procedure of heavy ion irradiation and subsequent etching (Figure 22.13). They investigated membranes with pore sizes of 0.4, 0.3, 0.2, and 0.1  $\mu\text{m}$  in fractionating proteins in fresh skim milk at  $48^\circ\text{C} \pm 2^\circ\text{C}$  and flow rates of 3.8, 1.9, and 1.0  $\text{m}\cdot\text{s}^{-1}$ . They reported that the 0.2  $\mu\text{m}$  membrane showed the best skim milk fractionation characteristics where nearly complete retention of caseins at all flow rates considered and whey protein permeation of up to 90% at the lowest flow value investigated were observed. They also noted constant whey protein permeation of around 50% and complete casein retention at all flow rates considered using 0.1  $\mu\text{m}$  membranes.

Aside from membrane morphology, various membrane module geometries were also studied to determine their appropriateness in various dairy processes. Operation of tubular ceramic membranes usually involves high TMP and pressure drop

**FIGURE 22.13** Scanning electron micrographs of the surface (a) and the internal structure (b) of a Rotrac capillary pore membrane. (From Klobes et al., *Bull. Int. Dairy Fed.*, 311, 13, 1996. With permission.)

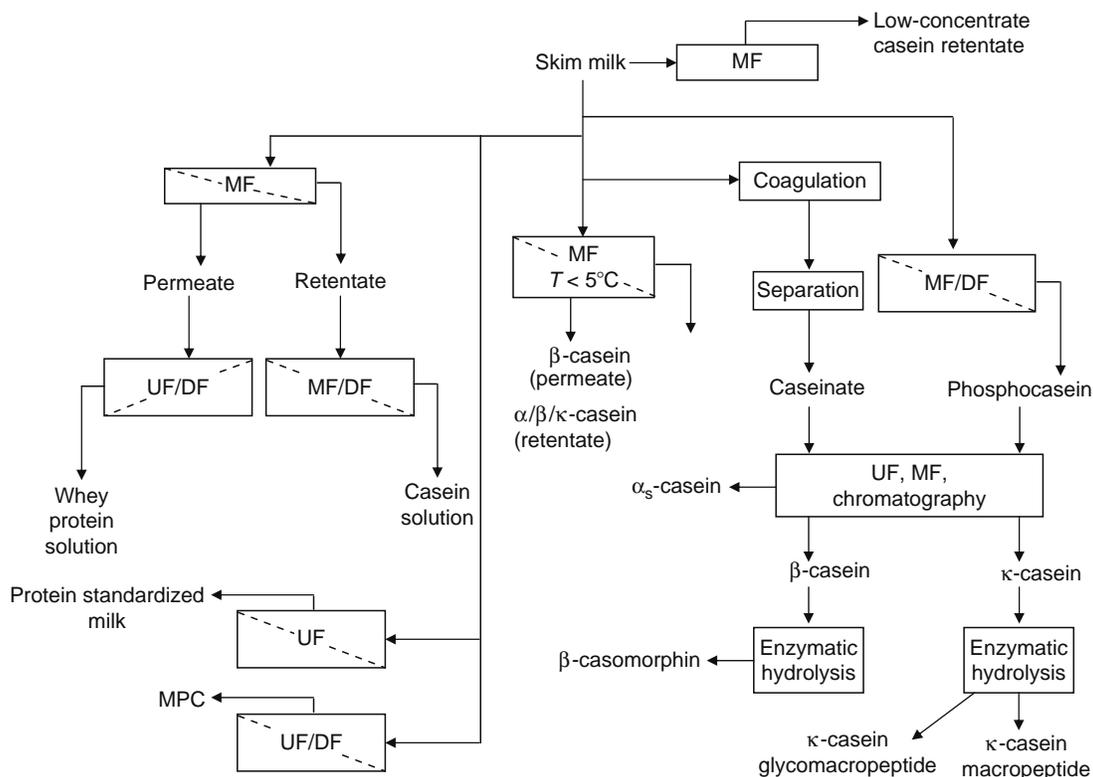

along the filter module, and requires recirculation of permeate to maintain uniform TMP and high permeation throughout the length of the module for a long period of time [9]. The evaluation of flat ceramic membranes for use in the wastewater treatment around 1996, and the reported energy-efficiency and cost-effectiveness of their operations due to small hydraulic diameter prompted studies to use these membranes in milk proteins standardization and whey concentration [186]. To date, however, they have not been utilized commercially in the dairy industry.

A recent development in MF technology is the microsieves, which are MF membranes with uniform narrow pore size distribution and a smooth inert silicon nitride surface, manufactured using micro-machining technology [6,187]. Due to the very low hydrodynamic resistance of microsieves and their open support structure, they enable high fluxes that can be two or three orders of magnitude larger than for conventional membranes even as they are operated at extremely low TMP, which are about two orders of magnitude lower compared to conventional membranes [6,187]. Because permeation in microsieves is faster, the accumulation of particles on the membrane surface may also take place faster compared to conventional MF membranes so that the large-scale MF of milk by microsieves is still in the investigation stage [187].

### 22.6.2 EMERGING APPLICATIONS OF MEMBRANES IN THE DAIRY INDUSTRY

Membranes can be used successfully in several fractionation stages of milk (Figure 22.14) [6,11]. As membrane materials and understanding of processing conditions for efficient operation continue to evolve, new applications of membrane technology in the dairy industry also continue to emerge. The continued development of the state-of-the-art ceramic membrane products that persist to thrive despite the cheaper polymeric membranes and the increasing understanding of fouling that leads to effective flux control contribute to the widespread use of membranes in the dairy industry. Such dynamism results in innovative products of novel applications and unique functionalities.

Microfiltration of milk to separate micellar casein and produce an intermediate for the recovery of individual caseins rather than producing a casein concentrate for cheesemaking alone is a goal of numerous efforts in dairy research. This opened opportunities for more specialized applications of MF in the dairy industry [70]. For instance, recent studies on the biological activities of milk components have propelled interest in recovering IgG in bovine colostrum using MF. Colostrum is a mixture of the lacteal secretions produced by the mammary gland during the three days following parturition [188]. It contains high amount of IgG and was found to have essential physiological action for many species and high efficacy in human clinical applications [188,189].

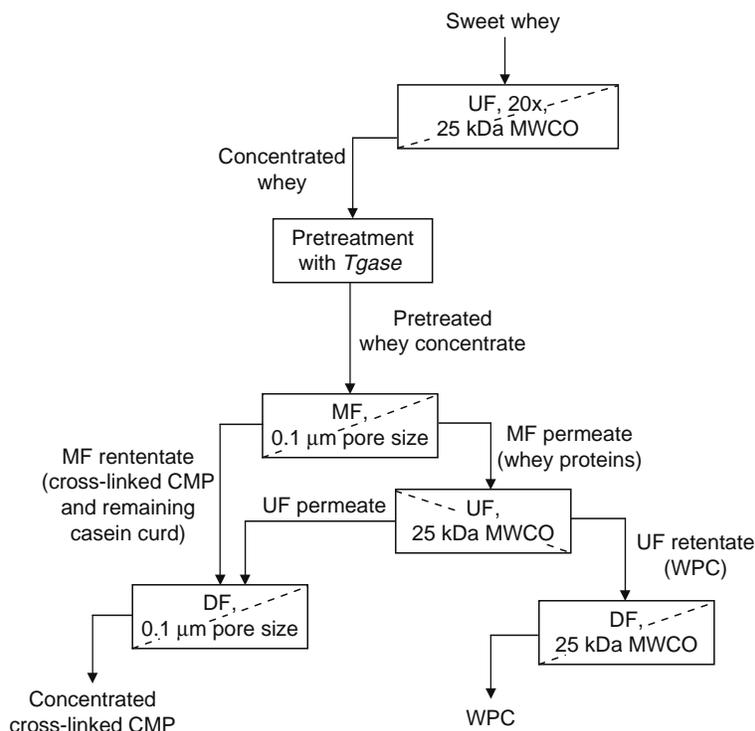

**FIGURE 22.14** Application of MF and UF in milk protein standardization and fractionation. (From Rosenberg, M., *Trends Food Sci. Technol.*, 6, 12, 1995. With permission.)

Using MF ceramic Membralox membranes of 0.1  $\mu\text{m}$  average pore size operated at UTMP of 0.4–0.5 bar (40–50 kPa) and temperature lower than 40°C, Piot et al. [188] employed the patented method developed by Garcin and Paviot [190] to recover “serocolostrum” as permeate, which is crystal clear, free of blood, and somatic cells as well as fat globules and casein micelles, and has high hygienic and bacteriological quality ( $<10 \text{ cfu}\cdot\text{mL}^{-1}$ ), from bovine, caprine, or equine colostrums. The colostrums were skimmed and diluted by 50% of KCl–NaCl saline solution or milk ultrafiltrate before MF. Continuous DF with 8–10 diavolumes of the saline solution followed to recover the whey fraction of colostrums, specifically to maximize the amount of IgG in the permeate. The authors reported about 10% losses of IgG to the cream in the skimmed colostrums and 5.0%–6.7% losses of IgG in the MF retentate. They suggested foregoing the cream separation step and proceeding directly to the MF step with prolonged DF to minimize the losses.

Another recent innovation involves native whey proteins recovery pioneered by Tolkach and Kulozik [191]. They introduced a novel membrane-based approach of separating native whey proteins from caseinomacropptide (CMP) in ultrafiltered and diafiltered sweet whey (Figure 22.15). They used the microbial enzyme transglutaminase (*Tgase*) to cross-link CMP molecules through their glutamine and lysine residues. Although native whey proteins themselves are rich in glutamine and lysine, they are resistant to enzymatic action, especially by *Tgase*, because of their compact globular shape [192,193]. The authors reported that about 92% of the original amount of CMP was cross-linked without affecting native whey proteins quantity and that the remaining CMP that was not cross-linked was mostly the glycosylated variety. The cross-linking of the CMP molecules widened the size difference between CMP and the whey proteins, and rendered effective separation of the two fractions by MF and subsequent DF in 0.1  $\mu\text{m}$  pore size ceramic membrane module operated at 0.4 bar (40 kPa) UTMP and 55°C. The MF permeate, which contained whey proteins, was ultrafiltered using polysulfone (25 kDa MWCO) plate-and-frame module and the UF permeate was used to diafilter the MF retentate, which contained the cross-linked CMP and the remaining fractions of casein fines (about 5%–10% of the total proteins).

A decade ago, Jost and Jelen [96] commented that the success of some of the novel processing applications of MF will depend on unique functionality and specific applications of the final fractions. Today, it is evident that with the use of MF, several advancements have been attained in the dairy industry, such as the dramatic improvement of the hygienic safety of dairy products, nutritional and bioactive properties of milk are kept intact or, at least, very minimally damaged, specific separations of micellar casein and of small and large fat globules. These remarkable developments opened new and diverse avenues in improving current manufacturing processes, product quality, and creating new milk derivatives for novel applications [8].

## 23.1 INTRODUCTION

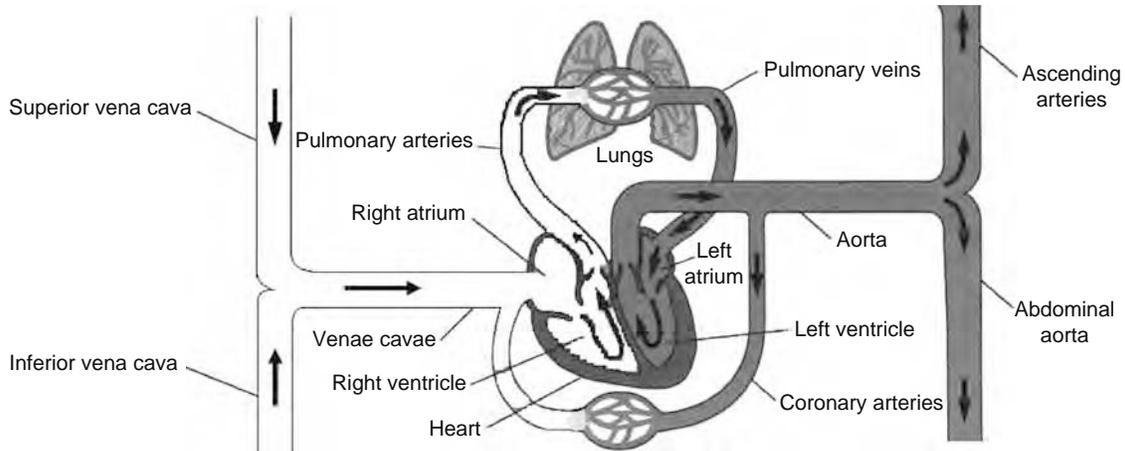

Cardiac surgery is generally performed on a motionless heart.\* The heart consists of two separate pumps: right ventricle pump and left ventricle pump. The right ventricle pumps oxygen-depleted blood to the lungs while the left ventricle pumps oxygen-rich blood to the body. Figure 23.1 shows the human circulatory system as well as the relationship between the heart and lungs. Cardiopulmonary bypass therefore must ensure that oxygen-rich blood reaches the cells in the body.

During cardiopulmonary bypass, blood from the vena cava is directed to the external cardiopulmonary bypass circuit, where it is oxygenated and returned to the aorta. Thus it is essential that an external blood oxygenator (BO) should be used to oxygenate the blood. An additional circuit is required to ensure that the heart is provided with oxygenated blood.

Figure 23.2 is a simplified schematic diagram of the cardiopulmonary bypass circuit. During cardiopulmonary bypass, a cannula is inserted into the right atrium to drain venous blood into the main blood reservoir. The cardiotomy reservoir receives blood that has been aspirated from the heart or pericardium. The cardiotomy reservoir usually includes a defoaming chamber. The cardiotomy reservoir also serves as a buffer storage reservoir in case there is a sudden change in blood pressure. Blood from the cardiotomy reservoir flows into the main reservoir. The blood from the blood reservoir is pumped through a BO,

---

\* Recently “beating heart” surgery has increased in popularity for more simple procedures where cardiac surgery is conducted on a beating heart. However cardiopulmonary bypass will be needed for more complicated procedures.

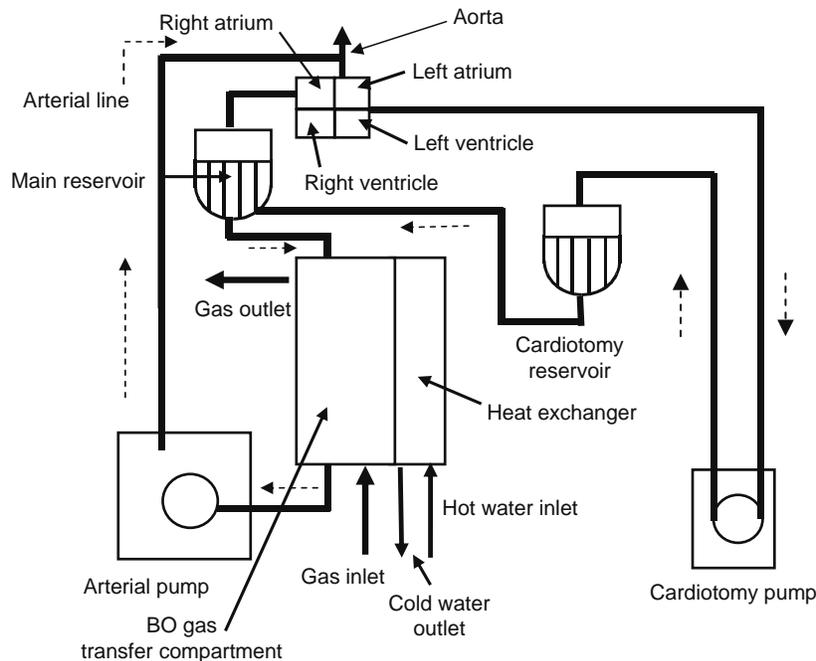

**FIGURE 23.1** Human circulatory system as well as the relationship between the heart and lungs.

which replaces the gas transfer function of the lungs; oxygenation of the blood, and removal of carbon dioxide. A heat exchanger is included with the blood oxygenator. Hot water is pumped through one side of the heat exchanger while the blood flows through the other side, allowing control of the patient's body temperature. A major concern during cardiopulmonary bypass is the entrapment of air in the blood. Antifoaming compounds, e.g., silica A, are usually added to the blood [1,2]. Further, blood filters (e.g., polyester or nylon filters with pore size between 20 and 40  $\mu\text{m}$ ) are used to remove any air bubbles that may be present. The blood returns to the body via a second cannula placed in the aorta.

The presence of an extracorporeal bypass circuit results in large heat losses from the blood. Thus an integral heat exchanger is essential to regulate the patient's body temperature. To decrease the oxygen demand during surgery, the patient's body temperature is often maintained at 5°C–10°C below normal body temperature.

The first cardiopulmonary bypass procedure was conducted on May 6, 1953 using a heart–lung machine invented by John and Mary Gibbon [3]. Today cardiopulmonary bypass procedures are routine. Figure 23.3 shows the increase in cardiopulmonary bypass procedures in United States from 1979 to 2002 [4]. From 1995 to 2002 about 700,000 cardiopulmonary bypass procedures were conducted each year in the United States. Among these, more than 50% of cardiopulmonary bypass procedures were conducted on patients above 65 years, while 40% were conducted on patients between 45 and 64 years of age.

**FIGURE 23.2** Simplified schematic presentation of the cardiopulmonary bypass circuit. Direction of blood flow is shown by the dashed arrows.

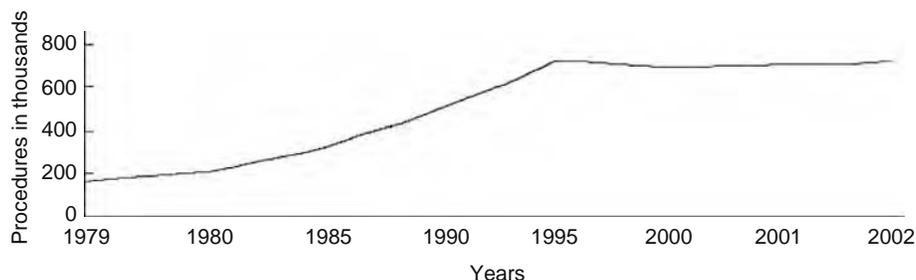

FIGURE 23.3 Cardiopulmonary bypass procedures conducted each year in the United States.

## 23.2 HISTORY

The BO is a major component of the cardiopulmonary bypass circuit. A tremendous amount of research, as evidenced by the numerous research papers and patents, has been devoted to the design of the highly efficient microporous membrane BOs available today. In the following section, the forerunners to today's microporous membrane BOs, the film and bubble BOs are briefly described.

### 23.2.1 FILM AND BUBBLE BOs

The original BOs were the film BOs. These BOs used rotating cylinders to spread blood in a continuously renewed thin film while oxygen flowed over the film of blood. Though there was direct contact between the blood and gas phases, the gas exchange efficiency was low leading to devices that had very large priming volumes. The first film BO was invented by von Frey and Gruber in 1885 [5]. Using the same principle, Gibbon developed his first film BO in 1937 [6]. After more than 10 years of testing, Gibbon performed the first successful open-heart surgery using his film BO in 1953 [3,7].

Next came the bubble BOs. In these devices, the gas exchange efficiency was increased by dispersing bubbles of oxygen in the blood, which resulted in significantly reduced priming volumes compared to the film BOs [8]. Since bubbling gas through blood leads to foam formation, silicone compounds were used as defoaming agents [9]. In 1955, DeWall et al. performed the first successful cardiopulmonary bypass procedure using a bubble BO [10].

Although the benefits of bubble versus film BOs were often debated, both have their own limitations. For film BOs, though the blood surface area is large, the gas transfer efficiency was often compromised by channeling of the blood flow [5,11,12]. Further, a large priming volume was usually required to obtain sufficient gas exchange. On the other hand, bubble BOs caused significant damage to the blood.

### 23.2.2 NONPOROUS MEMBRANE BOs

To improve the hemocompatibility of BOs, and avoid direct contact between the blood and gas phases, a nonporous membrane was placed between the blood and gas phases giving rise to membrane BOs [13–17]. The initial challenge in membrane technology was to produce reliable membranes with high permeabilities for  $O_2$  and  $CO_2$ . The first nonporous membrane materials included polyethylene, polypropylene, and ethylcellulose. The permeability of  $CO_2$  in these membrane materials was only five times greater than the permeability of  $O_2$ . Consequently, given the much lower  $CO_2$  concentrations of  $CO_2$  transfer were membrane limited.

The second generation of nonporous membranes was silicon based which displayed increased  $CO_2$  permeabilities. In 1965, Bramson et al. commercialized the first nonporous membrane BO [18]. Since the diffusion coefficient of oxygen and carbon dioxide in air is about four orders of magnitude higher than in blood, the gas side mass-transfer resistance was negligible. The major resistance to respiratory gas transfer was due to the membrane and the liquid side concentration boundary layer [19]. Though nonporous membrane BOs reduced blood damage, up to  $5.5 \text{ m}^2$  membrane surface area was often required to ensure adequate gas transfer rates.

### 23.2.3 MICROPOROUS MEMBRANE BOs

The next major advance in the development of membrane BOs came with the introduction of hydrophobic microporous membranes. These membranes were made from polypropylene or Teflon. Membrane pore diameters ranged from 0.02 to 0.6  $\mu\text{m}$ . Red blood cells on the other hand consist of biconcave discs with an average diameter of 6–8  $\mu\text{m}$ . Since the membranes are hydrophobic, the pores are gas filled. Even though many plasma proteins are much smaller than the membrane pores, the blood plasma cannot flow through the pores as long as the pressure drop from the blood side to the gas side is lower than the threshold value, called the breakthrough pressure. The respiratory gases pass through the membrane pores rather than the membrane material. Consequently, the major resistance to gas transfer is the blood side concentration boundary layer.

### 23.2.4 FLAT SHEET VERSUS HOLLOW FIBER

In 1980, microporous membrane BOs accounted for only 20% of all BOs sold in the United States [20]. At that time, the gas transfer performance of membrane BOs, such as the Baxter Travenol Modulung-Teflo and Travenol TMO (Baxter Travenol Laboratories, Inc., now Baxter International, Deerfield, Illinois), was not yet comparable with that of bubble BOs. Further the membrane BOs were complex to operate. During the early 1980s, the designers of membrane BOs started to focus on incorporating passive mixing of the blood to reduce the blood side resistance to gas transfer. For example, the Cobe CML (Cobe Cardiovascular, Arvada, Colorado) contained a microporous flat sheet membrane with a screen (spacer) in the blood channels to induce mixing [21]. The membrane surface area was reduced to 2.5 m<sup>2</sup>. The Johnson and Johnson Extracorporeal Maxima (Johnson and Johnson Cardiovascular, Anaheim, California) used cross-wound hollow fibers where the blood flowed outside the fibers [22]. By increasing the gas transfer efficiency of these BOs, the membrane surface area and priming volume were reduced. As a consequence of these improvements, by 1986, membrane BOs accounted for more than 60% of all BOs sold in the United States. This number further increased to 98% in 1992 and then to 99% in 1994. Today nearly 100% of BOs sold in the United States contain microporous membranes. In 1999, the total BO market was worth about \$460 million. In 2001, this number had risen to over \$500 million and is expected to be almost \$650 million in 2006 [23]. Table 23.1 summarizes some of the BO manufacturers today whereas Table 23.2 lists major BO membrane suppliers.

Today both flat sheet and hollow fiber BOs are sold though the hollow fiber geometry is more common. BOs with very low membrane surface areas (e.g., Sarns Turbo, 3M Health Care, Ann Arbor, Michigan; and Cobe Optima, Cobe Cardiovascular, have surface areas of 1.9 and 1.7 m<sup>2</sup>, respectively) have been built using carefully spaced mats of woven hollow fibers [24,25]. These woven hollow fibers provide uniform flow channels, which minimizes channeling of the blood. Figures 23.4 and 23.5 are schematic representations of typical flat sheet and hollow fiber BOs. Flat sheet BOs are made from a flat sheet hydrophobic membrane. To introduce passive mixing and provide proper flow distribution, screens are placed between membranes. During operation, gas flows on one side of the membrane, while blood is delivered to the other side, as shown in Figure 23.4. Typical flat sheet BOs include Cobe VPCML Plus and Cobe Duo (Cobe Cardiovascular).

Hollow fiber BOs use hydrophobic membranes. In most designs, the blood flows outside and across the fibers. Consequently, the fibers help disrupt the blood side concentration boundary layer. Hollow fiber and flat sheet BOs have almost equivalent hemocompatibility and gas exchange performance. However, the gross air handling is different due to differences in the packing density (total available membrane surface area per unit volume). For flat sheet BOs, the packing

density is usually less than  $400 \text{ m}^2 \text{ m}^{-3}$  while for hollow fiber BOs, the packing density can approach  $3000 \text{ m}^2 \text{ m}^{-3}$ . Table 23.3 summarizes some advantages and disadvantages of flat sheet and hollow fiber membrane BOs.

Gu et al. compared flat sheet and hollow fiber BOs in terms of pressure drop, shear stress, and activation of leukocytes or white blood cells [26]. They found that both configurations displayed similar gas transfer performance. However, the pressure drop along the blood flow path of the flat sheet BOs was higher than that for hollow fiber BOs. Moreover, activation of leukocytes in flat sheet BOs was greater.

### 23.3 DESIGN OF BOs

Designing improved BOs is complex, given the interdependence of the important design variables. Increasing the rate of gas transfer per priming volume of the device will minimize the transfusion requirements. This is particularly important, given the risk of contamination of the patients' blood by pathogens associated with the donated blood. Reducing the membrane surface

**FIGURE 23.5** Schematic diagram of hollow fiber BOs.  $C_1$  and  $C_0$  refer to the inlet and outlet oxygen concentrations in the liquid phase.

**TABLE 23.3**  
**Comparison between Flat Sheet and Hollow Fiber Membrane BOs**

Membrane Module	Advantages	Disadvantages
Flat sheet	Better consistency Air handling Low gas side pressure Low plasma weepage	Low packing density Poor pulse transmission High priming volume
Hollow fiber	High packing density More efficient Low priming volume	Priming more difficult High gas side pressure

area present will reduce the cost of the device. Finally, ideal designs are ones which disrupt the blood side mass-transfer boundary layer thus enhancing the rate of gas transfer yet minimizing blood damage.

**23.3.1 OXYGENATION AND DEOXYGENATION OF WATER**

Due to the complexity of dealing with human blood, many previous fundamental studies have focused on developing mass-transfer and friction factor correlations for BOs using Newtonian fluids such as water and glycerol water mixtures as a substitute for blood [27–35]. The use of a nonbiological, nonpathogenic blood analogue fluid to test BOs provides a number of advantages. Units of human and animal blood show a great deal of biological variability. Further a number of safety procedures, especially when using human blood, must be followed to minimize the risk of transmission of pathogens from the blood being tested to the operator.

The transfer of oxygen to Newtonian blood analogue fluids may be described by the following equation [36]:

$$N = K\Delta C \tag{23.1}$$

where

- $N$  is the total molar flux
- $\Delta C$  is the overall concentration difference
- $K$  is the overall average mass-transfer coefficient

A mass balance over the liquid phase results in the following expression for the overall average mass-transfer coefficient:

$$K = \frac{Q}{A} \int_{C_1}^{C_0} \frac{dC}{C^* - C} \tag{23.2}$$

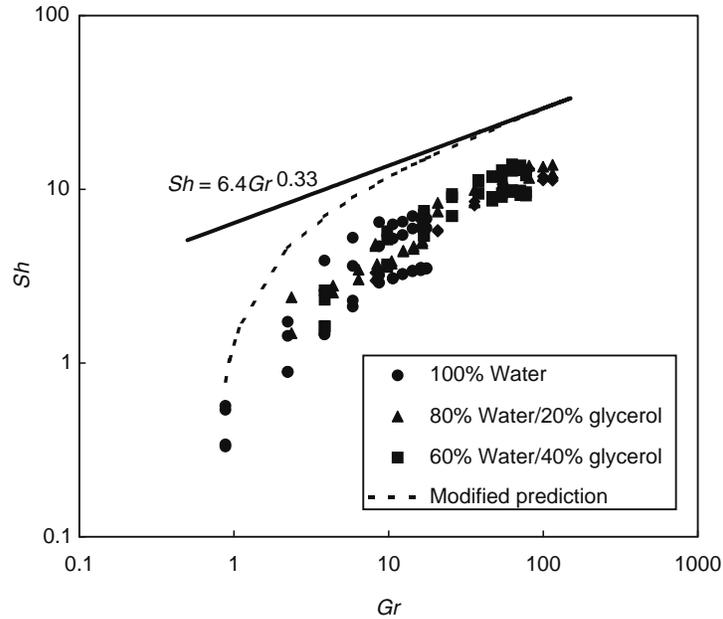

where

- $Q$  is the fluid flow rate
- $A$  is the membrane surface area
- $C_1$ ,  $C_0$ , and  $C^*$  are the inlet and outlet oxygen concentrations in the fluid, and the oxygen concentration in the fluid if it were in equilibrium with the gas phase, respectively; see Figures 23.4 and 23.5 [27,37]

Integration of Equation 23.2 results in the following equation, which may be used to calculate the mass-transfer coefficient from the experimentally determined oxygen concentration in the liquid phase:

$$K = \frac{Q}{A} \ln \left( \frac{C_1 - C^*}{C_0 - C^*} \right) \tag{23.3}$$

Since the liquid side concentration boundary layer represents the major resistance to gas transfer, the overall average mass-transfer coefficient may be approximated by the liquid side mass-transfer coefficient [27,38–40]. Experimentally, this means that the overall average mass-transfer coefficient is independent of gas flow rate.

**FIGURE 23.6** Mass transfer results for flat sheet BOs. Two different flat sheet BOs were tested. (From Goerke, A.R., Leung, J., and Wickramasinghe, S.R., *Chem. Eng. Sci.*, 57, 2035, 2002. With permission.)

### 23.3.1.1 Flat Sheet BOs

Goerke et al. [29] determined mass-transfer and friction factor correlations using the Cobe VPCML Plus and Cobe CML Duo (Cobe Cardiovascular). Water and water/glycerol mixtures were used as the liquid phases. Figure 23.6 shows the variation of the Sherwood number with the Graetz number where the Sherwood number and Graetz numbers are defined as [29]

$$sh = \frac{K(4B)}{D} \quad (23.4)$$

$$Gr = \frac{(4B)^2 u}{DL} \quad (23.5)$$

where

- $K$  is the overall mass-transfer coefficient
- $D$  is the diffusion coefficient of oxygen in the liquid fluids
- $B$  is the average half thickness of rectangular blood flow channel
- $L$  is the length of rectangular blood flow channel
- $u$  is the velocity

In Figure 23.6, different symbols are used for different liquids. As can be seen, the Sherwood number increases with increasing Graetz number.

Goerke et al. [29] noted that the correlation

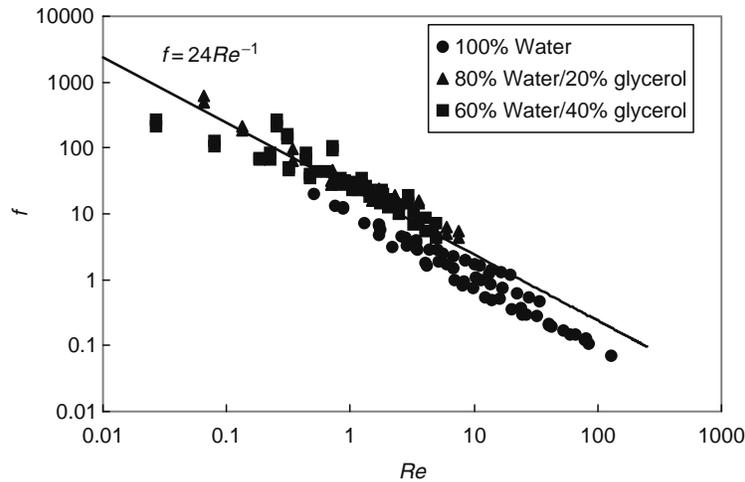

$$Sh = 6.4 Gr^{0.33} \quad (23.6)$$

does not fit the experimental data. Equation 23.6 represents the mass-transfer analogue of the L ev eque solution [41] modified for flow in rectangular ducts. The mass-transfer analogue of the L ev eque solution has been shown to predict the mass-transfer coefficient for flow in circular channels [41]. Goerke et al. used the following equations to describe their experimental data [29]:

$$Sh = 0.5 Gr \quad \text{for } 0.5 < Gr < 10 \quad (23.7)$$

$$Sh = 3.0 Gr^{0.33} \quad \text{for } 10 < Gr < 500 \quad (23.8)$$

At higher Graetz numbers, the experimental data lie parallel to but below the L ev eque solution. This is most likely because the screen, placed in the blood flow channel, touches the membrane. Thus the membrane surface area available for gas transfer is

**FIGURE 23.7** Variation of the friction factor with Reynolds number. Two different flat sheet BOs were tested. (From Zhang, Q. and Cussler, E.L., *J. Membr. Sci.*, 23, 333, 1985. With permission.)

less than the actual membrane surface area present in the BO. At lower Graetz numbers, small variations in the thickness of the blood flow channels can lead to compromised gas transfer.

Goerke et al. [29] assumed that the actual thickness of the blood flow channels may be described by a truncated normal distribution. They then derived the following expression for the effective mass-transfer coefficient that incorporates the effects of variations in channel thicknesses

$$\langle K \rangle = K \left[ 1 - \left( \frac{9KA}{Q} - 3 \right) \varepsilon_0^2 + L \right] \tag{23.9}$$

where  $\varepsilon_0$  is the standard deviation of the channel thickness divided by the mean thickness. As can be seen, use of Equation 23.9 gives a better fit to the experimental data at low flow rates (i.e., low Graetz numbers, see Figure 23.6).

The variation of the friction factor with Reynolds number for flat sheet BOs is given in Figure 23.7 [29] where the Reynolds number is defined as

$$Re = \frac{u(4B)}{\nu} \tag{23.10}$$

where  $\nu$  is the kinematic viscosity.  $f$  is the friction factor which can be calculated by

$$f = \frac{B}{L} \frac{\Delta P}{\frac{1}{2} \rho \nu^2} \tag{23.11}$$

where

- $\Delta P$  is the pressure drop for liquid flow through the membrane channel
- $\rho$  is the liquid density

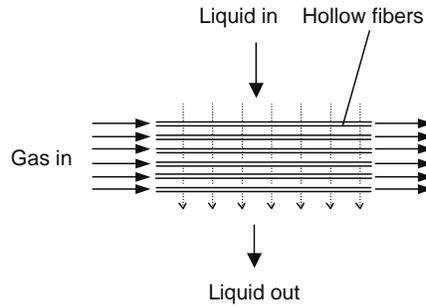

For laminar flow in rectangular ducts [42],

$$f = \frac{16}{Re \left[ \frac{2}{3} + \frac{11}{24} \frac{2B}{W} \left( 2 - \frac{2B}{W} \right) \right]} \approx \frac{24}{Re} \tag{23.12}$$

Equation 23.12, which is shown as a solid line in Figure 23.7, agrees very well with the experimental results [29].

### 23.3.1.2 Hollow Fiber BOs

Today most hollow fiber BOs are designed such that the gas phase flows inside the fibers and the blood flows outside and across the fibers (Figure 23.8). Like flat sheet BOs, several investigators have used a lumped parameter approach to determine mass-transfer and friction factor correlations for BOs. Different investigators have developed slightly different correlations. The differences in the correlations are probably indicative of the level of accuracy of this approach.

**FIGURE 23.8** Schematic diagram of hollow fiber BO where the blood flows outside and across the fibers.

Wickramasinghe et al. [28] studied various hollow fiber BOs. They found that for oxygen transfer into and out of water, a mass-transfer correlation of the form,

$$Sh = aRe^b Sc^c \quad (23.13)$$

could be used to describe the data. In Equation 23.13  $Sc$  is the Schmidt number defined as

$$Sc = \frac{\nu}{D} \quad (23.14)$$

In Equation 23.13,  $a$ ,  $b$ , and  $c$  are empirical constants. The Sherwood and Reynolds numbers are defined as

$$Sh = \frac{Kd_e}{D} \quad (23.15)$$

$$Re = \frac{ud_e}{\nu} \quad (23.16)$$

where  $d_e$  is the equivalent diameter defined as [30]

$$d_e = \left( \frac{\varepsilon}{1 - \varepsilon} \right) d_0 \quad (23.17)$$

where

$\varepsilon$  is the void fraction defined as the ratio of the empty volume within the mass-transfer chamber to the total volume of the mass-transfer chamber

$d_0$  is the outside diameter of the hollow fibers

They suggested the following correlation [28]:

$$Sh = 0.8Re^{0.47} Sc^{0.33} \quad (23.18)$$

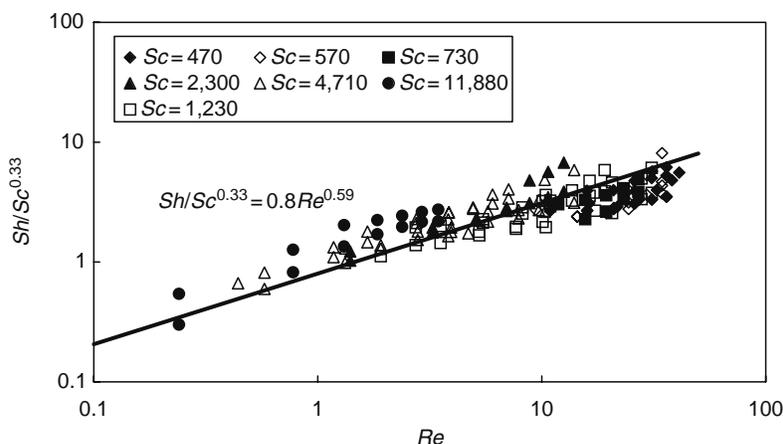

More recently, Goerke et al. [29] studied three commercially available hollow fiber BOs (Cobe Optima, Cobe Optima XP, and Cobe Optimin, Cobe Cardiovascular). They obtained slightly different mass-transfer correlations for BOs with different hollow fiber diameters:

$$Sh = 0.39Re^{0.59} Sc^{0.33} \quad \text{for } 200 \mu\text{m ID fibers} \quad (23.19)$$

$$Sh = 0.20Re^{0.59} Sc^{0.33} \quad \text{for } 280 \mu\text{m ID fibers} \quad (23.20)$$

In a later publication, Wickramasinghe et al. [30] varied the Schmidt number of the liquid phase by conducting experiments with various water/glycerol mixtures. The results are shown in Figure 23.9. They obtained the following mass-transfer correlation [30]:

$$Sh = 0.8Re^{0.59} Sc^{0.33} \quad (23.21)$$

**FIGURE 23.9** Variation of  $Sh/Sc^{0.33}$  with Reynolds number for Newtonian fluids. (From Wickramasinghe, S.R., Garcia, J.D., and Han, B., *J. Membr. Sci.*, 208, 247, 2002. With permission.)

It is likely that the correlations (Equations 23.18 through 23.21) are in fact the same, given the accuracy of the lumped parameter approach.

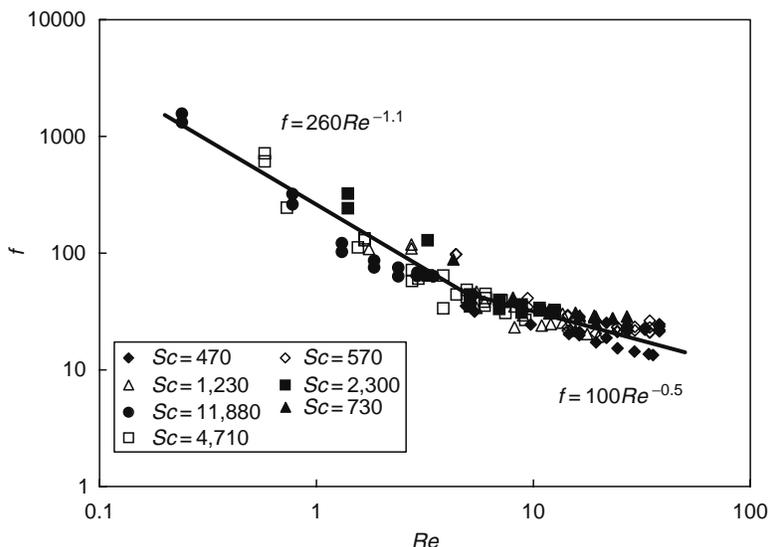

Wickramasinghe et al. [30] also determined the variation of the friction factor with Reynolds number. The results are given in Figure 23.10. They used the following correlations to describe the friction factor for flow across woven hollow fibers [30]:

$$f = 260Re^{-1.1} \quad 0.1 < Re < 5 \tag{23.22}$$

$$f = 100Re^{-0.5} \quad 5 < Re < 100 \tag{23.23}$$

The range of liquid flow rates used to generate the data in Figure 23.10 is similar to the blood flow rates used in clinical practice. Figure 23.10 shows that for Reynolds numbers between 5 and 10, the slope of the friction factor versus Reynolds number curve changes suggesting the onset of boundary layer separation. Boundary layer separation will lead to mixing of the blood and a decrease in the blood side mass-transfer resistance.

Catapano et al. [35] studied the mass and momentum transport in hollow fiber BOs. Water and oxygen were used as the liquid and gas phases, respectively. They investigated the effect of the shell void fraction ( $\epsilon$ ) and the membrane angle with respect to the main direction of liquid flow ( $\phi$ ). They proposed the following correlations [35]:

**FIGURE 23.10** Variation of friction factor with Reynolds number for Newtonian fluids. (From Wickramasinghe, S.R., Garcia, J.D., and Han, B., *J. Membr. Sci.*, 208, 247, 2002. With permission.)

$$Sh = \left( Re \frac{d_c}{4L} \right)^{0.15} \left( \frac{\varepsilon}{1 - \varepsilon} \right)^{-0.13} Sc^{0.33} (1.1 + 1.2e^{-0.1\phi}) \quad (23.24)$$

$$f = Re^{-0.43} (1 - \varepsilon)^{-1.22} (1.75 + 0.049\phi) \quad (23.25)$$

Their mass-transfer and friction factor correlations were derived for a range of Reynolds numbers between 20 and 60.

Rajasubramanian et al. [43] investigated oxygen transfer to saline in a commercial available hollow fiber BO (Avecor affinity BO, Avecor Cardiovascular Inc., Minneapolis, Minnesota). They obtained the following mass-transfer correlation:

$$Sh = 0.34Re^{0.18} Sc^{0.33} \quad (23.26)$$

Vaslef et al. [44] determined oxygen transfer rates in water using three commercial available hollow fiber BOs (SMO1 and Sarns Turbo Oxygenator, Sarns/3M, Ann Arbor, Minnesota; Bentley Univox, Bentley Laboratories, Irvine, California). They found that

$$\text{For SMO1: } Sh = 0.136Re^{0.832} Sc^{0.33} \quad (23.27)$$

$$\text{For Turbo: } Sh = 0.159Re^{0.751} Sc^{0.33} \quad (23.28)$$

$$\text{For Univox: } Sh = 0.256Re^{0.779} Sc^{0.33} \quad (23.29)$$

### 23.3.2 EFFECTS OF NON-NEWTONIAN BLOOD RHEOLOGY

The preceding studies used Newtonian fluids, generally water and glycerol water mixtures, to model blood. However, the rheological behavior of blood is complex. Blood is a shear-thinning, viscoelastic fluid. Further, blood also shows thixotropic properties due to its slow recovery from shear degradation and displays an apparent yield stress [45]. Blood rheology is often described in terms of two basic phenomena [46]: red cell deformation and red cell aggregation. Red cell deformation causes the viscosity of blood at high shear rates to be less than that obtained at low shear rates, while red cell aggregation causes a large increase in viscosity at low shear rates. At high cell concentrations, cell–cell interactions are also thought to play a critical role in determining the overall rheological properties of blood [47].

During cardiopulmonary bypass, addition of fluids such as anticoagulants leads to a reduction in the hematocrit or percentage of the total blood volume that is made up of red blood cells. Thus the elastic properties of blood do not affect blood flow in a BO [48]. Further, since the hematocrit of the blood is low, cell–cell interactions are likely to be less important. In modern BOs, the average relative shear stress on the blood is about 5–30 Pa [20]. Under these conditions, blood may be modeled as a shear-thinning fluid. Consequently, a Newtonian blood analogue fluid cannot model the variation of blood viscosity with shear rate.

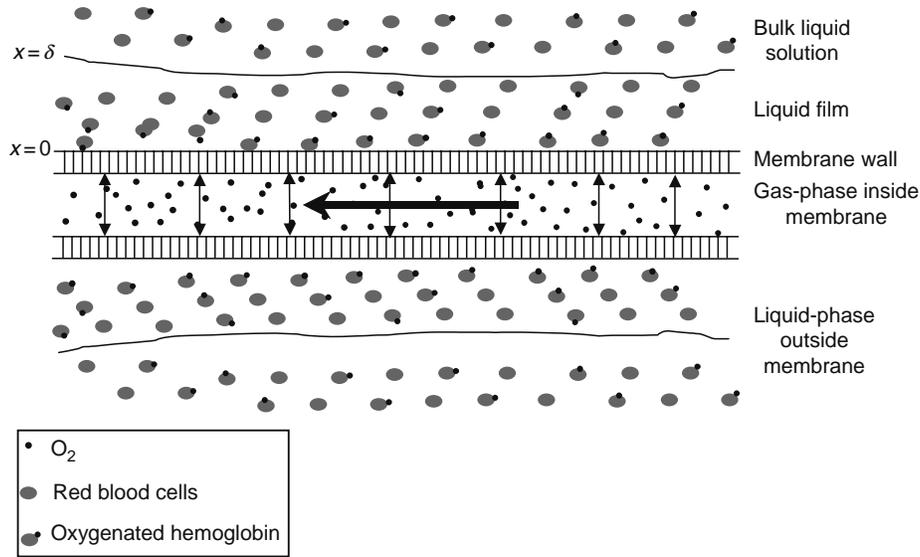

Wickramasinghe et al. prepared non-Newtonian blood analogue fluids by adding polyacrylamide and xanthan gums to water and glycerol/water mixtures [32]. Mann and Tarbell [49] found that xanthan gum solutions model the viscous and elastic behavior of blood more accurately than polyacrylamide solutions. For shear-thinning fluids, the kinematic viscosity is not constant but varies with the shear stress. By using generalized Reynolds and Schmidt numbers, assuming power law fluid behavior, Wickramasinghe et al. found that the results for non-Newtonian fluids can be described using the same correlations derived for Newtonian fluids [32–34].

### 23.3.3 EFFECTS OF OXYGEN BINDING TO HEMOGLOBIN

In human blood, oxygen not only dissolves in the plasma but also binds to hemoglobin. The reaction between oxygen and hemoglobin leads to an enhanced rate of oxygen transfer compared to nonreactive blood analogue fluids. Thus to predict the performance of a BO, the effect of the oxygen–hemoglobin reaction must be included in the mass-transfer coefficient. Based on film theory [50], Wickramasinghe et al. introduced a mass-transfer enhancement factor to account for the increased rate of oxygen transfer due to the oxygen–hemoglobin reaction [33,34]. Figure 23.11 is a schematic representation of the liquid film that is assumed to exist at the membrane surface.

Hemoglobin is a globular protein composed of four polypeptide chains each containing a heme group. The oxygen-binding curve for hemoglobin (i.e., percentage of saturation of hemoglobin as a function of oxygen partial pressure) may be described empirically assuming the reaction between hemoglobin and oxygen is given by the following expression:

**FIGURE 23.11** (See color insert following page 588.) Schematic representation of liquid film at the surface of a hollow fiber. (From Wickramasinghe, S.R. and Han, B., *Chem. Eng. Res. Des.*, 83(A3), 256, 2005. With permission.)

where

$n$  is a measure of cooperatively between heme units [51]

$k_1$  and  $k_{-1}$  are the forward and backward rate constants

An apparent equilibrium constant,  $K_E$ , based on Equation 23.30 may be defined as

$$K_E = \frac{k_1}{k_{-1}} = \frac{[\text{Hb}(\text{O}_2)_n]}{[\text{Hb}][\text{O}_2]^n} \quad (23.31)$$

where  $[\text{Hb}(\text{O}_2)_n]$ ,  $[\text{Hb}]$ , and  $[\text{O}_2]$  are the concentrations of oxygenated hemoglobin, nonoxygenated hemoglobin, and dissolved oxygen in the plasma, respectively.

Since the gas side resistance to mass transfer is negligible in microporous membrane BOs, only the liquid side film is considered. Mass transfer by convection within the film is negligible. Further there is no mass accumulation at any point within the film. Consequently, steady-state mass balances in the liquid film on  $[\text{O}_2]$ ,  $[\text{Hb}]$ , and  $[\text{Hb}(\text{O}_2)_n]$  lead to Equations 23.32 through 23.34 [36,52]:

$$0 = \frac{\partial[\text{O}_2]}{\partial t} = D_{\text{O}_2} \frac{\partial^2([\text{O}_2])}{\partial x^2} + nk_{-1}[\text{Hb}(\text{O}_2)_n] - nk_1[\text{Hb}][\text{O}_2]^n \quad (23.32)$$

$$0 = \frac{\partial[\text{Hb}]}{\partial t} = D_{\text{Hb}} \frac{\partial^2([\text{Hb}])}{\partial x^2} + k_{-1}[\text{Hb}(\text{O}_2)_n] - k_1[\text{Hb}][\text{O}_2]^n \quad (23.33)$$

$$0 = \frac{\partial[\text{Hb}(\text{O}_2)_n]}{\partial t} = D_{\text{Hb}(\text{O}_2)_n} \frac{\partial^2([\text{Hb}(\text{O}_2)_n])}{\partial x^2} - k_{-1}[\text{Hb}(\text{O}_2)_n] + k_1[\text{Hb}][\text{O}_2]^n \quad (23.34)$$

The general solution for Equations 23.32 through 23.34 is [53]

$$D_{\text{O}_2}[\text{O}_2] + nD_{\text{Hb}(\text{O}_2)_n}[\text{Hb}(\text{O}_2)_n] = a_1x + a_2 \quad (23.35)$$

$$D_{\text{Hb}}[\text{Hb}] + D_{\text{Hb}(\text{O}_2)_n}[\text{Hb}(\text{O}_2)_n] = a_3x + a_4 \quad (23.36)$$

where  $a_1$ ,  $a_2$ ,  $a_3$ , and  $a_4$  are empirical constants. Four boundary conditions are required. At the gas–liquid interface (surface of the membrane on the liquid side),  $x=0$ . Here,

$$[\text{O}_2] = [\text{O}_2]_0 \quad (23.37)$$

where  $[O_2]_0$  is the dissolved oxygen concentration in the liquid phase that is in equilibrium with the gas-phase concentration. At the outer edge of the stagnant film,  $x = \delta$ . Here

$$[O_2] = [O_2]_\delta \quad (23.38)$$

$$[Hb] = [Hb]_\delta \quad (23.39)$$

where  $[O_2]_\delta$  and  $[Hb]_\delta$  are the same as the dissolved oxygen and nonoxygenated hemoglobin concentrations in the bulk liquid.

Neither hemoglobin nor oxygenated hemoglobin can leave the liquid phase. Thus the fourth boundary condition states that the flux of total hemoglobin is zero.

$$D_{Hb} \frac{d[Hb]}{dx} + D_{Hb(O_2)_n} \frac{d[Hb(O_2)_n]}{dx} = 0 \quad (23.40)$$

The rate of oxygen transfer through the stagnant film is equal to the dissolved oxygen flux plus the oxygenated hemoglobin flux. Thus the oxygen flux,  $J$ , is given by

$$J = -D_{O_2} \frac{d[O_2]}{dx} - nD_{Hb(O_2)_n} \frac{d[Hb(O_2)_n]}{dx} = -a_1 \quad (23.41)$$

Substituting Equations 23.31 and 23.35 through 23.40 into Equation 23.41 results in

$$J = \frac{D_{O_2}}{\delta} ([O_2]_0 - [O_2]_\delta) \left\{ 1 + \frac{nD_{Hb(O_2)_n}}{D_{O_2}} \cdot \frac{1}{1 + \frac{D_{Hb(O_2)_n}}{D_{Hb}} K_E [O_2]_0^n} \cdot \frac{[O_2]_0^n - [O_2]_\delta^n}{[O_2]_0 - [O_2]_\delta} K_E [Hb]_\delta \right\} \quad (23.42)$$

In the absence of a chemical reaction between oxygen and hemoglobin, the oxygen flux  $J_0$  is given by

$$J_0 = \frac{D_{O_2}}{\delta} ([O_2]_0 - [O_2]_\delta) = k_0 ([O_2]_0 - [O_2]_\delta) \quad (23.43)$$

where  $k_0$  is the mass-transfer coefficient in the absence of chemical reaction. Comparing Equations 23.42 and 23.43,

$$k = k_0 \left\{ 1 + \frac{nD_{Hb(O_2)_n}}{D_{O_2}} \cdot \frac{1}{1 + \frac{D_{Hb(O_2)_n}}{D_{Hb}} K_E [O_2]_0^n} \cdot \frac{[O_2]_0^n - [O_2]_\delta^n}{[O_2]_0 - [O_2]_\delta} K_E [Hb]_\delta \right\} = k_0 E \quad (23.44)$$

where the term in brackets is the enhancement factor,  $E$ . The enhancement factor is a function of the oxygen partial pressure, as the oxygen partial pressure increases, the enhancement factor decreases.

The enhancement factor given by Equation 23.44 contains the diffusivity of oxygen hemoglobin and oxyhemoglobin. Since the hemoglobin is found within the red blood cells, the diffusivity of hemoglobin and oxyhemoglobin is the same as the diffusivity of the red blood cells. The diffusivity of red blood cells is significantly enhanced by rotation and deformation of the cells, which is a function of shear rate [33]. As the shear rate increases so does the diffusivity of the red blood cells and hence the mass-transfer enhancement factor given by Equation 23.44. Consequently, designs which maximize the diffusivity of red blood cells will display higher rates of gas transfer.

The enhancement factor given in Equation 23.44 assumes film theory. Other enhancement factors have also been described [54–56]. For example, Shimizu and Yoshida proposed the following equation to calculate the enhancement factor [54,56]:

$$E = \left( \frac{95,000}{P_{O_2}} \right)^{1/3} \left\{ 1 + 11.8 \left[ (1-s) \frac{Ht}{100} \right]^{0.8} - 8.9 \left[ (1-s) \frac{Ht}{100} \right] \right\} \quad (23.45)$$

In blood, oxygen is present in both dissolved and chemically reacted forms. Therefore, the oxygen concentration in blood is given by

$$C = C_C + C_P = \beta \left( \frac{Ht}{100} \right) S + \alpha P_{O_2} \quad (23.46)$$

where

$\beta$  is the maximum amount of oxygen that can combine with a unit volume of hemoglobin

$C_C$  and  $C_P$  are the oxygen concentration bound to hemoglobin and dissolved in the plasma, respectively

$S$  is the degree of oxygen saturation (oxyhemoglobin saturation), which is given by the ratio  $[\text{Hb}(\text{O}_2)_n]/[\text{Hb}]_t$ , where  $[\text{Hb}]_t$  is the total hemoglobin concentration (oxygenated and nonoxygenated) present

The degree of oxygen saturation is often described by the Hill equation [57–60]:

$$S = \frac{[\text{Hb}(\text{O}_2)_n]}{[\text{Hb}]_t} = \frac{(P_{\text{O}_2}/P_{50})^n}{1 + (P_{\text{O}_2}/P_{50})^n} \quad (23.47)$$

where  $P_{\text{O}_2}$  and  $P_{50}$  are the oxygen partial pressure and the oxygen partial pressure, respectively, at 50% hemoglobin saturation.

By combining Equation 23.46, Equation 23.2 can be rewritten as

$$K = \frac{Q}{A} \int_{C_{P,I}}^{C_{P,O}} \frac{dC}{(C^* - C_P)} = \frac{Q}{A} \int_{C_{P,I}}^{C_{P,O}} \frac{d[\beta(\text{Ht}/100)S + \alpha P_{\text{O}_2}]}{(C^* - C_P)} \quad (23.48)$$

where  $C_{P,I}$  and  $C_{P,O}$  are the oxygen concentration dissolved in the plasma in the inlet and outlet stream, respectively. By using the oxygen partial pressure to replace the dissolved oxygen concentration,

$$K = \frac{Q}{A} \int_{P_{\text{O}_2,I}}^{P_{\text{O}_2,O}} \frac{\beta(\text{Ht}/100)(dS/dP_{\text{O}_2}) + \alpha}{(P_{\text{O}_2}^* - P_{\text{O}_2})} dP_{\text{O}_2} \quad (23.49)$$

where  $P_{\text{O}_2,I}$ ,  $P_{\text{O}_2,O}$ , and  $P_{\text{O}_2}^*$  are the inlet and outlet oxygen partial pressure that would be in equilibrium with the oxygen in the blood and the oxygen partial pressure in the gas phase, respectively.  $dS/dP_{\text{O}_2}$  can be obtained by differentiating Equation 23.47.

Finally, the overall average mass-transfer coefficient in the absence of the reaction between oxygen and hemoglobin may be calculated from

$$K_0 = \frac{Q}{A} \int_{P_{\text{O}_2,I}}^{P_{\text{O}_2,O}} \frac{\beta(\text{Ht}/100)(dS/dP_{\text{O}_2}) + \alpha}{E(P_{\text{O}_2}^* - P_{\text{O}_2})} dP_{\text{O}_2} \quad (23.50)$$

Wickramasinghe et al. used bovine blood to evaluate the Cobe Duo and Cobe Optima XP BOs (Cobe Cardiovascular) [33,34]. By using  $K_0$  to calculate the Sherwood number, as well as the analogous Reynolds and Schmidt number for power law fluids, Wickramasinghe et al. found that results for bovine blood do collapse onto the same curve as the results for Newtonian and non-Newtonian blood analogue fluids. Their results are shown in Figures 23.12 and 23.13 [33,34].

Matsuda and Sakai proposed the following mass-transfer correlation for hollow fiber BOs [61]:

$$Sh = Sc^{1/3} Re^{2/3} \exp(3.29\varepsilon - 4.27) \quad (23.51)$$

However, the range of Reynolds numbers tested was very small being 2–20.

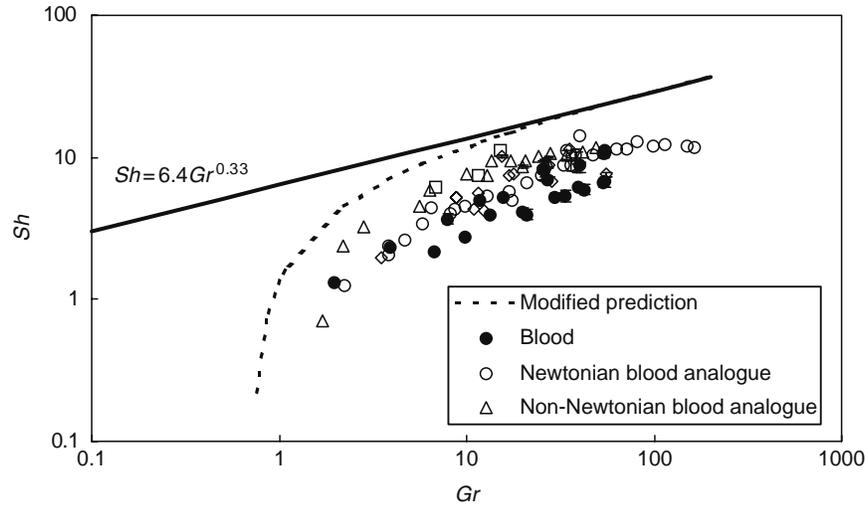

### 23.3.4 VALUE OF LUMPED PARAMETER APPROACHES

Table 23.4 summarizes some of the literature correlations. As can be seen most of these correlations were developed using Newtonian blood analogue fluids such as water and glycerol water solutions. These correlations may be used to help guide better BO designs. Table 23.4 indicates that correlations obtained by different researchers using different modules are not always the same. Thus caution is needed when using these correlations to ensure they are applicable to the operating conditions being considered.

## 23.4 CFD METHODS IN BOs

### 23.4.1 CFD APPLICATION IN BO STUDIES

Recently, computational fluid dynamics (CFD) models have been developed to guide the development of new BO designs [62–67]. Baker et al. developed a two-dimensional finite-difference model to solve the Navier–Stokes equation and to predict

**FIGURE 23.12** Variation of Sherwood number with Graetz number. Results are given for Newtonian and non-Newtonian blood analogue fluids and bovine blood for flat sheet BOs. The solid line depicts Equation 23.6. The dashed line gives the predictions of Equation 23.9. (From Wickramasinghe, S.R., Han, B., Garcia, J.D., and Specht, R., *AIChE J.*, 51, 656, 2005. With permission.)

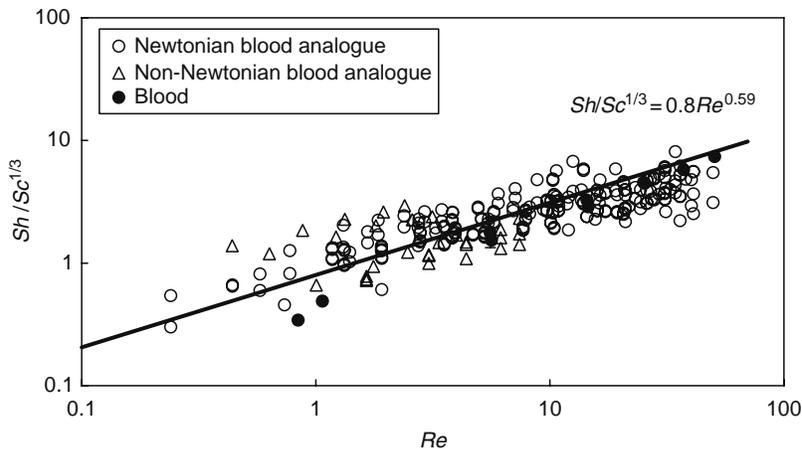

gas transfer to blood flowing outside hollow fibers [62]. Using this model, Baker et al. calculated the oxygen saturation profile and the velocity profile along the membrane module. They further compared their simulation results to experimental data for bovine and human blood. They obtained reasonable agreement.

Gage et al. developed a three-dimensional CFD model to predict the pressure drop in a membrane BO [63]. They modified a commercial membrane BO to allow pressure measurement along the fiber bundle in all cardinal axes. Close agreement was obtained between experimental and simulated pressure drops at lower flow rates. However, the simulated pressure drops were lower than the experimental results at higher flows.

Funakubo et al. used a CFD model to evaluate 10 artificial implantable lungs [64]. Their research focused on the occurrence of thrombogenesis. They built a prototype to verify their CFD predictions. They found a correlation between predicted areas of low flow and thrombus formation. Further although nearly identical low flow velocity conditions exist at both the inlet and outlet ports, thrombus formation occurs only near the outlet port, which agreed with detailed vectorial analysis. Gartner et al. also used a CFD approach to model flow effects on thrombotic deposition on a membrane BO [67].

### 23.4.2 LIMITATIONS

Although CFD has been widely used to model blood pumps and other membrane processes, its application in membrane BOs is very limited. Development of a CFD model requires simplifying assumptions. In their model, Baker et al. assumed that blood was statistically homogeneous; the reaction between oxygen and hemoglobin was fast; axial diffusion of gas was neglected;

**FIGURE 23.13** Variation of  $Sh/Sc^{1/3}$  with Reynolds number. Results are shown for Newtonian and non-Newtonian blood analogue fluids and bovine blood for hollow fiber BOs. Solid lines depict Equation 23.21. (From Wickramasinghe, S.R., Han, B., Garcia, J.D., and Specht, R., *AIChE J.*, 51, 656, 2005. With permission.)

$2 < Re < 6$	$Sh = 0.256Re^{0.779} Sc^{0.33}$ (Univox)					

metabolic oxygen consumption by blood was neglected; all flow components were parallel to the fiber axis; fibers were parallel with no fiber crossings; cross-sectional fiber distribution was a uniform triangular array; and the blood and gas flow were fully developed [62]. Other CFD studies use similar assumptions [63–65]. Clearly, the accuracy of the model depends on the validity of the assumptions made.

CFD predictions depend on accurate determination of various parameters. For example, in the CFD model developed by Gage et al. [63], the permeability of the fiber bundle was experimentally determined from pressure drop data obtained from water perfusion testing.

While these CFD models are helpful, a large number of experimental studies are still necessary. The accuracy of a CFD model needs to be verified experimentally. As commercially available CFD software becomes more sophisticated, these simulations will provide a powerful tool to help design better membrane BOs.

### 23.5 FUTURE TRENDS

In 2002, of the 709,000 open-heart surgeries conducted in the United States, 368,000 were for patients over 65 years of age. Another 261,000 were for patients between 45 and 64 while 41,000 for patients between 15 and 44 years of age [4]. Current membrane BOs are very efficient in terms of the rate of gas transfer. The total membrane surface area is around 2 m<sup>2</sup>. During operation, the effective blood film thickness (shown in Figure 23.11) is around 100 μm [20]. By further increasing the gas transfer rate, the total membrane surface may be further decreased. This will further decrease the priming volume as well as the cost of BOs. Since the dominant mass-transfer resistance for BOs is the blood side concentration boundary layer, further increases in gas exchange efficiency will most likely be achieved using newer module designs that involve blood flow augmentation. For example, centrifugal blood flow has been investigated [68]. Although these designs have yet to be commercialized, development of novel auxiliary equipment for these designs may improve their commercial viability.

The primary mode of failure for membrane BOs is due to plasma leakage through the pores of the hydrophobic membrane [69]. This leakage will cause a reduction in the gas transfer efficiency. Most commercial BOs are designed to operate without plasma leakage for at least 6 h. Plasma leakage may be minimized by using smaller membrane pore sizes or coating the membrane pores with a thin film [70]. However, this will lead to an increase in the membrane resistance to gas transfer.

During cardiopulmonary bypass, due to the contact between blood and the membrane surface, the patients' hematological and immune systems may be affected. Thus development of more hemocompatible BO membranes remains an important challenge. Since deposition and activation of platelets, leukocytes, and proteins are thought to be the primary responses that occur when blood contacts a BO membrane surface, the BOs hemocompatibility may be improved by developing materials that suppress adsorption of blood components.

### NOMENCLATURE

$a$	empirical constant
$a_1, a_2, a_3, a_4$	constants
$A$	membrane surface area (m <sup>2</sup> )
$b$	empirical constant
$B$	average half thickness of the rectangular channels (m)
$c$	empirical constant
$C$	concentration (mol L <sup>-1</sup> )
$C^*$	oxygen concentration in the liquid in equilibrium with the gas phase (mol L <sup>-1</sup> )
$C_C$	oxygen bound to hemoglobin (mol L <sup>-1</sup> )
$C_P$	oxygen dissolved in plasma (mol L <sup>-1</sup> )
$C_{P,I}$	physically dissolved oxygen in plasma at the inlet of the BO (mol L <sup>-1</sup> )
$C_{P,O}$	physically dissolved oxygen in plasma at the outlet of the BO (mol L <sup>-1</sup> )
$\Delta C$	overall concentration difference (mol L <sup>-1</sup> )
$D$	diffusion coefficient (m <sup>2</sup> s <sup>-1</sup> )
$d_e$	equivalent diameter (m)
$d_0$	outside diameter of the hollow fibers (m)
$E$	enhancement factor
$f$	friction factor
Ht	hematocrit (%)
$J$	flux (mol m <sup>-2</sup> s <sup>-1</sup> )
$J_0$	oxygen flux in the absence of chemical reaction between oxygen and hemoglobin (mol m <sup>-2</sup> s <sup>-1</sup> )
$K$	overall average mass-transfer coefficient (m s <sup>-1</sup> )
$K_E$	equilibrium constant (units depend on value of $n$ )

$K_0$	overall average mass-transfer coefficient in the absence of chemical reaction in the boundary layer ( $\text{mol m}^{-2} \text{s}^{-1}$ )
$k_1$	forward rate constant (units depend on value of $n$ )
$k_{-1}$	backward rate constant (units depend on value of $n$ )
$\langle K \rangle$	average mass-transfer coefficient for flow in polydisperse channels ( $\text{mol m}^{-2} \text{s}^{-1}$ )
$L$	length of rectangular channel (m)
$n$	measure of cooperativity between heme units
$N$	total molar flux ( $\text{mol m}^{-2} \text{s}^{-1}$ )
$P_{\text{O}_2}$	oxygen partial pressure (Pa)
$P_{\text{O}_2,1}$	inlet oxygen partial pressure in equilibrium with the oxygen in the blood (Pa)
$P_{\text{O}_2,0}$	outlet oxygen partial pressure in equilibrium with the oxygen in the blood (Pa)
$P_{\text{O}_2}^*$	oxygen partial pressure in the gas phase (Pa)
$P_{50}$	oxygen partial pressure at 50% hemoglobin saturation (Pa)
$\Delta P$	pressure drop (Pa)
$Q$	fluid flow rate ( $\text{m}^3 \text{s}^{-1}$ )
$S$	degree of oxygen saturation
$t$	time (s)
$u$	liquid velocity ( $\text{m s}^{-1}$ )
$W$	average width of rectangular blood flow channel (m)
$x$	distance variable (m)

**GREEK SYMBOLS**

$\alpha$	physical solubility of oxygen in blood ( $\text{mol L}^{-1} \text{Pa}^{-1}$ )
$\beta$	maximum amount of oxygen combined with a unit volume of hemoglobin ( $\text{mol L}^{-1}$ )
$\varepsilon$	void fraction of a BO
$\varepsilon_0$	standard deviation divided by the mean of the distribution of channel thickness
$\rho$	liquid density ( $\text{kg m}^{-3}$ )
$\nu$	kinematic viscosity of Newtonian fluids ( $\text{m}^2 \text{s}^{-1}$ )
$\tau$	shear stress (Pa)
$\dot{\gamma}$	shear rate ( $\text{s}^{-1}$ )
$\delta$	thickness of boundary layer (m)
$\phi$	membrane angle with respect to the main direction of liquid flow ( $^\circ$ )

**DIMENSIONLESS GROUP**

$Gr$	Graetz number, $(4B)^2 u / (DL)$
$Re$	Reynolds number, $u(4B) / \nu$ , $u d_c / \nu$
$Sc$	Schmidt number, $\nu / D$
$Sh$	Sherwood number, $K(4B) / D$ , $K d_c / D$

**SUBSCRIPTS**

e	equilibrium; effective
Hb	hemoglobin
$\text{Hb}(\text{O}_2)_n$	oxyhemoglobin
I	inlet
O	outlet
$\text{O}_2$	oxygen
t	total
0	reference point

## 24.1 INTRODUCTION

The ability to regulate transport across cellular boundaries is essential to the cell's existence as an open system [1]. There is a steady traffic of ions, molecules, polymers, and other species across the plasma membrane. Consider the chemical exchanges between a human muscle cell and the extracellular fluid that surrounds it. For example, sugars, amino acids, and other nutrients enter the cell, and waste products of metabolism leave the cell. The cell takes in oxygen for cellular respiration and expels carbon dioxide. It also regulates its concentrations of inorganic ions, such as  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Cl}^-$ , by shuttling them one way or the other across the plasma membrane. Mother Nature has created natural channels that are highly selective, that is, they allow certain molecules and ions to pass more easily than others (or they reject them). For example, there are highly specialized potassium protein channels that allow potassium cations to pass through with high selectivity than other ions. Other examples include water,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Cl}^-$ , glucose protein channels, nuclear pore, and complexes. The highly selective transportation of molecules and ions is controlled by molecular recognition between transporting species and protein channels present in the cell membranes.

Understanding and mimicking of the cellular transport processes are both challenging and rewarding from scientific and technological point of view. For example in certain inherited diseases (such as cystinuria), specific transport systems are either defective or missing [1]. Cystinuria is a human disease characterized by the absence of a transport system that carries cystine and other amino acids into kidney cells. Kidney cells normally reabsorb these amino acids from the urine and return them to the blood, but a person inflicted with cystinuria develops painful stones from amino acids that accumulate and crystallize in the kidneys. Similarly, there are many technological applications of these transport processes, e.g., bioseparations, bioextractions, and synthetic nano-bioreactors.

We have synthesized highly selective template-synthesized abiotic nanotube membranes that can be used as model systems for mimicking natural ion and protein channels. These nanotubes have diameters of the same order (1–100 nm) as those found

in the natural protein channels. We have designed the nanotube membranes to selectively recognize and transport small molecules and biopolymers by modifying the inner surface of nanotubes with molecular-recognition molecules. These systems are very useful as model systems for better understanding of transport processes of molecules and biopolymers through highly constrained nanotubes. These nanotube membranes have also found many applications in the areas of chemical- and bio-separations, biocatalysis, and drug detoxification.

Here, we will report on the design, synthesis, characterization, and applications of template-synthesized nanotube membranes. Then, we will briefly review the synthesis of the template-synthesized nanotube membranes. Some details of differential-surface chemistry on nanotubes, and nanotubes for bioextraction and biocatalysis are presented. We discuss in detail the drug detoxification using functionalized nanotubes [2], and epoenzyme-, enzyme- and antibody-immobilized nanotubes for enantiomeric separations, biocatalysis, and bioextractions [3–5]. We also describe our recent results on DNA-functionalized nanotube membranes with single-nucleotide mismatch selectivity [6], and the fabrication of artificial ion-channel using single-conical nanotube membrane [7].

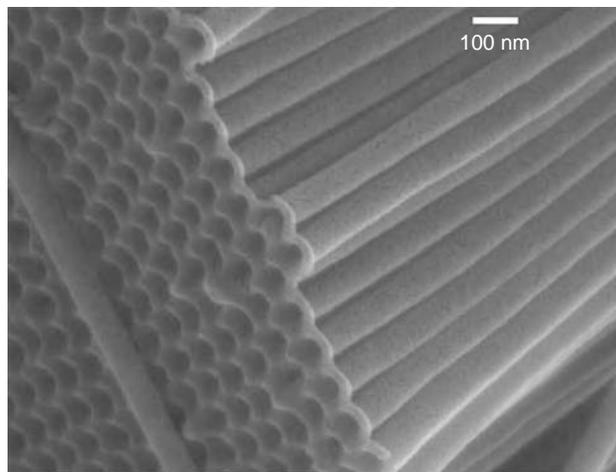

## 24.2 NOMENCLATURE OF NANOPARTICLES

In the literature, the tubular structures of interest to this review are called by various names including microtubules, microtubes, nanotubules, and nanotubes. This nomenclature can be simplified by noting that in this context, there is no difference between a tube and tubule; in this review we use only the name tube. Nano vs. micro is a more difficult issue because there is no universally accepted dimension scale above which a particle is micro, and below which it is nano. In our research group we have agreed that if a tube has at least one dimension that is 100 nm or less, it is called a nanotube.

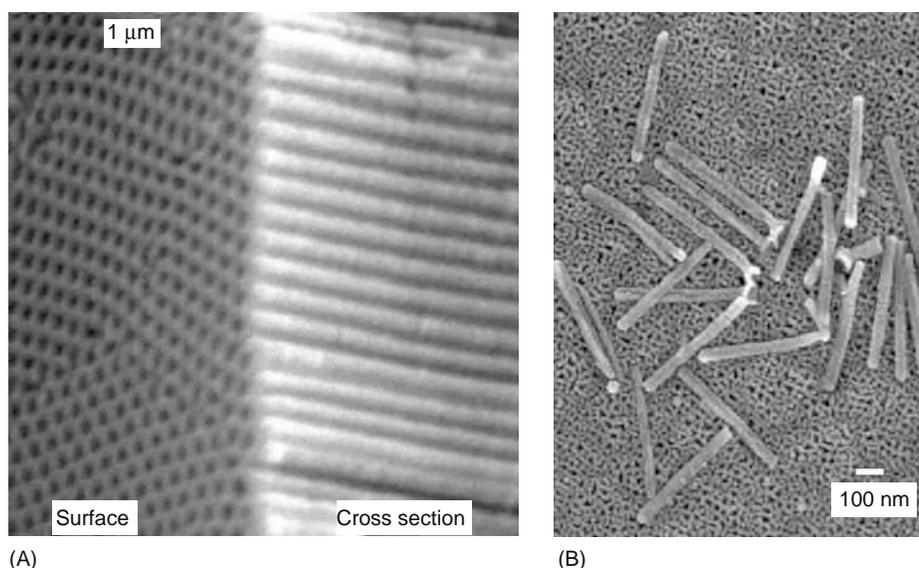

## 24.3 TEMPLATE SYNTHESIS OF NANOTUBES AND SOME RECENT ADVANCES

Spherical nanoparticles are typically used in such applications, but this only reflects the fact that spheres are easier to make than nanoparticles having other shapes. Micro- and nanotubes—structures that resemble tiny drinking straws (Figure 24.1)—are alternatives to spherical nanoparticles. Examples include organosilicon polymer nanotubes [8], self-assembling lipid microtubes [9–13], fullerene carbon nanotubes [14–17], template-synthesized nanotubes [4–6,18–22], and peptide nanotubes [23–26]. Nanotubes offer some interesting advantages relative to spherical nanoparticles for biotechnological applications. For example, nanotubes have large inner volumes (relative to the dimensions of the tube), which can be filled with any desired chemical or biochemical species ranging in size from nucleic acids and proteins to small molecules [4–6]. In addition, nanotubes have distinct inner and outer surfaces, which can be differentially chemically or biochemically functionalized [4]. This creates the possibility, for example, of loading the inside of a nanotube with a particular biochemical payload but imparting chemical features to the outer surface that render it biocompatible. Finally, nanotubes have open mouths, which make the inner surface accessible and incorporation of species within the tubes particularly easy.

The template method is a general approach for preparing nanomaterials that entail synthesis or deposition of the desired material within the cylindrical and monodisperse pores of a nanopore membrane or other solid [20–22]. Cylindrical nanostructures with monodisperse diameters and lengths are obtained, and depending on the membrane and synthetic method used, these may be solid nanowires or hollow nanotubes. This method has been used to prepare nanowires and nanotubes composed

**FIGURE 24.1** Scanning electron micrograph of an array of template-synthesized carbon nanotubes. These nanotubes are composed of disordered graphitic carbon. (From Miller, S.A., Young, V.Y., and Martin, C.R., *J. Am. Chem. Soc.*, 123, 12335, 2001. With permission.)

**FIGURE 24.2** Scanning electron micrographs. (A) The surface and cross section of a typical nanopore alumina template membrane prepared in the authors' lab. Pores with monodisperse diameters that run like tunnels through the thickness of the membrane are obtained. (B) Silica nanotubes prepared by solgel template synthesis within the pores of a template like that shown in (A). After solgel synthesis of the nanotubes, the template was dissolved and the nanotubes were collected by filtration. (From Lee, S.B., Mitchell, D.T., Trofin, L., Li, N., Nevanen, T.K., Söderlund, H., and Martin, C.R., *Science*, 296, 2198, 2002. With permission.)

of many different types of materials including metals, polymers, semiconductors, and carbons [20–22]. In addition, the template method can be used to prepare composite nanostructures, both concentric tubular composites [20,27] and segmented composite nanowires [28,29].

How one makes nanotubes within the pores of a template membrane can be illustrated by the carbon nanotubes shown in Figure 24.1 [30]. An alumina template (Figure 24.2A) was heated to 670°C and ethylene gas was passed through the membrane. This causes the ethylene to decompose on the pore walls to yield graphitic carbon nanotubes within the pores. The alumina template membrane can then be dissolved away and the carbon nanotubes are collected by filtration. These tubes have monodisperse outside diameters determined by the diameter of the pores in the template. The inside diameter is determined by the carbon deposition time. Other synthetic methods we have used include in-pore polymerization to make polymeric nanotubes, electroless deposition to make DNA nanotubes, metal nanotubes, and solgel chemistry to make nanotubes comprised of silica and other inorganic materials [20–22,27,30–34]. Templated silica nanotubes (*vide infra*) [4,5] are shown in Figure 24.2B. These nanotubes are of the same length, which is determined by the thickness of the template membrane.

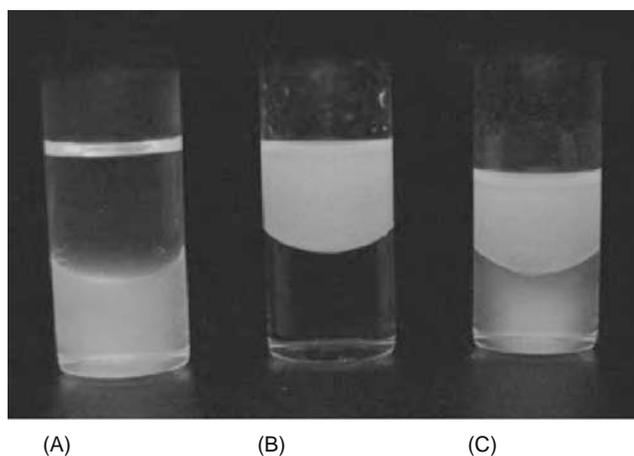

## 24.4 SILICA NANOTUBES

We have used these silica nanotubes as test vehicles to illustrate the power of the template method for preparing nanotubes for biomedical and biotechnological applications [4,5]. Silica nanotubes are ideal for such proof-of-concept experiments because they are easy to make, readily suspendable in aqueous solution, and because silica surfaces can be derivatized with an enormous variety of different chemical functional groups using simple silane chemistry with commercially available reagents [4,5].

### 24.4.1 ATTACHING DIFFERENT FUNCTIONAL GROUPS TO THE INSIDE VS. OUTSIDE SURFACES [4]

As noted above, one of the most important attributes of a nanotube is that it has distinct inner and outer surfaces that can be differentially chemical and biochemically functionalized. The template method provides a particularly easy route to accomplish this differential functionalization. The details of nanotube modifications using differential silane chemistry on nanotubes are available elsewhere [4]. In the following paragraphs, we briefly describe the results of differential-functionalized nanotubes and their applications in highly selective chemical and biochemical extractions [2,4].

To prove this concept, a set of nanotubes were prepared with the green fluorescent silane *N*-(triethoxysilylpropyl)dansylamide attached to their inner surfaces, and the hydrophobic octadecyl silane ( $C_{18}$ ) to their outer surfaces. These nanotubes were added to a vial containing water and the immiscible organic solvent cyclohexane, which were mixed and allowed to separate. Because these nanotubes are hydrophobic on their outer surfaces, they partition into the (upper) cyclohexane phase (Figure 24.3B). This may be in contrast to nanotubes that were labeled on their inner surfaces with the blue fluorescent silane triethoxysilylpropylquinineurethan, but were not labeled with any silane on their outer surfaces. When the same experiment is done on these

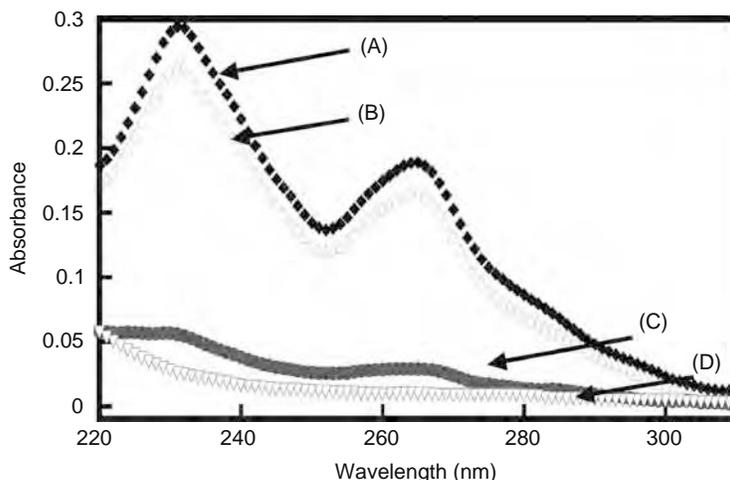

**FIGURE 24.3** (See color insert following page 588.) Photographs of vials containing nanotubes modified with two different fluorophores in two different solvent medium. (A) Cyclohexane (upper) and water (lower) under UV light excitation after addition of 10 mg of nanotubes with dansylamide on inner and  $C_{18}$  on outer surfaces, (B) quinineurethan on inner and no silane on outer surfaces, (C) 10 mg of both (A) and (B) nanotubes. 200 nm diameter nanotubes were used. (From Mitchell, D.T., Lee, S.B., Trofin, L., Li, N., Nevanen, T.K., Söderlund, H., and Martin, C.R., *J. Am. Chem. Soc.*, 124, 11864, 2002. With permission.)

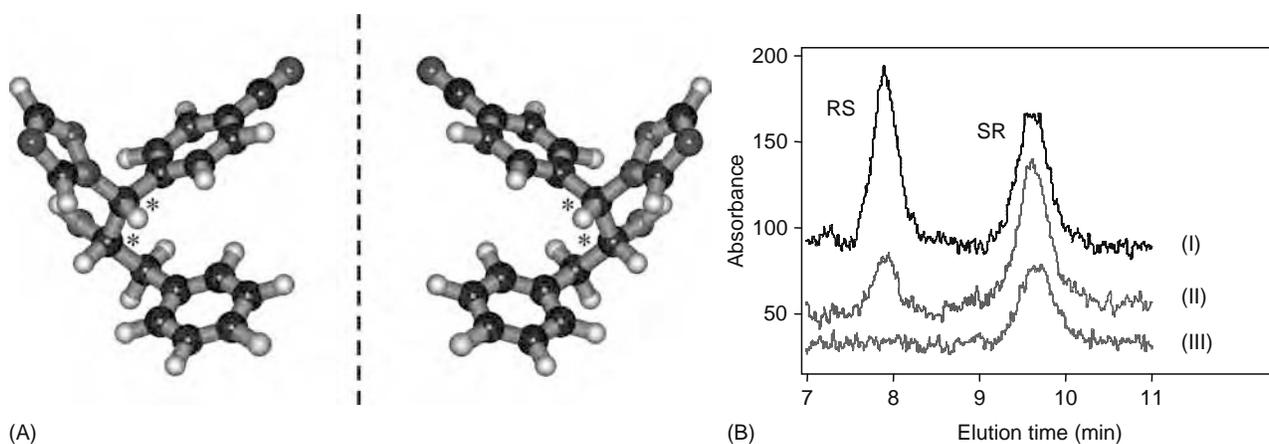

nanotubes, the quinineurethan fluorescence is seen only from the aqueous phase (Figure 24.3A). When both sets of nanotubes are added to the solvent mixture in the same vial, the tubes with the  $C_{18}$  outer surface chemistry go to the cyclohexane and the tubes with the silica outer surface chemistry go to the aqueous phase (Figure 24.3C).

#### 24.4.2 NANOTUBES FOR CHEMICAL AND BIOEXTRACTION AND BIOCATALYSIS: DEMONSTRATION OF POTENTIAL DRUG DETOXIFICATION USING NANOTUBES [2,4]

One application for such differentially functionalized nanotubes is as smart nanophase extractors to remove specific molecules from solution. Nanotubes with hydrophilic chemistry on their outer surfaces and hydrophobic chemistry on their inner surfaces are ideal for extracting lipophilic molecules from an aqueous solution. The hydrophobic molecule 7,8-benzoquinoline (BQ), which has an octanol/water partition coefficient of 10 [3,8] was used as a model compound for such nanophase solvent extraction experiments. Figure 24.4A shows the UV–Vis spectrum of control solution containing  $10^{-5}$  M aqueous BQ. A 5 mg of the silica-outer/ $C_{18}$ -inner nanotubes were suspended into 5 mL of  $1.0 \times 10^{-5}$  M aqueous BQ. The suspension was stirred for

**FIGURE 24.4** UV–Vis spectra showing the extraction of 7,8-benzoquinoline (BQ) from the aqueous solution by nanotubes with  $C_{18}$  silane on their inner surfaces. (A) UV–Vis spectrum of  $10^{-5}$  M aqueous BQ and (B) after extraction with  $SiO_2$  tubes (control experiments). (C) After first extraction with  $C_{18}$   $SiO_2$  tubes. (D) After second extraction with  $C_{18}$   $SiO_2$  tubes. (From Lee, S.B., Mitchell, D.T., Trofin, L., Nevanen, T.K., Soderlund, H., and Martin, C.R. Template-synthesized bionanotubes for separations and biocatalysis. *Carrier-Based Drug Delivery ACS Symposium 879*, ACS, Washington, DC, 2004, pp. 88–117. With permission.)

**FIGURE 24.5** (See color insert following page 588.) Enantioseparations. (A) 3-Dimensional structures of the RS enantiomer (left) and the SR enantiomer (right) of the drug FTB. The black, white, blue, red, and yellow balls are carbon, hydrogen, nitrogen, oxygen, and fluorine, respectively, and \* denotes the chiral centers. The geometry optimization was done by ab initio calculation with minimal basis set in HyperChem 6.03. The drug is in clinical trials by Hormos Medical Corp., Turku, Finland. (From Lee, S.B., Mitchell, D.T., Trofin, L., Li, N., Nevanen, T.K., Söderlund, H., and Martin, C.R., *Science*, 296, 2198, 2002. With permission.) (B) Chiral HPLC chromatograms for racemic mixtures of FTB before (I) and after (II, III) extraction with 18 mg/mL of 200-nm Fab-containing nanotubes. Solutions were 5% dimethylsulfoxide in sodium phosphate buffer, pH 8.5. (From Mitchell, D.T., Lee, S.B., Trofin, L., Li, N., Nevanen, T.K., Söderlund, H., and Martin, C.R., *J. Am. Chem. Soc.*, 124, 11864, 2002. With permission.)

5 min and then filtered to remove the nanotubes. UV spectroscopy showed that 82% of the BQ was removed from the solution (Figure 24.4C). When a second 5 mg batch of these nanotubes was added to the filtrate, more than 90% of the original amount of BQ was removed from the solution (Figure 24.4D). Control nanotubes that did not contain the hydrophobic C<sub>18</sub> inner surface chemistry extracted less than 10% of the BQ (Figure 24.4B). This proof of experiment clearly shows that nanotubes are possibly useful in applications involving drug detoxification and other chemical and biochemical extractions.

In principle, nanotubes with the C<sub>18</sub> inside extract any lipophilic molecule. This ability to sequester lipophilic molecules can be viewed as a generic type of extraction selectivity, which might be useful in some applications. However, nanotubes that have molecular-recognition capability and extract only one particular molecule from solution might also be useful. We have shown that antibody-functionalized nanotubes can provide the ultimate in extraction selectivity—the extraction of one enantiomer of a chiral drug molecule.

In collaboration with professor Hans Soderlund of VTT Biotechnology in Finland, we have been investigating an antibody that selectively binds one enantiomer of the drug FTB (Figure 24.5A), an inhibitor of aromatase enzyme activity [35]. This molecule has two chiral centers and thus four stereoisomers, namely, RR, SS, SR, and RS. Professor Soderlund supplied us with the F<sub>ab</sub> fragment [35] of an antibody that selectively binds the RS relative to the SR enantiomer. The antibody was produced against the drug 4-[3-(4-fluorophenyl)-2-hydroxy-1-[1,2,4]triazol-1-yl-propyl]-benzimidazole (FTB, Figure 24.5A). The selectively used antibody binds the RS enantiomer, and F<sub>ab</sub> fragments of this antibody were immobilized to both the inner and outer surfaces of the silica nanotubes. This was accomplished by dissolving the template membrane, collecting the nanotubes, and then dispersing them into a solution of the aldehyde-terminated silane trimethoxysilylbutanal. The nanotubes were then dispersed into a solution of the F<sub>ab</sub> fragments, which resulted in attachment of the F<sub>ab</sub> to the nanotubes via Schiff base reaction between free amino groups on the protein and the surface-bound aldehyde.

The F<sub>ab</sub>-functionalized nanotubes were added to racemic mixtures of the SR and RS enantiomers of FTB. The tubes were then collected by filtration and the filtrate was assayed for the presence of the two enantiomers using a chiral HPLC method (Figure 24.5B). Chromatogram I was obtained from a solution that was 20 μM in both enantiomers, and chromatogram II was obtained for the same solution after exposure to the F<sub>ab</sub>-functionalized nanotubes; 75% of the RS enantiomer and none of the SR enantiomer was removed by the nanotubes. When the concentration of the racemic mixture was dropped to 10 μM, all the RS enantiomers were removed (chromatogram III). Nanotubes containing no F<sub>ab</sub> did not extract measurable quantities of either enantiomer from the 20 μM solution.

We have also developed a chemistry that allows us to attach the F<sub>ab</sub> to only the inner surfaces of the nanotubes. While still within the pores of the template membrane, the inner surfaces were treated with 3-aminopropyltrimethoxysilane. The template membrane was then dissolved and the amino sites on the inner surfaces were coupled to free amino groups on the F<sub>ab</sub> fragment using the well-known glutaraldehyde coupling reaction [4]. When 18 mg of these interior-only F<sub>ab</sub>-modified nanotubes were incubated with 1 mL of a 10 μM racemic mixture of the drug, 80% of the RS (and none of the SR) enantiomer was extracted.

This corresponds to 0.44 nmol RS enantiomer per milligram tubes, whereas almost double that amount, 0.80 nmol/mg, was extracted by the nanotubes with  $F_{ab}$  on both their inner and outer surfaces.

Another example concerns the immobilization of a biocatalyst—the enzyme glucose oxidase (GOD)—to the silica nanotubes [4]. GOD was immobilized, on both the inside and outside surfaces, via the aldehyde silane route. These GOD-nanotubes (60 nm diameter) were dispersed into a solution containing 90 mM glucose and also the components of the standard dianisidine-based assay for GOD activity. A GOD activity of  $0.5 \pm 0.2$  units per milligram of nanotubes was obtained. These studies also showed that protein immobilized via the Schiff base route is not leached from the nanotubes, where GOD activity ceased when the nanotubes were filtered from the solution.

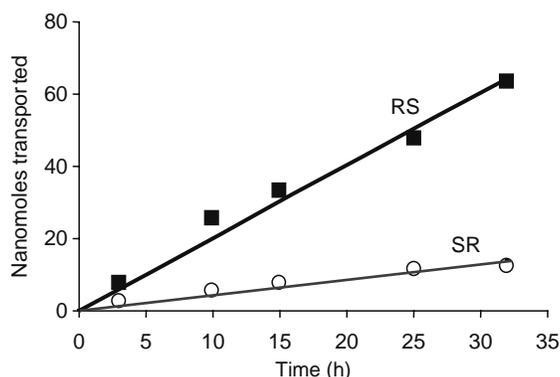

## 24.5 NANOTUBE MEMBRANES FOR BIOSEPARATIONS [3,5,6]

In all the examples cited above, the template membrane was dissolved away and the liberated nanotubes were collected by filtration. The nanotubes may also be left embedded within the pores of the template to yield a freestanding nanotube-containing membrane. We have shown that the nanotubes can act as conduits for highly selective transport of molecules and ions between solutions present on either side of the membrane [5,6,18,19]. For example, membranes containing gold nanotubes with inside diameters of molecular dimensions ( $<1$  nm) clearly separate small molecules based on the molecular size [19]. Gold nanotubes with larger inside diameters (20–45 nm) can be used to separate proteins, and, here again, rendering the nanotubes biocompatible is essential to prevent protein adsorption [36]. Generic chemical transport selectivity (lipophilic vs. hydrophilic) can also be imparted to these gold nanotube membranes [37]. We now present in details of bio-tailored nanotube membranes for separation of enantiomeric amino acids [3] and drug molecules [5], and nucleic acids [6].

### 24.5.1 ANTIBODY-FUNCTIONALIZED NANOTUBE MEMBRANES FOR SELECTIVE ENANTIOMERIC SEPARATIONS [5]

Chiral recognition is a fundamental and very important phenomenon that is observed in all biological systems ranging from single-cell organisms to most complex animals [38]. In fact, specificity and efficacy of many biological reactions depend upon chiral interactions because many biologically molecules and polymers are chiral; they interact more strongly with one enantiomer than another enantiomer. The biological activity of many enzymes depends upon the enantiomeric form of the interacting species, not simply chemical structure. Federal Drug Administration (FDA) requires drug manufacturers to evaluate the effects of individual enantiomers and to verify the enantiomeric purity of chiral drugs that are produced. FDA also mandates that the toxicity and pharmaceutical properties must be established independently for both enantiomers, even if the drug is to be marketed as a single enantiomer.

Enantiomer separation is a challenging problem because two enantiomers have the same physical and chemical properties; the traditional methods of separation (for example, chromatography) generally have relatively low enantiomeric separation selectivity coefficients. We have developed highly selective membrane-based separation methods for enantiomer drug molecules [3,5]. We have shown that membranes containing the silica nanotubes and the enantioselective FTB antibody  $F_{ab}$  fragment (Figure 24.5A) discussed above can be used to make membranes for chiral separations [5]. In this case, the nanotube membrane separates a feed half-cell containing a racemic mixture of the RS and SR enantiomers of FTB and a permeate half-cell that initially contains only buffer solution. The time course of permeation of the two enantiomers across the membrane was determined by periodically assaying the permeate solution. Results for a membrane containing  $\sim 15$  nm diameter silica nanotubes are shown in Figure 24.6 as plots of moles enantiomer transported vs. permeation time. We see that the flux of

**FIGURE 24.6** Enantioseparations using antibody-immobilized membranes. Plots of moles of each enantiomer transported vs. time for a silica nanotube membrane containing the enantioselective antibody  $F_{ab}$  fragment. The inside diameter of the nanotubes was  $\sim 15$  nm. (From Kohli, P., Harrell, C.C., Cao, Z., Gasparac, R., Tan, W., and Martin, C.R., *Science*, 305, 984, 2004. With permission.)

the RS enantiomer, the one bound by the antibody, is five times higher than the flux of the SR enantiomer. Because in principle, antibodies can be obtained that selectively bind to any desired molecule or enantiomer; this concept might provide a general approach for obtaining selectively permeable membranes for a host of enantio- and bioseparations.

Because it is the RS enantiomer that specifically binds to the immobilized anti-RS, these data suggest that this  $F_{ab}$  fragment facilitating the transport of RS enantiomer. Further evidence that it is the  $F_{ab}$  fragment that is facilitating the transport of RS is obtained from feed concentration of drug vs. flux curve, which showed Langmuirian-type curve.

We have not conducted detailed experiments to elucidate the effect of DMSO concentration on the molecular interactions of binding of  $F_{ab}$  to RS enantiomer drug molecule in PBS. The previous studies, however, have shown that the use of DMSO decreases the binding interactions between drug molecule and  $F_{ab}$ -immobilized silica in chromatography experiments [35]. Qualitatively, our studies agree with these results. We believe that there is an optimum binding affinity between drug and  $F_{ab}$  molecules that is expected to give highest transport selectivity coefficient; and that the addition of DMSO to the solution containing antigen (FTB drug) decreases the binding constant between FTB and  $F_{ab}$  molecules immobilized on inner walls of silica nanotube membranes. In our studies, we have found that there is an optimum concentration of DMSO (~15%) that maximizes the value of selectivity coefficient [5].

We now briefly discuss the possible molecular interactions between  $F_{ab}$  fragment and enantiomeric drug molecules. Our collaborators have produced  $F_{ab}$  fragments that bind only to RS enantiomer of FTB drug molecules, but they do not bind strongly to SR enantiomer [35]. The binding interactions between antibody and antigen depend upon many factors including cumulative interactions between the antibody and antigen as well as entropic factors involved in their binding process. In general, numerous weak electrostatic, hydrogen bonding, van der Waals forces, and hydrophobic interactions give strong and specific binding between antibody and antigen [39]. Although we have not conducted detail studies to elucidate the interaction between  $F_{ab}$  and drug molecules at molecular level, we believe that  $F_{ab}$ -fragments attached to silica nanotubes bind to RS enantiomers through various molecular interactions including hydrogen bonding, van der Waals, and hydrophobic interactions.

Another important factor that is important to consider is the orientation of antibody immobilized on the surface. This factor is very important to maximize the antibody availability for antigen binding because the binding between antigen and antibody requires right orientation of antibody for antigen binding. It is well known that histidine interacts strongly with copper and nickel ions. Therefore, one of the antibody immobilization methods to provide efficient, stable, and right orientation on surfaces for antigen-antibody reaction utilizes histidine-tagged antibodies onto copper- and nickel-containing surfaces [40]. The histidine modification of antibodies can be accomplished using conventional covalent bonding of antibody with a reactive histidine or this can also be accomplished using molecular biology (cloning) techniques. The modification of antibody with histidine should only be carried out only at  $F_c$  fragment of the antibody but not on the  $F_{ab}$  fragment. In principle, the immobilization of histidine tagged at  $F_c$  of antibody should provide surfaces with favorable antibody orientation for antigen-antibody reaction, where antibody-binding fragments ( $F_{ab}$ ) are away from surfaces, and antigens can approach  $F_{ab}$  without significant steric hindrance.

#### 24.5.2 FUNCTIONALIZED NANOTUBE MEMBRANES WITH HAIRPIN-DNA TRANSPORTER WITH SINGLE-BASE MISMATCH SELECTIVITY [6]

There appears to be no previous examples of either biological or synthetic membranes, where nucleic acid hybridization is used as the molecular-recognition event to facilitate DNA/RNA transport through the membrane [41,42]. If such membranes could be developed, they might prove useful for DNA separations and sensors needed, for example, in genomic research.

We now describe synthetic membranes in which the molecular-recognition chemistry used to accomplish selective-permeation is DNA hybridization. These membranes contain template-synthesized gold nanotubes with inside diameter of 12 nm, and a transporter DNA-hairpin molecule is attached to the inside walls of these nanotubes. These DNA-functionalized nanotube membranes selectively recognize and transport the DNA strand that is complementary to the transporter strand relative to DNA strands that are not complementary to the transporter. Under optimal conditions, single-base mismatch transport selectivity is obtained.

The gold nanotube membranes were prepared via the template synthesis [21,22] method by electroless deposition of gold along the pore walls of a polycarbonate template membrane [19,43]. The template was a commercially available filter (Osmonics), 6  $\mu\text{m}$  thick, with cylindrical 30 nm diameter pores and  $6 \times 10^8$  pores per square centimeters of membrane surface area.

The hairpin-DNA transporter (Table 24.1) was 30 bases long (30-mer) and contained a thiol substituent at the 5' end that allowed it to be covalently attached to the inside walls of the Au nanotubes [6]. The first six bases at each end of this molecule are complimentary to each other and form the stem of the hairpin, and the middle 18 bases form the loop (Table 24.1). The permeating DNA molecules were 18-mers that are either perfectly complementary to the bases in the loop, or contain one or more mismatches with the loop (Table 24.1). A second thiol-terminated DNA transporter was investigated (Table 24.1). This DNA transporter was also a 30-mer, and the 18 bases in the middle of the strand were identical to the 18 bases in the loop of the hairpin-DNA transporter. However, this second DNA transporter does not have the complementary stem-forming bases on either end and thus cannot form a hairpin. This linear-DNA transporter was used to test the hypothesis that the hairpin-DNA

provides better transport selectivity because of its enhanced ability to discriminate the perfect complement-permeating DNA from the permeating DNAs that contain mismatches.

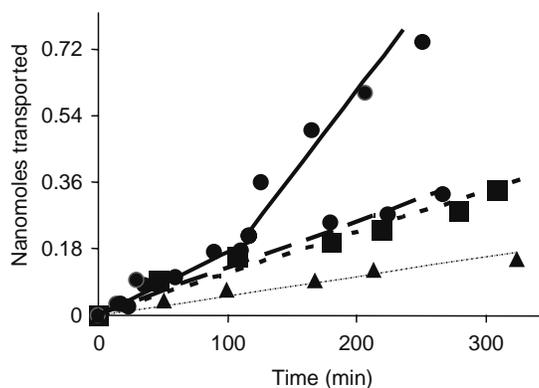

The transport experiments were done in a U-tube permeation cell [43] where the Au nanotube membrane separates the feed half-cell containing one of the permeating DNA molecules (Table 24.1) dissolved in pH 7.2 phosphate buffer (ionic strength ~0.2 M), from the permeate half-cell that was initially only buffer. The rate of transport (flux) of the permeating DNA molecule from the feed half-cell through the Au nanotube membrane and into the permeate half-cell was determined by periodically measuring the ultraviolet absorbance of the permeate half-cell solution, at 260 nm, that arises from the permeating DNA molecule.

Transport plots (Figures 24.7A and 24.8) show the number of nanomoles of the permeating DNA transported through the nanotube membrane vs. permeation time. When the hairpin-DNA is not attached, a straight-line transport plot is obtained for the perfect-complement DNA (PC-DNA, Figure 24.7A), and the slope of this line provides the flux of PC-DNA across the membrane (Table 24.2). The analogous transport plot for the membrane containing the hairpin-DNA transporter is not linear but instead can be approximated by two straight-line segments—a lower-slope segment at short times followed by a higher-slope segment at times longer than a critical transition time,  $\tau$ . This transition is very reproducible; for example, for a feed concentration of 9  $\mu\text{M}$ ,  $\tau = 110 \pm 15$  min (average of three membranes).

Figure 24.7A shows that the flux of the permeating PC-DNA in the membrane containing the hairpin-DNA transporter is at all times higher than the flux for an identical membrane without the transporter (Table 24.2). The hairpin-DNA is acting as a MR agent to facilitate the transport [3,5,44,45] of the PC-DNA. Additional evidence for this conclusion was obtained from

**FIGURE 24.7** (A) Transport plots for PC-DNA through Au nanotube membranes with (▲) and without (●) the immobilized hairpin-DNA transporter. Concentration in feed solution = 9  $\mu\text{M}$ . (B) Flux vs. feed concentration for PC-DNA. The data in squares and circles were obtained for a Au nanotube membrane containing the hairpin-DNA transporter. At feed concentrations of 9  $\mu\text{M}$  and above, the transport plot shows two linear regions. The data in squares were obtained from the high slope at longer times. The data in circles were obtained from the low-slope region at shorter times. The data in triangles were obtained for an analogous nanotube membrane with no DNA-transporter. (From Kohli, P., Harrell, C.C., Cao, Z., Gasparac, R., Tan, W., and Martin, C.R., *Science*, 305, 984, 2004. With permission.)

**FIGURE 24.8** Transport plots for a Au nanotube membrane containing the hairpin-DNA transporter. The permeating DNA was (● solid line) PC-DNA. (● dashed line) Single mismatch (end). (▲) Seven mismatch. (■) Single mismatch (middle). Concentration in feed solution = 9  $\mu\text{M}$ . studies of the effect of concentration of the PC-DNA in the feed solution on the PC-DNA flux. If the hairpin-DNA is facilitating the transport of the PC-DNA, this plot should show a characteristic Langmuirian shape [3,5]. Figure 24.7B shows that this is, indeed, the case for transport data both before and after the critical transition time,  $\tau$ . The analogous plot for the identical membrane without the hairpin-DNA transporter is linear (Figure 24.7B), showing that transport is not facilitated but rather described simply by Fick's first law of diffusion. It is interesting to note that the transition to the higher slope segment was not observed, during permeation experiments of total duration 300 min, for feed concentrations below 9  $\mu\text{M}$  (Figure 24.7B).

Analogous permeation data were obtained for the various mismatch-containing permeating DNA molecules (Table 24.2). The transport plots for these mismatch DNAs show only one straight-line segment (Figure 24.8), and their fluxes are always lower than the flux for the PC-DNA obtained from the high slope region of the PC-DNA transport plot (Table 24.2). Note in particular, the membrane containing the hairpin-DNA transporter shows higher flux for PC-DNA than for the two permeating DNAs that contain only a single-base mismatch.

To illustrate this point more clearly, we define a selectivity coefficient  $\alpha_{\text{HP,PC}/1\text{MM}}$ , which is the flux for the PC-DNA divided by the flux for a single-base mismatch DNA in the membrane with the hairpin-DNA transporter. The data in Table 24.2 provide  $\alpha_{\text{HP,PC}/1\text{MM}} = 3$ . The analogous selectivity coefficient for the PC-DNA vs. the DNA with seven mismatches is  $\alpha_{\text{HP,PC}/7\text{MM}} = 7$ . These selectivity coefficients show that nanotube membranes containing the hairpin-DNA transporter selectively transport PC-DNA and that single-base mismatch transport selectivity can be obtained.

The importance of the hairpin structure to membrane selectivity is illustrated by analogous transport data for membranes containing the linear-DNA transporter (Table 24.1). With this transporter, all the transport plots show only a single straight-line segment, and the fluxes for the single-mismatch DNAs are identical to the flux for the PC-DNA (Table 24.2), i.e., the single-base mismatch selectivity coefficient for this linear (LN) DNA transporter is  $\alpha_{\text{LN,PC}/1\text{MM}} = 1$ . The linear-DNA transporter does, however, show some transport selectivity for the PC-DNA vs. the seven-mismatch DNA,  $\alpha_{\text{LN,PC}/7\text{MM}} = 5$ .

We have also investigated the mechanism of transport in these membranes. In such MR-based facilitated-transport membranes, the permeating species is transported by sequential binding and unbinding events with the MR agent [3,5,44].

**TABLE 24.2**  
**Fluxes for Feed Concentration of 9  $\mu\text{M}$**

<sup>a</sup> Two fluxes are obtained because the transport plot shows two slopes (Figure 24.11A).

For these DNA-based membranes, the binding/unbinding events are sequential hybridization/dehybridization reactions between the permeating DNA molecule and the DNA transporter attached to the nanotubes. To show that hybridization occurred in the membrane with the hairpin-DNA transporter, the membrane was exposed to PC-DNA, and then to a restriction enzyme (Sfc I, New England Biolabs) (supplementary materials, [6]). If hybridization between the PC-DNA and the hairpin transporter occurred, this enzyme will cut the resulting double-stranded DNA such that the last five bases of the binding loop, and all the stem-forming regions, at the 3' end of the hairpin are removed. This reaction will substantially damage the binding site, and based on our earlier work [5], we predict that if this membrane is subsequently used in a permeation experiment, a lower PC-DNA flux should be obtained [6].

After exposure to the restriction enzyme, the membrane was extensively rinsed to remove the enzyme and DNA fragments and then used for a transport experiment with PC-DNA as the permeating species. Unlike the data in Figure 24.7A, the transport plot for this damaged-transporter membrane showed only one straight-line segment [6] corresponding to a flux of  $0.2 \text{ nmol cm}^{-2} \text{ h}^{-1}$ . This value is well below what we observe from membranes with undamaged DNA-hairpin transporter (Table 24.2). The damaged DNA transporter was then removed from the nanotubes and fresh DNA-hairpin transporter was applied. A subsequent transport experiment with PC-DNA showed a transport plot identical to that obtained before exposure to the restriction enzyme [6]. These data suggest that hybridization is, indeed, involved in the transport mechanism for the DNA-hairpin-containing membranes.

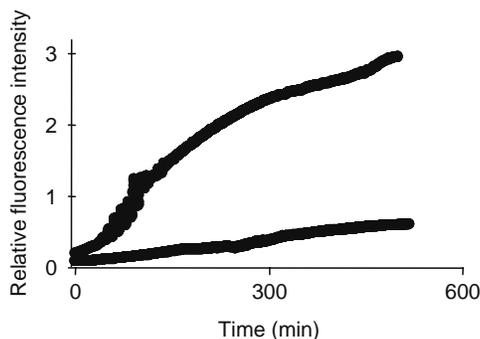

To show that dehybridization occurs on a reasonable timescale in these membranes, we exposed a hairpin-DNA membrane to a fluorescently labeled version of the PC-DNA (Table 24.1). The membrane was then rinsed with buffer solution and immersed into a solution of either pure buffer or buffer containing unlabeled PC-DNA. If the dehybridization reaction is facile, the fluorescently labeled PC-DNA should be released into the solution. We found that dehybridization does occur, but it is strongly accelerated when unlabeled PC-DNA is present in the solution (Figure 24.9). Hence dehybridization is much faster when it occurs by a cooperative process whereby one PC-DNA molecule displaces another from an extant duplex [46].

We have also investigated transport selectivity for a feed solution containing fluorescently labeled versions (Table 24.1) of both the PC-DNA and the single-mismatch DNA. The fluorescent labels allow for quantification of both these permeating DNAs simultaneously in the permeate solution. In analogy to the single-molecule permeation experiment, the flux of the PC-DNA was five times higher than the flux of the single-mismatch DNA [6]. To assess the practical utility of these membranes, transport studies with more realistic samples (such as cell lysates) will be needed.

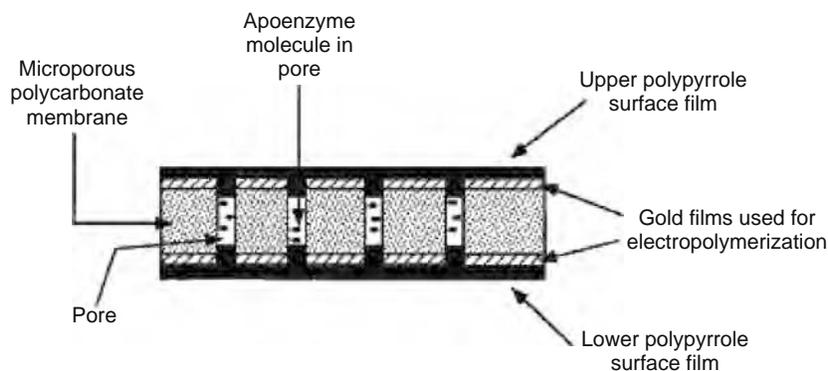

Finally, we have not observed a spontaneous transition from a low flux to a high flux state (Figure 24.7A) with our previous MR-based membranes [3,5]. The fact whether this transition is observed depends on the feed concentration suggests that the transition is a transport-related phenomenon. It is possible that this transition relates to the concept of cooperative (high flux) vs. noncooperative (low flux) dehybridization (Figure 24.9), but further studies, both experimental and modeling, will be required before a definitive mechanism for this transition can be proposed.

### 24.5.3 ENANTIOSEPARATIONS OF AMINO ACIDS USING APOENZYMES IMMOBILIZED IN A POROUS POLYMERIC MEMBRANE [3]

Most of amino acids are chiral and as discussed earlier, the chiral separation is a challenging problem. Another possibility to separate amino acids is to use enzymes that can recognize and selectively separate them. As enzymes also catalyze chemical reactions on substrate molecules that they bind to, this creates an unwanted problem because the reaction products must be separated in the following step. This problem can be circumvented by using apoenzymes as molecular-recognition transporter. Apoenzymes are enzymes that lack in their cofactors; they cannot transform substrates into products.

**FIGURE 24.9** Release of fluorescently labeled PC-DNA from a membrane containing the hairpin-DNA transporter. The fluorescently labeled PC-DNA was released into a buffer solution containing no unlabeled PC-DNA (lower curve) or into a buffer containing  $9 \mu\text{M}$  unlabeled PC-DNA (upper curve). (From Kohli, P., Harrell, C.C., Cao, Z., Gasparac, R., Tan, W., and Martin, C.R., *Science*, 305, 984, 2004. With permission.)

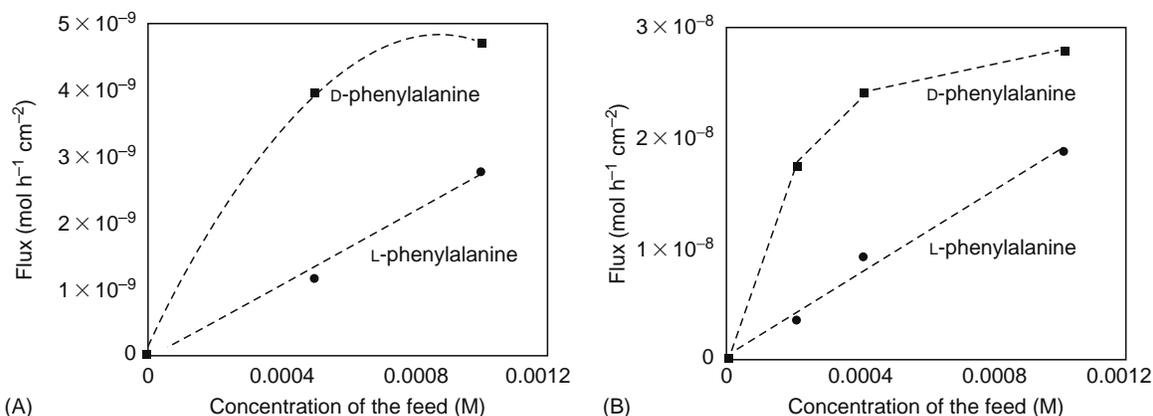

**FIGURE 24.10** Schematic cross section of the polypyrrole/polycarbonate/polypyrrole sandwich membrane with the apoenzyme entrapped in the pores. The membrane is drawn as coming out of the plane of the paper. The various components are not drawn to scale. (From Lakshmi, B.B. and Martin, C.R., *Nature*, 388, 758, 1997. With permission.)

We have used apoenzymes as molecular-recognition transporters for binding and selective transportation of molecules without production of unwanted chemical reactions on reactants. Figure 24.10 shows the design of membrane consisting of microporous polymer membrane sandwiched between two thin films of polypyrrole [3]. The apoenzymes are physically trapped within the pores of the membrane and polypyrrole films. More details regarding the fabrication of the membranes, materials, and experimental setup can be found in the Ref. [3].

The transport flux of ethanol for membranes loaded with alcohol dehydrogenase apoenzyme (apo-ADH) is found to be greater than nine times from those obtained for phenol. The flux vs. feed concentration curves for ethanol showed Langmuir-type isotherm. These observations clearly indicate that apo-ADH acted as molecular-recognition sites for ethanol, and it facilitates the transport of ethanol through the membranes.

To explore the enantioseparation of amino acids which is a more challenging and an interesting problem, D-amino acid oxidase apoenzyme (apo-D-AAO) was trapped in the membrane (containing 400 nm inner pore diameter). The transport fluxes vs. feed concentration of D-phenylalanine and L-phenylalanine through apo-D-AAO-containing membranes were investigated. We found that apo-D-AAO-containing membranes transport D-phenylalanine relative to L-phenylalanine with a selectivity coefficient of 3.3 (Figure 24.11A) [3]. Although the selectivity coefficients obtained using apo-D-AAO-trapped membranes are much higher than those obtained with chromatography-based separation methods, still higher selectivity coefficients are desired. One method to improve selectivity coefficients is to shutdown simple diffusional transport through membrane pores. This can be done by reducing the inner pore diameter of the membranes to reduce the diffusional transport of L-phenylalanine. When apo-D-AAO-trapped within 30 nm inner pore diameter membranes were used, a selectivity coefficient of 4.9 is obtained (Figure 24.11B). As expected the enantiomeric selectivity coefficients were increased, but the transport fluxes were also found to be smaller as compared to those obtained with apo-D-AAO loaded 400 nm pore diameter membranes.

**FIGURE 24.11** (A) Plots of D-phenylalanine and L-phenylalanine flux vs. concentration of these enantiomers in the feed solution for a D-amino acid oxidase apoenzyme (apo-D-AAO)-loaded membrane. The membrane had pores of 400 nm diameter and (B) as (A) but using a membrane with pores of 30 nm diameter (pore density  $6 \times 10^8$  pores  $\text{cm}^{-2}$ ). (From Lakshmi, B.B. and Martin, C.R., *Nature*, 388, 758, 1997. With permission.)

To improve transport rates without sacrificing selectivity, new type of membranes that contain conical pores are being developed. The conical pores containing membranes have much smaller diffusional resistance (higher diffusion coefficients) to molecules for most of the length of the nanotubes except at the narrower tip. We expect conical nanotube membranes to have much higher transport fluxes. The separation selectivity coefficients can be tuned by optimizing the diameter of the narrower tip (pore) in the membranes and by immobilizing molecular-recognition transporters on the inner nanotube walls at optimum concentrations. It is therefore possible to obtain much higher fluxes without sacrificing separation selectivity coefficients.

Recently, we have also conducted experiments with antibody-based nanotube membranes for very high selective protein separations [47]. We found that immobilization of antibodies on the inner walls of the nanotubes selectively bind and transport its antigenic-protein molecules across the membranes. Remarkably, we have routinely observed selectivity coefficients as high as 34 for antibody-based membrane separation. In principle, antibodies can be raised for any molecules, and the antibody-tailored membranes can be used as a general but highly selective separation method.

## 24.6 CONICAL NANOTUBES: MIMICKING ARTIFICIAL ION CHANNEL [7]

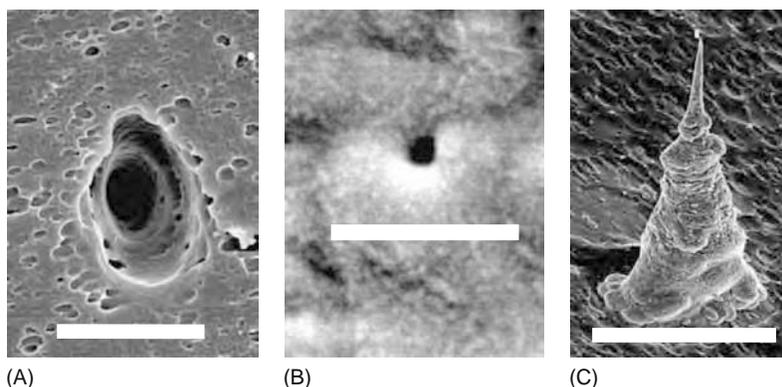

There is considerable interest in developing chemical devices that mimic the function of biological ion channels [48]. We recently described such a device, which consisted of a single conically shaped gold nanotube embedded within a polymeric membrane [49]. This device mimicked one of the key functions of voltage-gated ion channels—the ability to strongly rectify the ionic current flowing through it. The data obtained were interpreted using a simple electrostatic model (*vide infra*) [49].

While the details are still being debated [50a–c], it is clear that ion current-rectification in biological ion channels is more complicated and involves physical movement of an ionically charged portion of the channel in response to a change in the transmembrane potential [50d]. We report here the artificial ion channels that rectify the ion current flowing through them via this electromechanical [51] mechanism. These artificial channels are also based on conical gold nanotubes, but with the critical electromechanical response provided by single-stranded DNA molecules attached to the nanotube walls.

Single conically shaped nanopores were etched into 0.07 cm<sup>2</sup> samples of a 12 μm thick polycarbonate membrane [52]. For most of the studies reported here, the large diameter opening of the pore was 5 μm (Figure 24.12A) and the small diameter opening was 60 nm (Figure 24.12B). However, membranes having conical pores with large diameter openings of 5 μm and small diameter openings of 150 and 100 nm were also used. An electroless plating method [18] was used to deposit a correspondingly conical gold nanotube within the pore. This entails coating the pore walls, and membrane faces, with a thin (~10 nm) layer of gold. Because this layer is so thin, the large diameter opening of the conical gold nanotube remained 5 μm. An approximate measure of the diameter of the small opening (here after called the mouth) of the conical nanotube was obtained using a simple electrochemical method [52] (Table 24.3).

In the final step, single-stranded DNA molecules were covalently immobilized to the gold surfaces. The following are the thiol-terminated DNAs: 5'HS-(CH<sub>2</sub>)<sub>6</sub>-CGAGTCCATTCA3' (12-mer), 5'HS-(CH<sub>2</sub>)<sub>6</sub>-GACCGAGTC-CATTCA3' (15-mer), 5'HS-(CH<sub>2</sub>)<sub>6</sub>-CGCGAGAAGTTACAT GACCTGTAGACGATC3' (30-mer), 5'HS-(CH<sub>2</sub>)<sub>6</sub>-A<sub>45</sub>3' (45-mer), and 5'HS-(CH<sub>2</sub>)<sub>6</sub>-CGCGAGAAGTTACATGACCTG-TAGCTCGCG3' (30-mer hairpin) [6,7]. In all the experiments described here, the conically shaped gold nanotube was left embedded within the polycarbonate membrane. However, to prove that this nanotube is, indeed, conical, the membrane can be dissolved away and the liberated nanotube is imaged via electron microscopy (Figure 24.12C).

Current–voltage (I–V) curves for these artificial ion channels were obtained by mounting the membrane sample between the two halves of a U-tube conductivity cell [18]. Each half-cell was filled with ~5 mL of a 10 mM pH 7.0 phosphate buffer that was also 100 mM in KCl. A Ag/AgCl reference electrode was inserted into each half-cell solution, and a Keithley instruments

<sup>a</sup> Includes the (CH<sub>2</sub>)<sub>6</sub> spacer.

6487 picoammeter/voltage source was used to apply the desired transmembrane potential and measure the resulting ionic current flowing through the gold nanotube.

In our earlier work, the mouth diameter of the Au nanotubes was 10 nm, and the rectification observed resulted from electrostatic interactions between cations traversing the nanotube and fixed surface charge (due, e.g., to adsorbed Cl<sup>-</sup>) at the nanotube mouth [49]. This mechanism applies only when the mouth diameter is comparable to the thickness of the electrical double layer associated with the fixed surface charge, and this is not the case for the large mouth-diameter nanotubes used here (Table 24.3). This is proven by the fact that without attached DNA molecules, these nanotubes do not rectify, even though there is adsorbed Cl<sup>-</sup> on the nanotube walls (Figure 24.13A). In contrast, the DNA-containing nanotubes rectify the ion current,

**FIGURE 24.13** (See color insert following page 588.) (A) I-V curves for nanotubes with mouth diameter 40 nm containing no DNA (black) and attached 12-mer (blue), 15-mer (red), 30-mer (green), and 45-mer (orange) DNAs. (B,C) Schematics showing electrode polarity and DNA chain positions for on (B) and off (C) states. (From Harrell, C.C., Kohli, P., Siwy, Z., and Martin, C.R., *J. Am. Chem. Soc.*, 126, 15646, 2004. With permission.)

i.e., they show an on state at negative transmembrane potentials (anode facing the mouth of nanotube, Figure 24.13B) and an off state at positive potentials (Figure 24.13C).

The extent of rectification may be quantified via the ratio,  $r_{\max}$ , which is the absolute value of the current at  $-1$  V (on state) divided by the current at  $+1$  V (off state) (Table 24.3). The first four entries in Table 24.3 correspond to the nanotubes in Figure 24.13A. As is evident from the figure,  $r_{\max}$  increases with DNA chain length. The extent of rectification can also be controlled by holding the chain length constant, and varying the diameter of the nanotube mouth (Table 24.3). With one exception (*vide infra*),  $r_{\max}$  increases with decreasing mouth diameter.

We propose that rectification in these nanotubes entails electrophoretic insertion of the DNA chains into (off state, Figure 24.13C) and out of (on state, Figure 24.13B) the nanotube mouth. The off state is obtained because when inserted into the mouth, the chains partially occlude the pathway for ion-transport, yielding a higher ionic resistance for the nanotube. There is ample evidence in the literature to support this hypothesis. First, because DNA chains are anionic, they can be driven electrophoretically through nanopores, and during translocation, occlusion of the nanopores by the DNA causes a transient increase in the pore's ionic resistance [53]. Furthermore, in complete analogy to our model, if one end of a DNA chain is immobilized in an electrophoresis experiment, the chain extends linearly in the direction of the anode [54]. In addition, simulations of the electric-field strength in conical nanopores, identical to those used here, show that the field in the electrolyte solution in the mouth of the nanopore is  $1 \times 10^6$  V m<sup>-1</sup>, when the total voltage drop across the membrane is only 1 V [55]. This focusing of the electric field strength at the nanotube mouth means that there is ample field to extend the DNA chains toward the anode.

Further support for this model can be garnered from our experimental I–V data. First, the magnitudes of the on state currents in Figure 24.13A decrease with increasing DNA chain length. This is because even in the on state, the DNA chains partially occlude the mouth of the nanotube and increase the nanotube resistance. Second, while the general trend is that  $r_{\max}$  increases with decreasing mouth diameter, one exception was noted; the nanotube with the  $\sim 13$  nm mouth and the 30-base DNA rectifies less than the nanotube with the  $\sim 27$  nm mouth and this same 30-base DNA (Table 24.3). These data suggest that the DNA chain can be too long, relative to the mouth diameter, to allow for efficient rectification. Table 24.3 lists two relevant lengths of the DNA chains: the length if the chains were completely extended [53] and the radius of gyration [56] for the globular form. According to our model to rectify, the chain must have the freedom to extend linearly toward the anode. The nanotube with the 13 nm mouth is the only case where the length of the extended DNA chain is equivalent to the mouth diameter. We suggest that this makes it sterically difficult for the chains to reorient and insert themselves into the mouth, and this is why poor rectification is observed.

Third, according to our model, the DNA chain must have the flexibility to extend in the direction of the anode. This issue was explored by comparing the extent of rectification for a nanotube containing the conventional 30-base DNA and an identical tube containing a hairpin 30-base DNA. The hairpin-DNA [57] folds back on itself because the bases at one end of the chain are complementary to the bases at the other end, making the chain much less flexible. The nanotube containing this 30-base hairpin-DNA is a very poor rectifier, much worse than the same nanotube with the conventional 30-base DNA (Table 24.3).

## 24.7 CONCLUSIONS

We believe that nanotubes offer some important advantages for biotechnological and biomedical applications of nanoparticles. Because of its tremendous versatility in terms of materials that can be used, sizes that can be obtained, and chemistry and biochemistry that can be applied, the template method might prove to be a particularly advantageous approach for preparing nanotubes for such applications. However, this field of nanotube biotechnology is in its infancy, and there is much work to be done before products based on this technology are brought to the market place. For example, in our applications to date, we have incorporated the payload into the nanotubes by either covalent bonding or other chemical interactions. However, in some applications it might be useful to simply fill the nanotube with a payload and then apply caps to the nanotube ends to keep the payload encapsulated. Furthermore, it might be useful to have these caps fall off, thus spilling the payload, when a particular chemical or biochemical signal is detected. We are currently exploring routes for preparing such capped nanotubes. The issues of cost of production and mass production of nanotubes must also be addressed.

Finally, the synthetic nanotubes discussed here can be thought of as mimics of naturally occurring nanotubes–protein channels [7,58]; indeed, the cyclic peptide nanotubes have been used as artificial ion channels [26]. Ion channels open and close in response to chemical and electrical stimuli. We are developing synthetic nanotubes with similar voltage [7,18,49,59] and chemical [60] gating characteristics. These nanotubes can be used in smart membranes whose transport properties change in response to an electrical stimulus [18,59] and in sensing devices where a chemical stimulus turns on a current that can be measured in an external circuit [60]. One of major drawbacks of membrane-based separation method is low transport flux of separating molecules. The use of conical nanotubes-containing membranes can possibly eliminate low transport flux problem because conical pore-containing membranes are expected to have much larger porosity. We have fabricated conical nanotube membranes [7,49]; these membranes have potential of greatly increasing the transport flux without significantly losing the selectivity coefficients. Further, we report on separation of biomolecules and biopolymers using conical-nanotube membranes.

## ACKNOWLEDGMENT

This work was supported by the National Science Foundation (NIRT for Biomedical Nanotube Technology), DARPA, the Office of Naval Research, and the UF Engineering Research Center for Particle Science and Technology. We gratefully acknowledge our collaborator, professor Hans Soderlund, for contributions to the antibody research projects.

## 25.1 INTRODUCTION

The concept of emulsion liquid membranes (ELM) was first proposed by Li in 1968 [1]. Since their inception in the late 1960s they have been referred to as surfactant liquid membranes, double emulsion membranes or ELM. Regardless of the terminology used, the workings of such systems are as follows: they consist of an emulsion formed by an organic solvent and water, which can be stabilized by the addition of surfactant. This emulsion is then contacted with a continuous phase containing the desired solute, stirred to yield globules, and transported across the extremely thin membrane layer that separates internal phase droplets

inside the emulsion globule. The three phase dispersion can be either a water-in-oil emulsion dispersed in an aqueous phase (W/O/W) or an oil-in-water emulsion dispersed in an oil phase (O/W/O) [2]. According to Ho et al. [3], in general the internal phase droplets are small, with diameters in the order of 1–10  $\mu\text{m}$ . The emulsion globules, however, are much larger usually 0.1–2.0 mm in diameter. On completion of the extraction process, the emulsion needs to be broken/demulsified to recover the internal phase containing the concentrated solute.

Such systems are capable of providing extremely large membrane surface areas and are applicable in situations where the desired solute in the feed stream is in low concentration. Some of the attractive features of ELM systems include simple operation, high efficiency, extraction, and stripping in one stage, large interfacial area and scope for continuous operation [4].

However, these systems are disadvantaged by emulsion swelling, emulsion breakage, lack of stability, and the fact that modeling tends to be complicated and tedious. Despite these disadvantages ELM systems have found applications in numerous situations such as the removal of metal ions, acids and bases from wastewater streams, and the recovery of biochemical products.

The chapter deals with the workings of emulsion liquid membrane systems: the physicochemical properties, modeling of such systems, difficulties associated with these types of membrane systems, and their uses in chemical and biotechnological applications.

## 25.2 THEORY AND MECHANISM

The transfer of the solute from the bulk aqueous phase into the droplets of the internal phase can be via two mechanisms, referred to as type 1 and type 2 facilitations. In type 1 facilitation, the solute species in the continuous phase transfers into the internal phase and reacts with a chemical reagent present in this phase forming a product that is not capable of diffusing back through the membrane. Thus the solute concentration in the internal phase of the ELM is effectively zero. An example of type 1 facilitation is the removal of phenol from wastewaters. The process is illustrated in Figure 25.1.

In this figure, phenol from the continuous phase solubilizes in the membrane oil phase and then diffuses into the internal phase where it reacts with the sodium hydroxide to form sodium phenolate. Being an ionic species, it is not soluble in the oil phase of the membrane and is effectively captured in the internal aqueous phase. The concentration of phenol in the internal phase is effectively zero.

Type 2 facilitation is also known as carrier facilitated transport, since a carrier compound, that is, an extractant or complexing agent, solubilized in the organic phase is used to assist transfer across the membrane. In this situation, the solute of interest reacts with the carrier to form a complex that is only soluble in the membrane phase. The solute is de-complexed by a stripping solution contained in the internal phase. An example of such a process is the removal of a metal ion such as copper or zinc from wastewater by the extractant DEHPA (di-2-ethylhexyl phosphoric acid, represented as HL) as shown in Figure 25.2. In this case, the carrier also enhances the selectivity as most extractants are specifically designed to extract particular metal ions

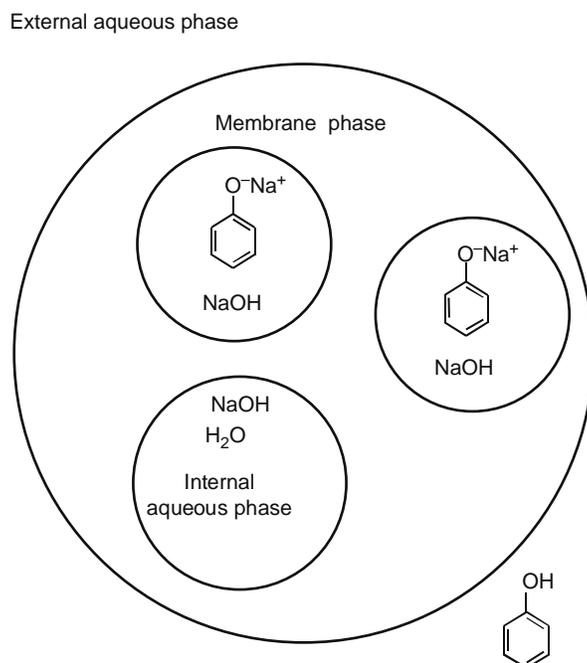

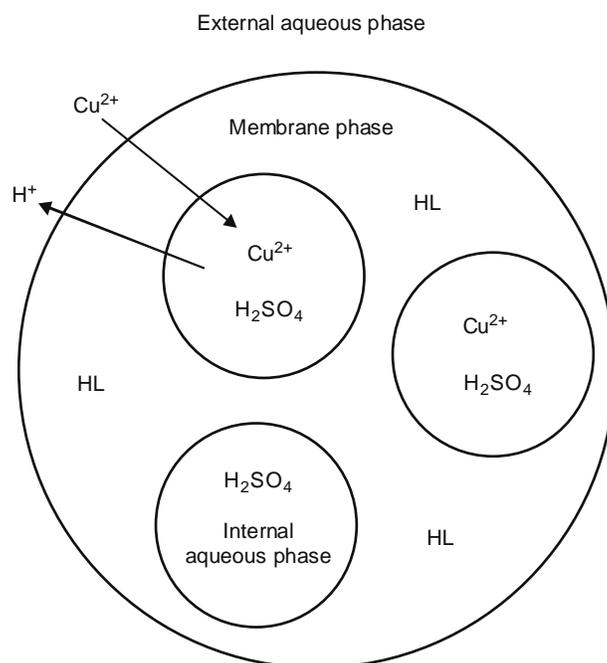

FIGURE 25.1 Schematic diagram of type 1 facilitation in an ELM system.

**FIGURE 25.2** Schematic representation of type 2 facilitated transport in an emulsion liquid system.

under given conditions. The metal ion,  $\text{Cu}^{2+}$  in the continuous phase reacts with the DEHPA in the oil phase to form the oil soluble complex,  $\text{Cu}(\text{HL})_2$ . Concentrated sulphuric acid in the internal aqueous phase strips the metal ion from the oil phase complex and transfers it into the internal phase, exchanging the metal ion for protons.

### 25.3 MODELING

A range of mathematical models were developed to explain solute transfer in ELM systems. Given the nature of these systems, most modeling efforts tend to end up as complicated mathematical structures with too many parameters and are far too tedious to be determined experimentally. The development of these models over the years has been discussed extensively [5–7]. Some of the development highlights are presented in the following sections.

#### 25.3.1 TYPE 1 FACILITATION

Mathematical descriptions of type 1 facilitation began with the pioneering work of Cahn and Li's [8] uniform flat sheet model, which was later adapted with limited success by Kremsec [9], Kremsec and Slattery [10] followed by the hollow sphere model of Matulevicius and Li [11] and later the reaction front concept of Kopp et al. [12].

Models for type 1 facilitation can be divided into two main categories: the state of the art advancing front models and the reversible reaction models.

The advancing front model first proposed by Ho et al. [3] assumes that the solute reacts instantaneously and irreversibly with the internal phase reagent at the reaction surface, which advances into the globule as the reagent is consumed. This model assumes an uniform globule size described by the Sauter mean diameter, no coalescence between emulsion globules, no circulation within the emulsion drop, local equilibrium exists between the internal phase and the membrane phase. The model does not account for mass transfer resistance in the external phase. Fales and Stroeve [13] as well as Stroeve and Varanasi [14] extended the advancing front model to include external phase mass transfer resistance outside the emulsion globules, that is, in the continuous phase.

Teramoto et al. [15] and Bunge and Noble [16] incorporated reaction reversibility in describing the transport process in the emulsion globule. Teramoto et al. [15,17,18] also developed models that accounted for diffusion in the emulsion drops and the drop-size distribution of the W/O emulsion. Kataoka and coworkers [19,20] developed the work of Teramoto et al. [15,17,18] by proposing a model with parameters that could be determined independently or through correlations in the literature.

Teramoto et al. [21] verified that the correlation used in the model of Bunge and Noble [16] was the most accurate of the correlations without adjustment parameters, because of the introduction of the apparent increase of the internal phase diffusivity caused by the diffusion of the reaction product between the solute and the internal stripping reagent (Baird et al. [22]). This effect was not included in the models proposed by Teramoto et al. [17] and Kataoka et al. [20]. Lin and Long [23] tried to

upgrade the model proposed by Bunge and Noble [16] to discard the simplification of considering an average value for the effective diffusivity and its variation with concentration in the model equations, but they ended up developing a slightly different model.

Chan and Lee [24] assumed that a reaction equilibrium existed in both the internal and external continuous phases. They also incorporated the overall mass transfer resistance in their model as well as accounting for leakage of the internal phase into the external phase as did Borwankar et al. [25], Liu and Liu [26], and Boyadzhiev et al. [27]. The reversible model was later extended by Baird et al. [22] to predict the extraction rate for multicomponent systems. A comparison study of the advanced front model and the reversible reaction model for multicomponent systems undertaken by Wang and Bunge [28] found the latter to be significantly better for mixtures of organic acids.

Yan et al. [7] proposed a model based on the model of Ho et al. [3], where the possibility of kinetic control of the stripping reaction is added as well as the mass transfer resistance inside and outside of the emulsion globules. Correia and de Carvalho [29] have presented a comparison between several models for the recovery of 2-chlorophenol from aqueous solutions by ELM, where they proposed the effective upgrade of the Bunge and Noble [16] model. The same authors present an application of the Yan et al. [7] model for the recovery of 4-hydroxybenzoic acid from aqueous solutions by ELM [29,30].

Although most models have been developed for batch extraction, the need to extend to continuous systems has been recognized by researchers (e.g., Rautenbach and Machhammer [31] and Datta et al. [32]).

A selected summary of the various systems, models, and observations for type 1 facilitation is presented in Table 25.1.

### 25.3.2 TYPE 2 FACILITATION

These models take into account the diffusion of the carrier and the metal ion–carrier complex in the emulsion globules. They must also account for the reversible reactions at the external and internal interfaces.

In developing a model for the extraction of copper, Teramoto et al. [34] included external phase mass transfer and also considered leakage. Kataoka et al. [35] included mass transfer resistance in the peripheral thin membrane layer. The results of such models have complicated equations with too many parameters. Lorbach and Marr [36] in what is considered to be the state of the art model, simplified the system by assuming a constant sum of the free and complexed carrier concentration. They also assumed constant pH in the external phase, eliminating mass transfer resistance in the peripheral thin membrane layer. Ortnier et al. [37] extended the model of Lorbach and Marr [36] for countercurrent column separations but found it too complicated.

Yan [38] further simplified the equations for batch extractions by assuming an irreversible, first-order extraction reaction between the solute and the carrier, irreversible first-order stripping reaction between the complex carrier and the internal reagent and constant distribution coefficients. Weiss et al. [39] proposed an empirical model for the extraction of mercury. Recently, Banerjea et al. [40] and Chakraborty et al. [4] presented an unsteady-state mathematical models to explain type 2 facilitation.

A selected summary of the various systems, models, and observations for type 2 facilitation is presented in Table 25.2.

### 25.3.3 MODEL PARAMETERS

Here, some of the physical parameters used in the various models are examined in terms of their contribution to the overall stability and effectiveness of the ELM system.

#### 25.3.3.1 Internal Droplet Size

Extraction and stripping efficiency is greatly enhanced with smaller droplets due to an increased surface area for diffusion. In the study of copper ion extraction, Cahn et al. [45] have shown that the average size of the internal phase droplets significantly influence the extraction rate. They also report that smaller droplets enhance membrane stability and retard leakage. The internal phase and its impact on the ELM process are discussed in Section 25.4.

#### 25.3.3.2 Emulsion Globule Size

According to Gu et al. [46], the size of the emulsion globule, generally characterized by the Sauter mean diameter or radius, is dependent on the viscosity of the emulsion, the type and concentration of the surfactant, and the method of mixing used to form the ELM. The emulsion globule size controls the surface area available for mass transfer between the emulsion and the continuous external phase. In a given volume of an emulsion dispersed in a continuous phase, the smaller the size of the globule, the larger will be the number of globules and therefore the larger the available surface area.

As shown by many studies, the globule size is characterized by the Sauter mean diameter or radius. This diameter/radius must be experimentally determined by photographic and microscopic techniques [34], or be estimated from correlations [47] that are often limited to the system for which they were developed. While the availability of correlations for ELMs is limited,

**TABLE 25.1**  
**Models for Type 1 Facilitated Transport**

Solute	Membrane Phase	Internal Phase	Model Description	Observations	References
Aniline, <i>m</i> -toluidine, <i>p</i> -toluidine	5 vol% SPAN 80, kerosene	0.2–0.4 M HCl	Mass transfer model in which diffusion in the emulsion drop, external mass transfer around the drop, phase, and chemical equilibria are taken into account.	The model satisfactorily predicted the experimental trends observed. A correlation for effective diffusivity in the emulsion globule is presented.	[15]
Phenol, cresol	5 vol% SPAN 80, kerosene	NaOH or LiOH	Modified mass transfer model in which diffusion in the emulsion drop, external mass transfer around the drop, phase, and chemical equilibria and the drop-size distribution of the W/O emulsion are taken into account.	Satisfactory agreement between experimental data and the model.	[17]
Phenol (data of Ho et al. [3])	1 wt% SPAN 80, 3 wt% ENJ 3029, 96 wt% S100N	1.5 wt% NaOH	An extension of previous diffusion models with the incorporation of reaction equilibrium. This model includes the reversibility in the reaction of solute with the reagent present in the internal droplets.	Excellent agreement between experimental data and the model.	[16]
Amines data of Teramoto et al. [15,17]			Mass transfer model that takes into account reversible reactions in both internal and external phases, external continuous phase mass transfer resistance, interfacial resistance, and diffusion within the emulsion globule. The leakage effect of the internal phase due to membrane rupture was also incorporated.	Satisfactory predictions of experimental data obtained for weak acids and bases.	[24]
Acetic acid	8 wt% E644 polyamine, 72 wt% kerosene, 19 wt% paraffin	3 M NaOH	Mass transfer model that accounted for the mass transfer both inside and outside the emulsion globules, the reaction between the diffusing component and the internal reagent in the globules jointly. A perturbation solution to the resulting nonlinear equations contained the parameters <i>Bi</i> and <i>Da</i> .	The model predictions showed that when <i>Da</i> was less than 5 or larger than 200, the overall process was controlled by reaction or diffusion, respectively, and for intermediate values of <i>Da</i> by reaction and diffusion jointly. The model predictions were in good agreement with the experimental data for batch extraction of acetic acid.	[7,33]
500 ppm <i>o</i> -chlorophenol	1–6 wt% ECA 4360 nonionic polyamine, LOPS (Exxon)	2.5 M NaOH	General model for physical transport of solute disregarding any chemical reaction effects. The model accounted for the continuous phase resistance and the interfacial resistance and permeation through a composite emulsion globule. It also quantified the loss in extraction efficiencies by leakage due to membrane breakage.	Satisfactory agreement between experimental and the model predictions with the best fit being achieved with the lowest surfactant concentration.	[25]
Phenol	5 vol% ECA 4306J, kerosene	0.1 M NaOH	General permeation model in which the emulsion drop is composed of the inner core of emulsion phase and the peripheral thin oil layer. The model accounted for chemical reactions, diffusion in the emulsion phase, in the peripheral thin oil layer of the emulsion drop, in the external aqueous film.	All parameters required for simulation can be estimated from the diameters of the emulsion drop and internal water droplet. Experimental results for the batch permeation of phenol were in good agreement with results computed by the model.	[19,20]
<i>m</i> -nitroaniline, <i>m</i> -toluidine	7 wt% SPAN 80, heptane, NaCl	0.1–1.0 M HCl	A new equation for the effective diffusivity of weak bases in the W/O emulsion.	This model is an improvement of the previous model [15,17].	[21]
2-Chlorophenol	2 wt% ECA 4360J, 98 wt% Shellsol T	0.5 M NaOH	Used the advancing front model and three reversible reaction models: Bunge and Noble [16] model, Lin and Long [23] model, modified Bunge and Noble model.	Both sets of models were found to predict the experimental data with reasonable accuracy implying that in the case of 2-chlorophenol the role of reversibility is negligible.	[29]
Aniline	2 vol% SPAN 80, isoparaffin	HCl	Mass transfer within the emulsion globule considered by shrinkage of the unreacted internal zone and the reversible reaction between solute and internal reagent.	Good agreement for the continuous system. Discrepancies at high stirrer speed and residence time.	[31]

**TABLE 25.2**  
**Models for Type 2 Facilitated Transport**

Solute	Extractant	Membrane Phase	Internal Phase	Model	Observations	References
Chromium	0.5 vol% Aliquat 336	1.5 vol% Paranox 106, 5 vol% decanol, kerosene	0.005–0.01 M NaOH	Unsteady-state mathematical model based on the advancing front model of Ho et al. [3] considers a reaction front to exist within the emulsion globule and assumes instantaneous and irreversible reaction between the solute and the internal reagent at the membrane-internal droplet interface.	Simulated curves were found to be in good agreement with the experimental data.	[40]
Citric acid	40 vol% Alamine 336	4 vol% C9232, mineral oil, 8 vol% chloroform	2.5 M NaOH	Modified shrinking core model that accounts for globule aggregation and emulsion break-up.	Model was tested by varying the system parameters. Good agreement between experimental and calculated results.	[43]
Copper Zinc	LIX64N DEHPA	4 vol% SPAN 80, kerosene	0.5 M H <sub>2</sub> SO <sub>4</sub>	General permeation model in which the emulsion drop comprises the inner core of emulsion phase and the peripheral thin oil layer. The model accounted for chemical reactions, diffusion in the emulsion phase, in the peripheral thin oil layer of the emulsion drop, and in the external aqueous film.	All parameters required for simulation can be estimated from the diameters of the emulsion drop and internal water droplet. Experimental results for the batch permeation of copper and zinc were satisfactorily predicted by the model.	[19,20]
Copper, nickel, chromium, iron	10 vol% DEHPA	5 vol% SPAN 80, 80% v/v kerosene + 5% v/v heptane	0.5–1.0 N HCl	Unsteady-state mathematical model based on the advancing front model of Ho et al. [3] neglects external phase mass transfer resistance and the effect of membrane breakage and has no adjustable parameters.	The results obtained from the numerical model were found to be in agreement with the experimental data. A semiempirical correlation between the distribution coefficient and the equilibrium external phase metal ion concentration was developed for use in the modeling.	[3]
Europium	5 vol% 2-ethylhexyl phosphoric acid mono-2-ethylhexyl ester (PC-88A)	4 mol% SPAN 80, kerosene or dodecane	1.5 M HCl	Mass transfer model built on to the immobilized hollow spherical emulsion globule [24].	Model calculations found to agree with experimental data within experimental error limits.	[41]
Gold	1% N503	4% E644, kerosene	0.1 M Na <sub>2</sub> SO <sub>3</sub>	Mass transfer model that accounts for mass transfer and first-order reactions both inside and outside the emulsion globules.	Good agreement between model predictions and the experimental data compared to the advancing front model of Ho et al. [3] and the external boundary layer and membrane diffusion controlled model of Yan [38].	[38]
Nitrate	Tri- <i>n</i> -octyl amine (TOA)	4 vol% SPAN 80, kerosene	Na <sub>2</sub> CO <sub>3</sub>	Modified diffusion model that assumes that the solutes react reversibly with the internal reagents and the effective diffusivity of the solutes in the emulsion globules is dependent upon the local solute concentration in the membrane phase.	Model predictions deviated from experimental data at longer contact times.	[44]

**TABLE 25.2 (continued)**  
**Models for Type 2 Facilitated Transport**

Solute	Extractant	Membrane Phase	Internal Phase	Model	Observations	References
Phenylalanine	4% v/v DEHPA	3% v/v SPAN 80, 93% v/v kerosene	1.5 M HCl	Model accounted for external phase mass transfer resistance, the interfacial reaction resistance, diffusion within the emulsion globule as well as leakage of the internal phase due to membrane breakage.	The model satisfactorily predicted the experimental results, but deviations at low external phase pH and longer contact time were observed. Depending on the experimental conditions, the transport of phenylalanine was governed by mass transfer in the external phase boundary layer, by diffusion within the membrane phase or by a combination of these effects.	[26]
Tellurium	5% DEHPA	3% SPAN 80, kerosene	5.0–6.0 M acid	A diffusion controlled film model that accounts for both the continuous phase and membrane phase resistance in the form of a Biot number.	Good agreement between computed and experimental data. Model capable of predicting the effect of parameters such as Biot number, ratio of emulsion phase volume to continuous phase volume, and membrane thickness on the rate of extraction. The continuous phase resistance was the controlling factor for the extraction of tellurium.	[42]
Zinc	3.5 wt% di(2-ethylhexyl) dithiophosphoric acid (DTPA)	2 wt% ECA 4360, 94.5 wt% Shellsol T	5 N H <sub>2</sub> SO <sub>4</sub>	Mass transfer model based on extraction and stripping reactions that also account for diffusion of the loaded carrier molecules into an emulsion globule.	Good agreement between experimental data and the model predictions. Reaction at the outer interface is important in the transfer process.	[18]

several are reported for oil/water and water/oil systems. A summary of the various correlations for the Sauter mean diameter in oil/water and emulsion systems is presented in Table 25.3.

### 25.3.3.3 Biot Number

Biot number,  $Bi$ , is the ratio of the mass transfer resistance inside the emulsion globules to that of the external phase [5] and is given by Equation 25.1:

$$Bi = kR/\alpha_e D_e \quad (25.1)$$

where

$k$  is the external phase mass transfer coefficient

$R$  is the radius of the emulsion globule (see Section 25.3.3.2 and Table 25.3)

$D_e$  is the effective solute diffusivity in the emulsion mixture and can be estimated from the Jefferson–Witzell–Sibbett equation [3,5–7]

$\alpha_e$  is the distribution coefficient of the solute between the external and membrane phase at equilibrium (dimensionless)

The external phase mass transfer resistance becomes insignificant if the Biot number is  $<20$ . At very high Biot numbers mass transfer resistance in the external phase can be neglected [7]. In general, the Biot number is  $>20$  as a result of good mixing needed to minimize the globule size to obtain a high mass transfer surface area, and therefore the external phase mass transfer resistance is negligible.

If  $k$  is significant, polydispersity of the emulsion globules will need to be considered since the Biot number is dependent on globule size. Correlations for  $k$  are available in the literature [33,41,74–80]. Distribution coefficient data should be experimentally determined for a given system. Data for some systems are available from the literature [21,38,42,81–83].

**TABLE 25.3**  
**Correlations for the Sauter Mean Diameter of the Dispersed Phase Droplets/Globules in Oil/Water and Emulsion Systems**

Correlation	System	Conditions	References	Parameters
$d_{32}/d_s = Bf_\phi W_e^{-0.6}$	Carbon tetrachloride/water, iso-octane/water	$\phi = 0.10-0.40$	[48]	$\Delta\rho$ = density difference between (W/O) emulsion and the continuous phase
$d_{32}/d_s = B(d_s/T)^{-b} W_e^{-0.6}$	Cyclohexane/water	$\phi = 0.50$	[49]

$d_{32}/d_s = 0.75 W_e^{-0.6} \phi^{0.36} (\mu_c/\mu_d)^{0.11} (1 + F^{sw})^{1/3}$	solute: lactic acid			
	silicone oil/water	—	[72]	
	0.3 M Cyanex 302, 1%-5% v/v Arlancel C, kerosene/water	$\phi = 0.025-0.067$	[73]	
	solute: cadmium sulfate			

Several studies have modeled and attempted to quantify the effect of the Biot number on ELM performance, including Yan et al. [7,33] and Huang et al. [84].

### 25.3.3.4 Damköhler Number

The Damköhler number,  $Da$ , represents the ratio of the reaction rate to the diffusion rate inside the globule [7] and is given by Equation 25.2:

$$Da = \phi_{\text{int}} k_1 R^2 / \alpha_e D_e \quad (25.2)$$

where

$\phi_{\text{int}}$  is the volume fraction of the internal aqueous phase in the emulsion globule

$k_1$  is the reaction rate constant

$\alpha_e$ ,  $R$ , and  $D_e$  are as previously defined

Yan et al. [7] have shown that in the case of batch extraction of acetic acid from dilute solution (using an ELM), when  $Da$  is  $<5$  or  $>200$ , the overall process is controlled by reaction or diffusion, respectively, and by a combination of reaction and diffusion for intermediate values of  $Da$ .

## 25.4 EMULSION LIQUID MEMBRANE PROCESS

Emulsion liquid membrane process can be divided into three stages: 1. emulsification, 2. permeation and settling, and 3. demulsification. Each stage and associated critical parameters are described in the following sections.

### 25.4.1 EMULSIFICATION

The components of an ELM system are the diluent, surfactant, internal aqueous phase, continuous phase, and carrier in the case of type 2 facilitation. Emulsification is usually achieved by high speed or ultrasonic stirrers for batch operations and high-pressure static dispersion or colloid mills for continuous mode [46]. The presence of a surfactant is necessary to ensure adequate stability of the emulsion during the extraction process. However, an ultra stable emulsion is not desirable as it will lead to difficulties in the demulsification stage. For the effective working of an ELM all components must be carefully chosen and each composition is critical. Some of the desirable properties of the various components are listed in the following sections.

#### 25.4.1.1 Surfactants

Surfactant is a key component for the formation of a stable emulsion. Ideal surfactant properties, apart from being relatively cheap and nontoxic include [46]:

1. Virtually no water is carried during operation to prevent/reduce osmotic swelling (see Section 25.4.2.2).
2. No reaction with the extractant in the membrane phase. Any possible reaction should enhance the extraction rather than cause decomposition of the extractant.
3. Low interfacial resistance to mass transfer.
4. Inhibition to demulsification.
5. Solubility in the membrane phase, but not in the internal and external phases.
6. Stability in the presence of acids, bases, and bacteria.

It has been observed that as the hydrophilic lipophilic balance (HLB) value of the surfactant increases, the stability of the emulsion decreases [85]. The contribution of the surfactant to stabilization and swelling is discussed in Sections 25.4.2.1 and 25.4.2.2, respectively.

Stevens et al. [86] proposed the replacement of the surfactant with fluids to modify the rheological properties and stabilize the emulsion. The aim was to slow the drainage of the film between the coalescing drops, thereby increasing the stability of the membrane. Their study on the removal of chromium with Alamine 336 showed that the emulsion stability could be controlled with the addition of small amounts of polymer to the organic phase and that demulsification could be achieved by heating the system.

#### 25.4.1.2 Diluents

The diluent in which the extractant and surfactant are solubilized is a major component of an ELM system. It impacts on the membrane properties such as distribution coefficient and diffusion coefficient and on the effectiveness of the membrane system. Apart from being relatively cheap and readily available, the desired properties of the diluent include [46]:

1. Low solubility in the internal and external aqueous phases.
2. Compatibility with the extractant and surfactant and the inability to form new phases.
3. Moderate viscosity (not too low as to compromise membrane stability).
4. Having a density that is sufficiently different to the aqueous phase.
5. Low toxicity and high flash point.

In general aliphatics are preferred to aromatics as they are more likely to meet most of the listed requirements. To date the most commonly used diluents for ELM systems include kerosene, isoparaffin, cyclohexane, toluene, Shellsol T, heptane, decane, dodecane, nitrobenzene, S100N, and Escaid 110. The pros and cons of specific diluents will be discussed in Section 25.4.2.1.

### 25.4.1.3 Carriers

Carriers tend to be lipophilic and can exhibit quite high interfacial activity [87]. They generally decrease the stability of the ELM due to competitive adsorption (with the surfactant) at the interface [88]. In addition, some carriers have high affinity for water (hydration of their polar groups). Transport of hydrated water can also occur during the metal-carrier complex formation if the metal ion is present as a hydrated complex in the external phase and transports the waters of hydration to the complex formed with the carrier [89]. This effect is more serious in the case of carrier molecules containing many oxygen atoms (such as DEHPA and TOPO) as opposed to those that contain nitrogen (such as LIX64N and Aliquat 336) [89,90]. The interaction of the carrier with the surfactant to form complexes that reduce the free surfactant content of the emulsion has also been reported [90].

Several carriers/extractants/ligands are available commercially for the extraction of acids, bases, elements such as copper, cobalt, nickel, zinc, iron, chromium, precious metals, and the rare earths. The physicochemical properties of the various commercial extractants available for type 2 facilitation have been previously reported by Gu et al. [46] and Cox [91], and the chemical behavior of these extractants can be broadly classified into three categories:

1. Acidic extractants, chelating or non-chelating containing one or more ionizable proton, combine with a metal ion to form a neutral complex. Carriers in this category include hydroxyoximes (P50 (Acorga), LIX 84, LIX 65N, LIX 64N, LIX 860 (Cognis), SME529 (Shell));  $\beta$ -hydroxyquinolines (Kelex 100 (Witco));  $\beta$ -diketones (LIX 54, acetylacetone); carboxylic acids (naphthenic acids, versatic acids); alkyl phosphorous compounds such as organophosphoric acids (DEHPA, DBP); organophosphonic acids (PC 88A, Ionquest 801); organophosphinic acids (Cyanex 272, DTPA); and ionizable crown ethers.
2. Basic or anion exchangers, generally quaternary ammonium compounds and alkylamines, extraction is dependent on the ability of the metal ion to form an anionic species in the aqueous phase and then be extracted as an ion-pair by the amine salt.  
Included in this category are the high-molecular weight primary amines (Primene JMT); secondary amines (Amberlite LA-2); tertiary amines (TOA, TNOA, Alamine 336); and quaternary alkylammonium salts (Aliquat 336).
3. Solvating extractants compete with water for a position in the first solvation shell of the metal ion. The replacement of water molecules by these reagents facilitates the transfer of the metal-ion complex into an organic phase.

Commercial solvating extractants include phosphine oxides (TOPO, Cyanex 923) and phosphorous esters (TBP).

The key criterion in selecting a carrier/extractant is that it and the complex formed must be soluble in the membrane phase, but not soluble in both the internal and continuous phases [46]. Further precipitation within the membrane or at the interfaces must be prevented. To ensure successful stripping, it is necessary to have a solute-complex of moderate stability so as to maximize the effectiveness of the stripping agent [46]. The effect of carrier concentration on the stability of ELM systems is discussed in Section 25.4.2.1.

### 25.4.1.4 Internal Phase

Parameters relating to the internal phase such as volume fraction of the internal aqueous phase, pH, and volume ratio of membrane phase to internal aqueous phase impact on the working of an ELM system. Discussion of the role of the internal phase in terms of swelling, leakage, permeation, and settling is found in Sections 25.4.2.1 through 25.4.2.3.

## 25.4.2 PERMEATION AND SETTLING

Following emulsification, the emulsion is dispersed by mechanical agitation into the external feed phase containing the solute to be extracted. The efficiency of this extraction process is dependent on several parameters as discussed below.

### 25.4.2.1 Composition

A water-in-oil emulsion dispersed in an aqueous phase (W/O/W ELM) is generally stabilized by the addition of a surfactant. In the case of type 2 facilitation, a carrier species is also present. The concentration of these additives together with the composition of the internal aqueous phase, external aqueous phases, and the permeation conditions influence the properties of the ELM system. These effects are summarized as follows:

*Effect of Surfactant Concentration:* Emulsion stability generally increases with increasing surfactant concentration [92,93]. As discussed in Section 25.4.2.3, an increase in surfactant concentration leads to the lowering of leakage due to an increase in the mechanical resistance of the membrane. An increase in this parameter also increases the membrane phase viscosity as well as its resistance to mass transfer including water mass transfer, thus reducing osmosis [89,94].

However, increasing surfactant concentration has the drawback of reducing globule drop size and increasing the interfacial area available for mass transfer of both solute and water. This effect is enhanced in the case where the surfactant molecules themselves have an affinity for water [95,96]. If the surfactant concentration exceeds the critical micelle concentration (cmc), water transport in W/O/W systems by reversed micelles can occur [89,97]. An increase in concentration of some surfactants such as SPAN 80 also leads to an increase in the entrainment of the external phase during permeation promoted by an excess of surfactant molecules [71,98]. Miesiac et al. [99] found that in the case of penicillin G separation, the choice of surfactant could control not only the extraction rate, but also the back transfer rates of the hydrolysis products.

As the surfactant is of key importance in the stability of the ELM much work has been carried out in the area of surfactant development. Wan et al. [100] observed that higher molecular weight surfactants demonstrated much better properties. They have developed a new polymeric-type surfactant: LMA with molecular weights in the range 5,976–56,798 g/mol. Zhang et al. [101] report that LMS-2 is more stable than Span 80 for phenol removal. The anionic, sulfonic-type surfactant EM301 leads to lower swelling than Span 80 and E644 according to Li and Shi [94]. LYF-G2 (sulfonate polybutadiene) showed better emulsion stability than ECA 4360 (polyamine) and EM 301 (surfactant polyisobutylene) for an aqueous HCl feed [102]. Draxler et al. [103] reported that P18 (maleic anhydride/1-octadecene copolymer surfactant) is more compatible with the hydroxyoxime extractant, while Span 80 and polyamine are not. Improved membrane formulation was noted with the addition of 2.5%–5% v/v cyclohexanone [85] as a result of preferential micellization with Span 80, which reduced swelling. Kakoi et al. [104] have developed surfactants that served as both emulsion stabilizer and carrier.

*Volume Fraction of the Internal Phase:* Decreasing the volume fraction of the internal phase will lead to a more stable emulsion in terms of osmosis and leakage due to the increase in the membrane phase layer around the internal droplets [93,105,106]. However, this leads to an increase in surfactant content in the emulsion and a consequent increase in the probability of entrainment [107].

Maximum stability is attained when saturation of the adsorbed surfactant layer is reached. In the case of high-volume fraction at a specific surfactant concentration, if the adsorbed layer is unsaturated, the emulsion stability decreases. In a low-volume fraction case, if the specific surfactant concentration is too high, emulsion stability is also decreased. Therefore, while an increase in surfactant concentration may increase the stability of the internal phase, the absolute stability of the ELM may be decreased [88].

*Carrier Concentration:* Mass transfer rates can be increased by increasing the carrier concentration [41], however, increasing the carrier concentration usually increases swelling and lowers the emulsion stability [33,108]. Other studies have found limits to the carrier concentration where further increases do not lead to an increase in extraction rates as the mobility of the carrier is stifled due to an increase in viscosity [34,41].

*Continuous Phase Composition:* Emulsion liquid membrane properties can be significantly influenced by changing the composition of the external aqueous phase. Emulsion stability can be improved by an increase in the viscosity as a result of the decrease in the rate of fluid drainage between the liquid films [88]. An increase in ionic strength of the external phase has been shown to cause a decrease in entrainment phenomena during permeation. This has been attributed to an alteration of the structure of the interface between the emulsion and the external phase promoted by the presence of electrolytes in the external phase. A reduction in osmosis also occurs due to a reduction in the chemical potential difference between both sides of the membrane [94,98].

*Internal Phase Composition:* As with the continuous phase, the internal phase properties also influence the properties of the ELM. Ionic strength, pH, and the presence of organic species will impact on the stability of the ELM. Emulsion liquid membranes work on the basis that the polar substances (usually high concentrations of acid or base) contained in the internal phase are impermeable to the membrane phase. However, the presence of the surfactant can cause the uptake of these compounds by the formation of reverse micelles [97].

Ma and Shi [109] report on the influence of the internal phase composition on breakage rate in the removal of acetic acid by an ELM system. They found that for a given surfactant concentration and stirring rate, increasing the concentration of NaOH in the internal phase led to an increase in emulsion breakage. These observations have been confirmed by Yan et al. [110] who proposed that high internal reagent concentrations lead to thinning of the electrical double layer, decreasing the stability of the ELM. Bart et al. [89] report on the exponential increase in osmosis with increasing acidity of the internal phase. Care should be taken to ensure that the internal phase reagent concentration is sufficient to effect removal of the solute but not so high as to destabilize the system.

*Internal Phase Droplet Diameter:* Drop size increases with increasing volume [34,41]. However, increasing the drop size will reduce the thickness of the membrane phase and lead to a lower mass transfer resistance. Optimization is a trade-off between interfacial area reduction and the increase in the mass transfer rate because of the reduced membrane thickness and thus small mass transfer resistance [107].

*Diluent and Additives:* There is no doubt that both diluents and any additives have an impact on the efficiency of the ELM system.

Kinugasa et al. [98,111] noted that in the case of aliphatic hydrocarbons, the ELM becomes more stable with increasing number of carbon atoms, while those composed of aromatics, such as toluene, were less stable to mechanical forces. Lin and Long [44] found kerosene to be the more efficient diluent than S100N for nitrate extraction. Kumbasar and Tutkun [112] report that kerosene is a better-performing diluent than STA90 NS for gallium removal by ELM. Lee et al. [41] studied several diluents for europium extraction and report that while *n*-dodecane and kerosene are somewhat similar, xylene demonstrated much lower extraction efficiency. They speculate that the difference may be due to the steric chemistry and polarity effects imposed on the carrier, in this case PC 88A.

Strzelbicki and Schlosser [113] report that the addition of alkylphenol sulphides to ELMs containing ECA 4360 accelerates cobalt ion extraction by DEHPA. Skelland [114] and Skelland and Meng [115] proposed the modification of the rheological properties of the organic phase by the addition of small quantities of polyisobutylene, polybutadiene, or polystyrene. As noted by Shere and Cheung [116], emulsions prepared with high viscosity oils are generally more stable. The effect of such additions includes increases in the membrane viscosity and stability together with a reduction in the amount of surfactant required for stabilization which in turn could lead to a reduction in swelling. Skelland and Meng [115,117] have reported improved performance for the extraction of benzoic acid, phenol, and ammonia with such modifications.

*Permeation Conditions—Stirring Speed, Time, and Temperature:* Turbulent contact of the continuous and emulsion phases can lead to the emulsification of the continuous phase into the emulsion (secondary emulsification) [73]. Swelling also increases with increasing stirring speed [118,119]. Several studies have sought to optimize stirring speed and minimize breakage [41,44]. Gallego-Lizon and Perez de Ortiz [73] state that swelling increases with contact time and may cause emulsion rupture, limiting the operational contact time. Bart et al. [89] report that the degree of osmosis is approximately linear with residence time. The transfer of water across the membrane depends on the temperature that affects the formation of surfactant aggregates, viscosity of the membrane, and the emulsion viscosity.

#### 25.4.2.2 Swelling in Emulsion Liquid Membranes

As mentioned earlier, one of the disadvantages of ELM systems is their tendency to undergo swelling. There are two types of emulsion swelling, namely, osmotic swelling and entrainment swelling. In the case of W/O/W-type systems osmotic swelling occurs as a result of water transfer from the continuous phase into the internal phase due to the large difference in osmotic pressure between the internal and external aqueous phases [120]. Entrainment swelling is caused by the entrainment of the external phase into the internal phase due to the repeated coalescence and re-dispersion of emulsion globules during the dispersion operation thus causing an increase in the volume of the internal phase [33,120].

The disadvantages of swelling are dilution of the separated product in the internal phase, an increase in membrane rupture/breakage, and an increase in agitation power required to disperse the emulsion [121].

Swelling is usually quantified in terms of the swelling ratio, which is defined as the ratio of the diameter of the W/O/W globule at time,  $t$ , to that at time  $t = 0$  [120].

The consequences of swelling according to Yan and Pal [122] are

1. Rapid increase in the internal phase volume
2. Sharp increase in the viscosity of the emulsion
3. Possible breakdown of the globules
4. Retardation of the solute enrichment process
5. Reduced separation efficiency
6. Adverse effects on the final demulsification process

Several mechanisms have been proposed to explain swelling in ELM globules [89,94,122]:

1. Molecular diffusion of water from the external phase to the internal phase [123]
2. Micelle-assisted transport of water from the external phase to the internal phase [124]
3. Water transfer via hydration of the surfactant molecules [123]
4. Entrainment and emulsification of the external aqueous phase due to the presence of excess surfactant; also called entrainment swelling or just entrainment [95,111,117,121]

In most situations, mechanisms (i) and (iii) are the probable reasons for swelling.

Studies on the measurement of swelling in ELM systems have been reported by many, including Li and Shi [94], Wan and Zhang [120], Itoh et al. [121], Yan and Pal [122], and Ramaseder et al. [125]. Yan and Pal [119] proposed an online technique for the measurement of swelling in these systems.

Different methods [120] such as volume variation, internal phase droplet size variation, viscosity variation, density variation, tracer method, Karl-Fischer method, and electrical conductivity have been employed in the measurement of emulsion swelling. The data obtained tends to be as varied as the methods used [120]. One major drawback is that none of the above methods is capable of determining both emulsion swelling and membrane breakage in the same experiment. Further, osmotic swelling cannot be differentiated from entrainment swelling.

Some general observations on swelling in ELM systems suggest that the swelling ratio is dependent on the following four factors [94,119,120,122]:

*Type and Concentration of the Surfactant:* Wan and Zhang [120] observed that both entrainment and osmotic swelling were dependent on the surfactant: in the order of increasing swelling: SPAN 80 > Lan113A > ENJ-3029 > LMA. They note that the low-molecular weight SPAN 80 with a large hydrophilic group mainly comprised oxygen with high electronegativity will have a higher hydration capacity and larger diffusivity compared to the others with high-molecular weight and their hydrophilic group mainly comprised nitrogen with relatively low electronegativity. LMA has the lowest hydration capacity and diffusivity. Li and Shi [94] observed the following order of increasing swelling: SPAN 80 > E644 > EM301, under a given set of conditions. Yan and Pal [119] observed increasing swelling rates with increasing surfactant (EMSORB2500) concentration up to 5 wt% and then a drop with further addition of surfactant.

*Background Electrolyte Concentration:* Since the chemical potential difference between the external and internal phases is the driving force for osmotic swelling [90,120] an increase in the chemical potential difference will result in an increase in osmotic swelling. Wan and Zhang [120] show that electrolyte concentration differences between external and internal phases have no significant effect on entrainment swelling, while this is not the case for osmotic swelling.

*Volume Ratio of the Oil (Membrane) Phase to the Internal Phase:* This parameter can affect the surfactant concentration at the interface of the membrane/aqueous phases and in the bulk membrane phase, affecting emulsion swelling [120]. Both entrainment and osmotic swelling increase with increasing volume ratio of the oil (membrane) phase to the internal phase. The effect of this parameter is also dependent on the surfactant present [120].

*Stirring Speed:* The emulsion is generally dispersed into a large excess of the continuous phase. To maximize mass transfer a large interfacial area is required and this requires a high stirring speed. Increasing the stirring speed not only increases the interfacial area but can also lead to membrane swelling [94] and membrane breakage [120]. Therefore, optimization of the stirring speed is required. This process has been found to be dependent on the surfactant type [94,106,120].

Emulsion swelling is one of the major drawbacks in the use of this technology in industrial situations. For example, the economic advantages of ELM, over conventional solvent extraction for copper processing are lost with a swelling ratio in excess of 30–40 [102]. In terms of processing, an emulsion swelling of about 10% is considered acceptable [45].

### 25.4.2.3 Membrane Leakage

Membrane leakage/rupture/breakdown where the previously extracted solute as well as the stripping reagent are released into the feed stream impacts on the extraction efficiency of the ELM system. It is generally agreed that the properties of the surfactant, diluent, the internal phase, and its volume fraction have significant effects on membrane leakage [46]. Membrane leakage at the rate of ~0.1% is allowable for a practical process [126]. Leakage in ELM systems is well documented: Bunge et al. [93] studied encapsulated phase leakage during ELM extraction of copper ions. They found that the type of surfactant had an impact in that ECA 4360 showed greater encapsulated phase leakage than ECA 5025. The leakage rate decreased with increasing surfactant concentration with a limit at 3 wt%. Leakage is strongly dependent on the volume fraction of the membrane phase with leakage rates increasing greatly when this volume fraction was >0.5. They also noted that the presence of surface active carriers contributed to leakage. Borwanker et al. [25] found that the rate of leakage by membrane rupture is usually a function of surfactant concentration and agitation speed. Okazaki et al. [106] report that the W/O emulsion droplets were not affected by the apparent viscosity of the W/O emulsion but by the organic phase viscosity. They also observed that leakage increased with increasing volume of the internal aqueous phase, leakage was affected by the osmotic pressure difference and that the type of tracer had no effect. In an effort to quantify the effects of such parameters, Okazaki et al. [106] propose two correlations for the leakage rate constant conditional on the osmotic pressure difference between the inner and outer aqueous phases. Shere and Cheung [116] studied the influence of internal phase volume fraction, surfactant concentration, agitation speed, and emulsifying device on leakage. As expected, leakage was significantly dependent on the volume fraction and surfactant concentration. They also found that the use of a high-speed blender rather than an ultrasonic dispenser, for making the emulsion, causes faster leakage and noted that although the viscosity of the emulsion increases if a high-speed blender is used, the stability acquired is offset by the increase in the size of the microdroplets formed with this device. In general, emulsions prepared with a high energy density input such as the ultrasonic method will have smaller

droplets. This will enhance the membrane stability, provided the surfactant concentration is high enough. Smaller droplets also give a large area for interfacial mass transfer [46].

Efforts to compute breakage/leakage in W/O/W include the work of Boyadzhiev et al. [82], Kinugasa et al. [98], Okazaki et al. [106], Martin and Davies [127], and Goto et al. [128]. Nakano et al. [129] report on leakage in O/W/O systems.

### 25.4.3 DEMULSIFICATION

As stated earlier, after extraction the membrane must be broken and the solute recovered. The breaking or demulsification of a loaded emulsion is one of the most important steps in the process as the membrane phase must be available for recycling [46].

The demulsification process can be divided into three stages [130]:

1. Droplet coalescence and growth
2. Droplet settling
3. Coalescence of the large water and oil droplets with their respective continuous phases in the coalescer

To date, chemical or physical treatment is the method used for demulsification.

#### 25.4.3.1 Chemical Treatment

This treatment involves the addition of a demulsifier. For example acetone [85], *n*-butanol [130,131], and 2-propanol [132] have been found to be effective demulsifying agents for particular applications. Although this method is effective, it modifies the properties and prevents reuse because additional separation steps for recovery and recycling are required. Further recovery of the demulsifier by distillation is expensive [101,131].

#### 25.4.3.2 Physical Treatments

Physical treatments include heating, centrifugation, high shear, ultrasonics, solvent dissolution, and the use of high-voltage electrostatic fields [46]. Other nonconventional methods, such as microwave demulsification [134] and the use of porous glass membranes [135], have also been investigated.

##### 25.4.3.2.1 Heat Treatment

The advantages of heat treatment [131] are reduction in the density and viscosity of the oil and an increased solubility of the surfactants in both the oil and water phases. This in turn leads to a weakening of the interfacial film. The main disadvantage is that heat treatment by itself is slow demulsification kinetics.

##### 25.4.3.2.2 High Shear

Emulsion liquid membranes can be effectively demulsified by high shear. A variation on this is to employ centrifugation as a first step, followed by processing in a high shear device [46].

##### 25.4.3.2.3 High-Voltage Electrostatic Fields

By using high-voltage electrostatic fields not only can faster coalescence be achieved, but also the organic phase can be recycled. The mechanisms of electrostatic demulsification are not completely understood. The general belief is that the electric field can polarize and elongate water droplets, neighboring water droplets, after acquiring induced charge from the electric field, will attract each other and coalesce to form a larger drop.

The use of electrostatic fields believed to be the most efficient and economic method of demulsification [46] will be discussed further in terms of equipment used, operating parameters, and proposed models for the process.

*Equipment:* Several types of ac and dc electrostatic coalescers have been developed. Documented equipment for electrostatic demulsification includes the continuous insulated electrode coalescer [130,136], two-phase insulated electrodes in parallel [126], circular coalescer [137], continuous coalescer [138], horizontal insulated electrode [130], box electrostatic demulsifier [139], tubular coalescer [140], and batch cylinder demulsifier [141]. Design criteria for electrostatic demulsifiers have been reported by Draxler and Marr [142] and Draxler et al. [143].

*Operating Conditions:* Parameters such as applied voltage, frequency, waveform, temperature, stirring, and additives have been shown to have an impact on the demulsification process. Kataoka and Nishiki [144] enhanced demulsification with increasing voltage as did Wang et al. [141], Fujinawa et al. [145], and Hauertmann et al. [146]. However, there are limits to maximize voltage that can be applied before formation of a stable sponge emulsion (a high water content water-in-oil emulsion) as noted by Larson et al. [131].

Feng et al. [138] found that coalescence efficiency could be improved with increasing frequency. Draxler et al. [103] demonstrated that for a given degree of demulsification the voltage could be reduced if the frequency was enhanced. It has

been shown that under constant voltage an optimum frequency exists, below which the demulsification rate was enhanced with increasing frequency, but above which the rate decreased with increasing frequency [147–149].

A square waveform has been shown to be more effective than a triangular or sine form [102,148,149]. The proposed explanation of this is that under the same peak voltage, the square waveform offers longer time to act on the water droplets to be coalesced.

Both stirring and temperature elevation have been shown to accelerate demulsification [130,138,150]. Hsu and Li [130] report that insulation material having a dielectric constant  $>4$  offered better demulsification performance. Goto et al. [140] report on the effect of surfactant type on demulsification.

*Modeling:* Many researchers, including Goto et al. [140], Wang et al. [141], Fujinawa et al. [145], and Hano et al. [150], have attempted to quantify the rate of demulsification. In a recent development, Ichikawa et al. [151] and Ichikawa and Nakajima [152] proposed a theory for electrostatic demulsification of O/W emulsions (by low-external electric fields) based on the Poisson–Smoluchowski equation. Their theory revealed that the applied field induced demulsification according to the following mechanisms [152]:

1. Applied field induced a steady-state current of ions in the aqueous phase, which in turn generated an electric field in the aqueous phase.
2. Electric field in the aqueous phase rearranged surface charges on the oil droplets to compensate the field gradient on the surface of each droplet, which caused the polarization of the electrostatic surface potential.
3. Polarization lowered repulsive osmotic pressure in the overlapped diffuse electrical double layers of the droplets and accelerated demulsification.

## 25.5 APPLICATIONS

Documented applications of ELMs include [2,46,153–158]:

1. Wastewater treatment, e.g., removal of zinc, removal of radioactive materials and nuclear wastes, recovery of nickel from plating wastes, and phenol removal.
2. Biochemical processing, e.g., recovery of penicillin and erythromycin.

A summary of a number of systems studied in both categories is presented in Tables 25.4 through 25.8. While the majority of the work to date has been on W/O/W systems, studies on the use of O/W/O systems for the removal of various oils have been reported [1,216,217,129].

## 25.6 PILOT PLANT STUDIES/COMMERCIAL APPLICATIONS

As stated earlier, one of the major advantages of ELM technology is the creation of systems with very high surface area to volume ratios. As noted by Kentish and Stevens [218], with such systems, large interfacial areas can be achieved in units that occupy significantly less floor space and cost much less than traditional solvent extraction columns. This has led to the commercialization of this technology for the extraction of zinc [157,219], phenol [219], and cyanide [219] from wastewater. Pilot plant studies have also been conducted on the use of ELMs for the removal of contaminants such as cadmium [220], copper [221], chromium [160], and zinc [157,219] from wastewaters. Details of some pilot plant and commercial studies are given in Table 25.9. Other plants for the removal of zinc have been noted in the literature [157]: Glanzstoff AG, Austria (7000 L/h), CFK Schwarza, Germany (200 L/h), and AKZO/Ede, the Netherlands (200 L/h).

## 25.7 CONCLUDING REMARKS

Nearly 40 years since the initial reporting of the emulsion liquid membrane concept and the many potential applications discussed in the literature, very few commercial plants are operating successfully. This technology offers a number of distinct advantages including reduction in the volume of organic, the large interfacial area, hence transfer rates are compared with traditional solvent extraction. However, issues of osmotic swelling, the stabilization, and destabilization of the emulsion remain

a problem. Also, the influence of surface active impurities on the stabilization process is an issue during reuse of these systems. These challenges to the industry implementation of this technology remain as barriers to more wide spread application. At present, however, the technology has found some application in the treatment of relatively low-concentration waste streams where other technologies are not economical. Hence experience in these applications will drive further development and confidence in this technology and so find its niche in the available separation technologies.

**TABLE 25.9**  
**Pilot Plant and Commercial Applications of ELM Systems**

Application	Company	Plant Size	External Phase	Membrane Composition	Internal Phase	Demulsifier	Efficiency
Removal of copper from mine solutions [221]	Bureau of Mines, United States	Pilot plant: 90–159 L/h	0.12–1.4 g/L Cu(II)	5.0–7.5 wt% Acorga M5640, 1.0 wt% Paradox 100, 91.5–94 wt% 50–50 Isopar	8.5–20 g/L Cu(II), 160–165 g/L H <sub>2</sub> SO <sub>4</sub>	5–8 kV, 60 Hz	>90%
Removal of copper from synthetic mine solutions [45]	Davy McKee Company, United Kingdom	18 L/h	500 ppm Cu(II), pH 2.5	2.5 wt% LIX 64N, 2.0 wt% polyamine, 95.5 wt% S100N	30 g/L Cu(II), 150 g/L H <sub>2</sub> SO <sub>4</sub>	—	95%
Removal of cadmium [220]	Delft University of Technology, the Netherlands	Pilot plant: 90 L/h	100 ppm Cd	0.5%–1.0% Alamine 304 in Shellsol D 70, 0.5–1.0% ECA 4360J	1 M HNO <sub>3</sub> , 10 mM KNO <sub>3</sub>	Electrostatic splitter 3 kV, 4 kHz	95%
Removal of phenol [187,219]	Nanchung Plastic Factory, Guangzhou, PR China	Pilot plant: 200–250 L/h Commercial plant: 400–500 L/h	350–925 mg/L phenol	3.5 wt% LMS-2, 6.7 wt% liquid paraffin, 89.8 wt% kerosene	5 wt% NaOH	Coalescer EC-1 20 kV, 0.6–25 kHz, 50 mA, capacity 20 L, 32–55 L/h	99.6%

## SYMBOLS

$B$	constant
$b$	constant
$b_1$	constant
$B_2$	constant
$B_3$	constant
$Bi$	Biot number
$Da$	Damköhler number
$D_e$	effective solute diffusivity in the emulsion mixture
$d_{32}$	Sauter mean diameter of the dispersed phase droplets/globules
$d_s$	stirrer or impeller diameter
$f_\phi$	ratio of actual mean drop diameter to diameter at $\phi = 0.1$
$F^{sw}$	swelling factor
$k$	external phase mass transfer coefficient
$k_1$	reaction rate constant
$N_{vi}$	$(\rho_c/\rho_e)^{1/2} \mu_d \varepsilon^{-1/3} d_{32}^{1/3} / \gamma$
$R$	radius of the emulsion globule
$Re$	Reynolds number
$P$	power input
$T$	vessel diameter
$t_c$	circulation time
$V$	volume of the fluids
$V_e$	total volume of the external phase
$V_i$	total volume of the internal phase
$V_m$	total volume of the membrane phase
$We$	Weber number = $\omega^2 d_s^3 \rho_c / \gamma$

## Greek Symbols

$\alpha_e$	the distribution coefficient of the solute between the external and membrane phase
$\alpha_i$	the distribution coefficient of the solute between the internal and membrane phase
$\Delta\rho$	density difference between (W/O) emulsion and the continuous phase
$\gamma$	interfacial tension between the membrane and the external phase

$\varepsilon$	$P/V(1 - \phi_{av})\rho_c$
$\varepsilon_{av}$	average energy dissipation rate per unit mass
$\varepsilon_{max}$	turbulence kinetic energy dissipation rate per unit mass
$\mu_c$	dynamic viscosity of the continuous phase
$\mu_d$	dynamic viscosity of the dispersed phase
$\nu_c$	kinematic viscosity of the continuous phase
$\rho_c$	density of the continuous phase
$\phi$	volume fraction of the dispersed phase
$\phi_{av}$	vessel average of $\phi$
$\phi_{int}$	volume fraction of the internal aqueous phase in the emulsion drop
$\omega$	stirring rate

## 26.1 INTRODUCTION

### 26.1.1 CELL PLASMA MEMBRANE AND BIOTECHNOLOGICAL POTENTIAL

Cells are the basic building units of living organisms, which are bounded by intricate plasma membrane guarding the cell interior. Life or death of a cell critically depends on the intactness of outer membrane whose structure and function are intense research curiosity and also, a potential source of developing various technologies for biomedical and industrial applications. Over the years, considerable understanding of cell membrane structure and function has been obtained but much remains to be learned. It is fairly well established that plasma membrane of mammalian cell mainly consists of lipids, proteins, and cholesterol, and a bilayer of lipids forms the core structure separating the cell interior from the exterior surroundings. The recent impetus in biotechnology has propelled membrane research to unravel the molecular design and function of cellular membrane with the hope of developing novel products and processes. A few tools and devices based on membrane have already been developed and employed for practical applications in medicine, industry, and biotechnology. Modeled after cell membrane, liposomes have been prepared in laboratory, which have found numerous biological, medical, and industrial applications. The precision, speed, and sensitivity with which real cell membranes regulate molecular transport, sense tiny concentration of substances, carry out intermolecular communications have much to offer in developing strategic and biocompatible materials, sensor devices, and signal processor technologies. Extensive recent research has provided a few physical and chemical methods to overcome natural transport barrier of membrane, opening many new prospects for cellular engineering and membrane biotechnology. For example, methods have been developed to introduce exogenous molecules into a variety of plant, bacterial, and mammalian cells but some limitations are encountered. Obviously, gaining access to the cell interior without affecting cell viability holds enormous potential to basic research in exploring the tiny internal world of living cells and in providing exciting new opportunities to modify cellular composition in controlled fashion with prospects in nanoscience, biomolecular engineering, cell membrane fusion and intermembrane trafficking and communication, signaling, sensing processes, etc. that are at work in living cell function. To cope with the harsh variable surroundings, cells have evolved antenna network and implanted microswitches on their membrane surface, which allow them to sort specific ligands and deal with the external stresses for maintaining their survival. The precise steps involved in these functions have remained intriguing but they may offer a whole new opportunity for developing devices to recognize and sort out ensemble of molecules required for numerous applications in diagnostic medicine, pollution science, signal processing, and cell biotechnology. The key to success in achieving newer practical applications largely lies in delineation of molecular design of membrane architecture and in accomplishing the controlled permeabilization of plasma membrane. Advanced imaging methods have aided enormously in learning the intricate dynamic structure and function of cellular membrane, which have generated a host of new opportunities for biomolecular engineering, medicine, and structural science.

### 26.1.2 PERMEABILITY BARRIER AND ELECTROPORATION PHENOMENON

Biological cell membrane is composed of phospholipid bilayer core of a few nanometers thickness, which controls molecular transport and separates cellular interior from the surrounding. Cells possess an intrinsic electrical potential across their membrane due to concentration gradient of ions between the cytosol and surroundings, which plays vital role in regulation of a variety of their functions [1,2]. During the late 60s and early 70s, it was observed that application of high intensity, short duration electric field across cells beyond a certain threshold value dramatically increased the permeability of their membrane allowing entry of otherwise impermeant exogenous substances (Figure 26.1). This phenomenon is popularly called electroporation [3] (and references therein). A variety of external bioactive substances, such as, enzymes, drugs, genes, signaling molecules, and DNA constructs, can be incorporated into cells, which has opened many new prospects in cell biology, biotechnology, and medicine. Scientists have long aimed to change natural makeup of plant, bacterial, and animal cells by introducing external DNA with defined traits but efforts were hampered due to tight bilayer membrane barrier. Over the years, a number of bacterial, yeast, plant,

**FIGURE 26.1** Biological cell in electric field and entrapment of exogenous substances.

and mammalian cells have been electroporated for introduction of drugs, genes, enzymes, DNA, and other substances providing a valuable tool and technology for drug loading, cancer treatment, gene therapy, cell fusion, etc. [3].

### 26.1.3 SCOPE AND OUTLINE

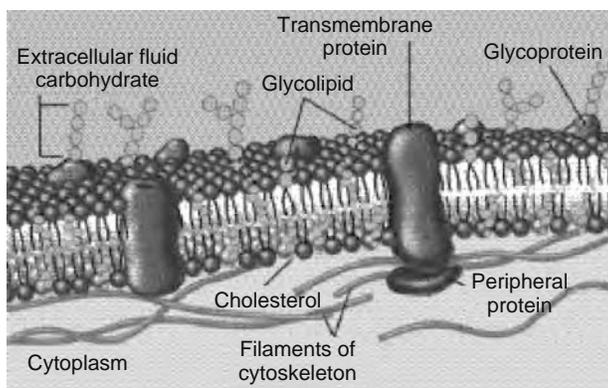

The area of membrane science and technology is witnessing rapid progress and several devices and procedures are under development for biomedical and industrial applications. This article is confined to description of cell membrane electroporation/permeabilization with examples of a few biomedical technologies for potential practical applications. The phenomenon of cell electroporation has attracted scientists from both basic science as well as engineering disciplines and, currently, it is viewed as an engineering alternative to biological methods for the genetic engineering of cells.

This chapter presents a brief review of basic and applied aspects of cell membrane electroporation with relevance to cell biology, biotechnology, and medicine. The content material is certainly not intended to be exhaustive. To enable the reader better grasp the phenomenon of electroporation, a brief account of physical–chemical aspects of cell membrane and basic mechanisms of membrane electroporation/permeabilization have been included. The factors that affect the electroporation efficiency of cells have been outlined including a brief mention of technical advances in electroporator instrumentation. Some applications based on membrane electroporation have been described which are relevant to cell biology, health care, and industry. Cell fusion, loading of impermeant exogenous molecules into cells, electroporative drug and gene delivery, and introduction of DNA and proteins have briefly been described. Recent progress on industrial applications, such as, sterilization of water and liquid food and single-cell electroporation, and their future potential applications in biotechnology have been described.

## 26.2 PHYSICOCHEMICAL ASPECTS OF CELL MEMBRANE

### 26.2.1 PHOSPHOLIPID BILAYER

The core structure of cell plasma membrane is made of phospholipids arranged in a bilayer with embedded proteins. The phospholipids are amphipathic in nature having both hydrophilic and hydrophobic moieties. The lipids are packed in the bilayer such that the polar head groups face water and the nonpolar segments form the core, insulating the cell interior from the surroundings (Figure 26.2). The bilayer is a self-organized basic membrane structure (5–10 nm thick). The nature and composition of phospholipids control the physical properties of membrane. Though basic skeleton of the bilayer remains unchanged, the composition of the lipids widely differs in bacteria, plant, and mammalian cells. There are three major membrane lipids, namely, phospholipids, glycolipids, and cholesterol which are prevalent in mammalian cells. Of these, the

**FIGURE 26.2** Schematic fluid mosaic model of cell membrane structure.

phospholipids are the most abundant. A typical phosphoglyceride molecule consists of a glycerol backbone, a phosphorylated alcohol, and two fatty acid chains (Figure 26.2). The fatty acids consist of long hydrocarbon chains (14–24 carbon atoms) and may be either saturated or have one or more unsaturated chemical bonds in their structure. Glycolipids are the sugar-containing lipids and in animal cells, the glycolipids are derived from sphingosine. Cholesterol forms another important class of lipids, which is mostly present in the eukaryotes and rarely in prokaryotes. Eukaryotic cells have an abundance of the cholesterol in the plasma membrane. The phospholipids and the glycolipids can readily form vesicles (liposomes) with one or multiple concentric spherical bilayers in aqueous medium, which can be easily prepared in laboratory and they serve as model of membrane. Lipid bilayers are the backbone of the biological membrane [1].

### 26.2.2 MEMBRANE PROTEINS

The cell plasma membrane consists of a variety of proteins associated with the lipid bilayer and they perform multitasks in cell function. The control of transport of ions and molecules across membrane is accomplished through specialized function of membrane proteins. These proteins are distributed in membrane on the outer surface, some on the inner surface, and some others are transmembrane proteins with external and cytoplasmic domains. The majority of the transmembrane proteins are the ion channels or signaling proteins. Generally, lipid to protein ratio is 60:40 but this ratio is found variable in different cells and types of membranes. Membrane proteins impart the dynamic structure and selectivity to membrane function. Both proteins and lipids show motional and diffusion properties within the bilayer structure.

### 26.2.3 FLUID MOSAIC MEMBRANE STRUCTURE

Jonathan Singer and Garth Nicolson proposed the fluid mosaic model of the plasma membrane in 1972 based on the available experimental results [1]. The model suggested that essentially, the membranes were two-dimensional solutions of lipids with proteins incorporated into them forming a mosaic structure (Figure 26.2). This model of membrane structure is widely accepted and continues to be the central to our present understanding of membrane structure. The model is based on following salient features: (1) most phospholipids and glycolipids are arranged in bilayer structure, which has a dual role of acting as a solvent for the proteins forming structural assembly and conferring a permeability barrier to membrane, (2) a small proportion of the lipids closely interact and are in intimate contact with the membrane proteins, (3) membrane proteins are free to diffuse laterally in the lipid matrix unless restricted but they are not free to rotate from one side to the other, and (4) lipids are able to diffuse laterally and they also exhibit flip-flop across the bilayer. Major functions of membrane, e.g., selectivity, receptivity, transport, etc., are attributed to proteins present in their structure.

### 26.2.4 PHYSICAL ORGANIZATION

The major physical forces, which help the membrane to maintain their structure, consist of hydrophobic and hydrophilic interactions, electrostatic forces, and van der Waals interactions. The main driving force for formation of the bilayer originates from the hydrophobic interactions and van der Waals interaction forces between hydrocarbon chains of the lipid molecules. The hydrophobic forces control the order and packing of lipids and electrostatic interactions between the polar head groups and their interaction with water molecules contribute to bilayer stabilization. The bilayer is continuous and it exhibits semirigid properties. The fluid nature of the membrane is governed by the lipid composition and the nature of the forces that exist between the constituent lipids and proteins. Due to fluid lipid bilayer, the diffusion constant for a phospholipids is  $\sim 1 \text{ m}^2/\text{s}$ ,

which means a lipid molecule can travel from one end of the cell to the other in  $\sim 1$  s. Nature seems to have chosen the two fatty acid chain phospholipids as basic building block of the membranes because they self-associate in water at very low concentrations and are very hydrophobic, which imparts the internal high lateral tension within the bilayer enabling them exhibit self-healing of structural bilayer alterations including induced transient leaks. Lipids suspended in excess of water tend to form liposomes, which exhibit high degree of stability due the energy minimization principles between the energy needed to bend the bilayer and the energy gained by avoiding the exposure of the hydrophobic regions to water [2]. The self-assembly property of the phospholipids allows formation of liposomes in the laboratory which are magic bags consisting of the bilayer containing an aqueous core, which can be prepared from a variety of lipids and can entrap both hydrophobic and hydrophilic therapeutic drugs with novel prospects in pharmaceutical technology and drug delivery.

### 26.2.5 MOLECULAR TRANSPORT AND PERMEABILITY BARRIER

The plasma membrane carries out the job of specialized and fool-proof security to cell interior with a semipermeable barrier for molecules, allowing some and denying others for entry or exit. The controlled and selective permeability protects cells against unwelcome guest molecules and disallows vital cytosolic molecules to leave and thus maintaining the natural integrity of the cell/organelle. The cellular membranes show high sensitivity and exceptional selective permeability to ions, small solutes, and macromolecules including invading organisms. Channels specific to a particular solute or ion mediate control of the molecular transport across bilayer membrane. Cell membranes are structurally and functionally asymmetric, i.e., the outer and the inner surfaces of biological membranes present different interfaces perhaps an essential component of molecular design for functional sophistication. Mammalian cells have predominance of phosphatidylcholine in the outer layer and phosphatidyl serine in the inner layer. The membrane fluidity is controlled by the nature of the fatty acids of the membrane lipids; the saturated fatty acids tend to make the membrane rigid, whereas the unsaturated acids make them fluid basically due to the bending in the unsaturated hydrocarbon chain.

The transport of the molecules across the membranes takes place in highly regulated fashion for both active, i.e., using metabolically useful energy, and passive, i.e., without any energy requirement. The transport of water seems to occur freely through diffusion process. The transmembrane proteins act as gates or channels for specific ions. The ion channel proteins are called so because they allow only unidirectional passage of ions, e.g.,  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Ca}^{2+}$  channels. There are other proteins that allow the passage of other essential biomolecules. Molecules can be transported across membrane through passive diffusion and facilitated or active transport processes. In addition to plasma membrane, mammalian cells have a several intracellular membranous network in subcellular organelles through which they control molecular trafficking within the cell.

### 26.2.6 METHODS TO OVERCOME BILAYER BARRIER

Extensive research on the attempts to overcome the bilayer membrane barrier has resulted in the emergence of several different methodologies for partial and temporary cell membrane permeabilization. The prominent among them are chemical permeabilizers, liposomal interactions, ultrasonication, ionizing radiation, and electroporation.

The liposome can be made in such a way that they mimic the cellular plasma membrane and drugs/other potential impairment molecules can be loaded in the aqueous core or bilayer milieu of the liposome. Generally, the liposomal membrane fuses with the cell plasma membrane and releases the contents into the cytosol. Thus, liposomes provide an effective tool for overcoming the bilayer barrier and deliver drugs to targets in cells.

A number of chemicals, such as, ammonium chloride, poly(ethylene glycol) (PEG), and calcium salts, have been found to facilitate entry of external molecules into cells, though to a limited extent. Exposure of cells to ionizing radiation, ultrasonic waves, and electric fields has been found to overcome membrane barrier allowing exchange of molecules between cell interior and surroundings. Each method, however, is faced with its own merits and demerits imposing restrictions. In the following sections, the methodology of overcoming the membrane barrier by exposure of cells to external electric field is described with some details.

## 26.3 CELL MEMBRANE ELECTROPORATION

### 26.3.1 BASIC PRINCIPLE

When cells are placed in external applied electric fields, they experience an electric force. Electroporation involves the use of short, high voltage pulses to overcome barrier of the cell membrane. When a cell is submitted to an external electric field of high intensity and short duration ( $\text{kV/cm}$ ,  $\mu\text{s}$ ), transient and dramatic increase in the permeability of the plasma membrane occurs beyond a point. This phenomenon is popularly called electroporation or electroporeabilization, which allows entry of otherwise impermeable exogenous molecules into the cell interior. This phenomenon has been an active area of research in biology and bioelectrochemistry for more than three decades [3,4] and has found many applications in cell biology,

biotechnology, and medicine. The following sections discuss the fundamentals of membrane electroporation and various factors that affect the cell electroporation efficiency.

### 26.3.2 RESTING AND INDUCED TRANSMEMBRANE POTENTIAL

An intrinsic ionic charge gradient across the membrane exists because of semipermeable nature of membrane, which maintains a difference in the concentration of the ions between the cytosol and the extracellular matrix. This difference results in a definite potential across membrane of the normal cells, which is called the resting potential. Normal plant cells, mammalian muscle cells, and neurons have resting potential values of about  $-120$ ,  $-90$ , and  $-70$  mV, respectively. Along with the resistance to the flow of ions, membrane also exhibits a capacitance,  $C_m$ , which is given by

$$C_m = \frac{Q}{V_m} \quad (26.1)$$

where

$Q$  is the net excess positive or negative charge on either side of the membrane

$V_m$  is the potential across the membrane

The typical value of the membrane capacitance is  $\sim 1 \mu\text{F}/\text{cm}^2$  of membrane surface area. A general equation governing the potential difference across the membrane is given by

$$E_k = \frac{RT}{ZF} \ln \frac{P_K[K^+]_O + P_{Na}[Na^+]_O + P_{Cl}[Cl^-]_{IN}}{P_K[K^+]_{IN} + P_{Na}[Na^+]_{IN} + P_{Cl}[Cl^-]_O} \quad (26.2)$$

where

$R$  is the ideal gas constant

$F$  is the Faraday constant

$Z$  is the charge

$T$  is the temperature in Kelvin

$[K^+]_O$  and  $[K^+]_{IN}$  are the concentrations of potassium ions outside and inside the cell, respectively

$[Na^+]_O$  and  $[Na^+]_{IN}$  are the concentrations of sodium ions outside and inside the cell, respectively

$[Cl^-]_O$  and  $[Cl^-]_{IN}$  are the concentrations of chloride ions

The  $P$ 's stand for the partial pressures of the ionic species

A biological cell can be viewed as an electrical entity which can be represented by an equivalent circuit.

### 26.3.3 BIOPHYSICAL BASIS OF MEMBRANE ELECTROPORATION

The cell can be imagined to be a nonconducting sphere with an inner side equipotential. For a spherical cell placed in an externally applied electric field,  $E_e$ , the transmembrane potential at any point on the cell membrane due to the applied field is obtained from Laplace's equation and is given by  $V_m$  or  $\varphi_m$

$$\Phi_m = 1.5r_{\text{cell}}E_e \cos \theta \quad (26.3)$$

where

$r_{\text{cell}}$  is the radius of the cell

$\theta$  is the angle between the radius vector of the point at which the potential is measured in the direction of the electric field

Factor 1.5 represents a constant for the spherical geometry of the cell (Figure 26.1)

At  $\theta = 0$ ,  $\Phi_m = 1.5r_{\text{cell}}E_e$  and at  $\theta = \pi$ ,  $\Phi_m = -1.5r_{\text{cell}}E_e$ . The difference in the transmembrane potential between the two diametrically opposite points of the cell surface is  $3r_{\text{cell}}E_e$ . Thus, rapid application of the electric field results in the membrane polarization changes that can locally deform the membrane leading to formation of leaks or pores. For a cell of radius  $r_{\text{cell}} \sim 10 \mu\text{m}$ , to produce a transmembrane field  $\Phi_m \sim 0.5$  V, the required applied field is  $\sim 300$  V/cm [5–8]. However, this is the effect of the direct field (DC). This equation implies that larger is the radius of a cell, smaller will be the field required to reach threshold value for permeabilization to occur. It is implicit that bacteria will require larger fields than mammalian cells and also, while plasma membrane can be permeabilized at a particular field value, subcellular network of membrane, e.g., mitochondrial, Golgi, lysosomal membranes would largely remain unaffected.

When an alternating field (AC) is applied on the cell, Equation 26.3 is modified as follows:

$$\Phi_{\text{mAC}} = \frac{1.5r_{\text{cell}}E_e \cos \theta}{[(1 + \omega t_{\text{mem}})]} \quad (26.4)$$

where

$t_{\text{mem}}$  is time

$\omega$  is the angular frequency of the AC field

$C_m$  is the membrane capacitance

It may be noted that for  $\omega = 0$ , Equation 26.4 gives rise to Equation 26.3. The changes in the transmembrane potential have been experimentally observed and quantitatively measured.

#### 26.3.4 ELECTROPORATION THRESHOLD

The resting transmembrane potential is important for threshold of membrane permeabilization. The dependence of the transmembrane potential  $\Phi_m$  (Equation 26.1) on the radius and the magnitude of the applied electric field make electroporation a threshold phenomenon. When the field reaches a certain threshold value, a transient reorganization of the phospholipid bilayers takes place, making the membrane temporarily more conducting [4–9]. Evidently, at a constant applied electric field, the electroporation efficiency will depend on the cell size. For a particular cell type, there exists a particular threshold value of the electric field. Thus, electroporation is a threshold process and each type of cell displays its characteristic threshold beyond which membrane permeabilization occurs. The length of the pulse does not seem to alter the threshold voltage for a particular cell. Studies have shown that exposure of cells to multiple pulses of subcritical voltage does not permeabilize membrane [10].

#### 26.3.5 MECHANISM OF ELECTROPORATION

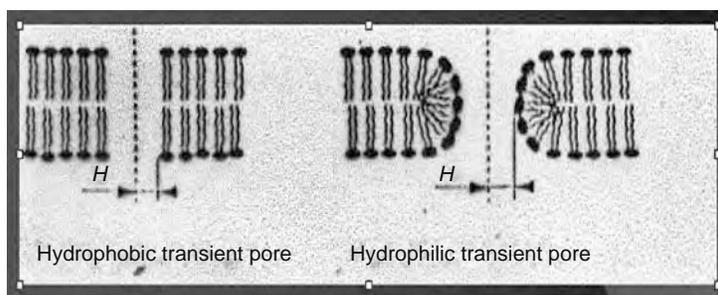

The application of the electric field imposes modulations on the intrinsic membrane potential, which gives in to induced field force beyond a critical stage. This enhanced permeability is believed to be due to a lipid bilayer membrane reorganization [11–13], which can under certain situations convert to structural membrane defect leading to the formation of hydrophilic pores [10]. These induced pores allow the molecules and ions, which are otherwise impermeable to diffuse through membrane [11–15]. However in cellular membrane, the pores are transient and the resealing or reversal begins after withdrawal of the electric fields [16,17]. Contrary to this view, some researchers suggest structural change in membrane state and prefer to call it electropermeabilization [18] and others suggested local electrical breakdown of membrane when cells were exposed to fields beyond critical threshold value [13].

##### 26.3.5.1 Pore Model

Different models have been suggested for observed increase in dramatic membrane permeability under external field. According to one model, permeability increase occurs because of the formation of pore, a hypothetical microstructure of transient nature, in the bilayer portion of a cell membrane. In this model, it has been suggested that rupture of a lipid bilayer underlies the induction of pore formation. As suggested by Chizmadzhev and coworkers [14,15], the initial hydrophobic pores formed can be hypothesized to any size, with radii from zero upward, whereas in contrast, the conversion of hydrophobic pores into hydrophilic pores can take place and they are believed to have a minimum size that is related to the phospholipids head group size and several head groups are needed to involve in formation of hydrophilic pores (Figure 26.3). It is also suggested that possible transient structures for hydrophilic pores may involve a block complex or the cell membranes may involve membrane macromolecules. The concept of pore formation is based on bilayer or planar membrane studies [10–12]. Some scientists believe that electroporation of cellular membrane is peculiar and prefer to call it electropermeabilization and have some reservation about the pore model [18,19]. In actual cell membrane, electroporation process seems to follow complicated mechanism, which is a subject of research and debate.

##### 26.3.5.2 Mechanical Breakdown Model

Another model suggested by researchers consists of the dielectric breakdown of membrane beyond threshold, which largely represents irreversible pores and is believed to be more prevalent in planar bilayer membrane though its occurrence in cells was reported [13]. According to this model, because of action of induced opposite charges across bilayer, thinning of bilayer occurs and at weak locations of bilayer, compression pressure wins resulting in increased thinning of membrane which ruptures beyond a field point due to electromechanical force [8,20]. These concepts are a matter of scientific debate and require

**FIGURE 26.3** Schematic model for hydrophobic and hydrophilic pore formation by electroporation.

clarification from more research but currently most widely accepted model is the formation of micropores in membrane by the action of high voltage external electric field.

### 26.3.6 RESEALING OF ELECTROPORATED MEMBRANE

Resealing characteristics determine the viability as well as nature and size of exogenous molecules for incorporation into electroporated cells [21–24]. The composition of the membrane differs from one cell type to another, and consequently, the obtained electroporation efficiency of cells. In addition, it is evident from Equation 26.3 that the magnitude of induced membrane potential depends on the shape and dimension of the cell.

Exposure of cells to short duration of pulses usually causes reversible micropore formation, which either under certain conditions slip to irreversible hydrophilic pores or may reseal under favorable experimental conditions. The later results in the survival of electroporated cells, which allows several biomedical applications, such as, loading of drug, incorporation of bioactive molecules, gene transfer, etc. However, electric fields causing higher transmembrane potential changes and longer prevailing permeabilization can produce irreversible membrane damage causing cell death [22–25]. The irreversible membrane electroporation is suggested to arise from rupture of a part of the cell membrane creating a permanent hole or due to secondary effects leading to lysis of cells as a result of chemical imbalances caused by the molecular movement across the pores [14,15]. Use of square wave pulse allows control of amplitude and duration separately. In optimized conditions, it is possible to achieve 95% of cells permeabilized with minimum loss of viability in the treated cell population (~5% cells) [26].

### 26.3.7 FACTORS THAT CONTROL ELECTROPORATION OUTCOME

Over the years, extensive research on cell electroporation has revealed that the efficiency of cell poration is governed by several factors, such as, physical, electrical, biological, and suspension medium [22–25,27]. Therefore, optimization of electroporation parameters for each type of cell and for a particular desired application becomes essential for successful outcome. There are several parameters that should be considered for optimization of electroporation outcome especially for in vitro electroporation experiments.

#### 26.3.7.1 Electrical Parameters

##### 26.3.7.1.1 Field Strength and Pulse Shape

External field strength and the shape of electric pulse field play a major role in the electroporation efficiency. The applied electric field is generally DC rectangular or exponentially decaying pulses of variable duration. A rectangular pulse is generated from high voltage power supply, whereas discharging a capacitor through sample containing circuit generates exponential pulse. Research has revealed the dependency of electroporation efficiency on pulse shapes, i.e., shape of the electric pulse being of the type exponential decay, or square wave pulses (Figure 26.1). Use of square wave pulses is suggested preferable over exponential type to eliminate solution conductivity effects on electroporation efficiency. More recently, it has been shown that the electroporation outcome of cells also depends on the type of square wave pulses, namely, monophasic and biphasic [28]. The biphasic square wave pulses have been reported more efficient in causing permeabilization. Although square wave and exponentially decaying pulses were most frequently used, some experiments have used trapezoidal pulses for possible controlled pulse rise and fall time [23]. Fields of a few kilovolts for mammalian cells and pulse durations of microsecond to millisecond ranges have generally been used. When experiments are conducted using population of cells, a trade-off is observed between cell viability and transfection efficiency. Optimization of field strength, pulse length, number of repetitive pulses, and electrode geometry are known to affect the electroporation efficiency.

### 26.3.7.2 Experimental Conditions

#### 26.3.7.2.1 Electrodes and Pulsing Medium

Electroporation efficiency depends on the parameters of electric pulses that are delivered to the treated cells using specially designed electrodes and electronic devices. In vitro experiments usually employ parallel plate types of electrodes made of inert metals like stainless steel or platinum but needle types of electrodes are also used for tissue electroporation [24,25,27,28] as well as for tumor treatment applications [29–32]. There are two types of electroporator devices available: devices with voltage output and those with current output. However, a voltage output device seems to be preferable, which is widely used for diverse applications.

#### 26.3.7.2.2 Pulsing and Incubation Medium

Composition of electroporation buffer is an important factor affecting electroporation yields. Ionic strength of cell suspension medium needs control, which determines resistance of the cell suspension and resultant RC time constant of the field pulse. Medium supplemented with  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in  $\sim\text{mM}$  concentration range is found to promote efficiency of transformation and cell viability. Erythrocytes electroporated in isotonic buffer in the presence of EDTA or membrane specific drugs showed significant modification in hemolysis response to electroporation [33,34]. Use of square wave pulse removes the medium conductivity mediated effects on cell/tissue electroporation outcome. Generally, cells are pulsed in suspensions of sucrose, mannitol, or sorbitol. Electroporation as well as incubation of pulsed cells can be carried out in medium containing usual cell culture recipes.

#### 26.3.7.2.3 Post Electroporation Incubation Temperature

The temperature of the samples during pulse application and subsequent incubations decisively affects the cell electroporation outcome. Post pulse incubation temperature determines the rate and magnitude of resealing of the electroporated cell membrane: higher the incubation temperature, greater is the percentage cell recovery [35–40]. Results from author's laboratory have shown that the rate and extent of resealing of electroporated human erythrocytes was dependent on the temperature of post pulsing incubation [40]. Higher percentage of hemolysis was found in erythrocytes electroporated and incubated at 4°C. For DNA transfer goals in cells, it has been shown that cooling at the time of permeabilization and subsequent incubation at higher temperature increased transfer efficiency and cell viability [36–40].

### 26.3.7.3 Biological Factors

For the identical experimental conditions, electroporation efficiency depends on the type of cells; the composition of the membrane, shape, and size of cells strongly influences the electroporation efficiency [40–42]. In electroporation of bacteria, the growth phase of cell has significant influence on transformation efficiency, which is higher for cells harvested and electroporated from mid-log phase. However, cells from stationary phase can also be transected with reasonably good efficiency. Mammalian cell can be electroporated at relatively lower fields but pulse length controls the entry of external molecules into cells.

## 26.4 ELECTROPORATION DEVICES

There are many types of electroporation devices capable of delivering electric pulses widely varying in shape, amplitude, and frequency of pulses. Design of sample cuvette and electrode geometry affects the transfection yield. Chambers with parallel electrodes provide uniform fields enabling all cells in the sample exposed to same field. Small sample volumes of 10–100  $\mu\text{L}$  are suitable for parallel plate electrodes. Normally, electrode gap is kept 1–2 mm and field strength across electrode is calculated from voltage divided distance between electrodes ( $V/d$ ). The major components of electroporator consist of the electronic circuit (pulse generator) with discharge switch, electrodes, and cuvette/petri dish.

### 26.4.1 ELECTRIC PULSE GENERATORS

The electric pulse generator (also called electropulsator) is essentially an electronic circuit that is capable of generating steady pulses of defined shapes, voltages, and frequencies. The type and parameters of the electric pulses are characteristics of a particular machine and the output is defined as per the circuit. Most commonly used electroporators provide for exponentially decaying electric pulses. Some of the new generation medical electroporators are capable to produce square wave electric pulses of high voltage. Biorad Gene Pulser, Progenitor Pulse Controller from Hoefer, and BTX Transfecto 100 are designed to produce variable pulses of wide amplitudes and they are most commonly used. More advanced commercial electroporator models (e.g., BTX HT 96-Well Electroporator System, electroporator from Inovio Biomedical Corporation and others) have improved features in terms of field parameters, automation, and larger sample handling capability.

### 26.4.2 CUVETTES AND ELECTRODES

For in vitro studies, specially designed corvettes with parallel plate electrodes are generally employed. The separation between the electrodes ranges (1 to a few millimeters). Electroporation cuvettes are available commercially. Cells suspended in

electroporation buffer are filled in the cuvette and subjected to electric pulses. For *in vivo* studies, parallel plate electrodes with adjustable width are favored. Parallel plates are generally used for application of electric field on solid tumors. For example, solid tumor grown in leg of mice can be easily placed between the electrodes and subjected to electroporation. For the electroporation of deep-rooted tumors, specially designed needle electrodes are used. Sanghvi and Mishra have extensively investigated electroporation of human erythrocytes and have demonstrated the effectiveness of the square wave electroporation over the exponential pulses using the electroporator, which was designed and developed indigenously [28,43] (models: BARC/RB&HSD/01-04, Technology Transfer BARC 2005). Often, vernier caliper types of electrodes have been used for the clinical trials of electrochemotherapy (ECT) in cancer. A variety of sample chambers from spectrophotometer cuvettes to tong type have been used.

## 26.5 SOME APPLICATIONS OF ELECTROPORATION

Electroporation has been demonstrated in a variety of bacteria, yeast, plant, and mammalian cells. Experiments have been carried out using artificial bilayer membranes, cell suspensions, single cells, and biological tissues. A wide range of applications in biotechnology and medicine have been demonstrated using electroporation method, e.g., cell fusion and hybridoma for antibody production, ECT for treatment of cancer, electroloading of drugs for drug delivery, gene transfection for variety of biotechnological goals, gene therapy in treatment of diseases including cancer therapy, food sterilization, etc.

### 26.5.1 CELL FUSION AND HYBRIDOMA TECHNOLOGY

Cell fusion continues to be of great importance in understanding the underlying fundamental processes and for various practical applications through nuclear material transfer in agriculture and medicine because of speed of fusion process, high efficiency of fusion, and possibility of fusing two defined and chosen diverse cells [3,4,35]. Electroporated cell membrane acquires fusogenic state due to surface structural changes, such as, loss of lipid asymmetry, pore formation, etc., and molecular details are under exploration. Usually, cells are brought in contact by dielectrophoresis force using high frequency and low amplitude AC field. Under suitable conditions, pearl chains of cells are formed by application of AC fields and subsequent application of DC pulse causes fusion of permeabilized cells to occur. This technology has been extended to the production of hybrid cells of both plant protoplast and mammalian cells [3,44]. The hybridoma technology involves production of hybrid cells by the fusion of the two or more types of cells into a giant cell. Fusion of lymphocytes with myeloma cell has been used to produce antibodies in therapeutic applications. The phenomenon of electro-cell fusion has been extensively investigated from a fundamental viewpoint and numerous applications such as crop improvement in plant science have been demonstrated. In view of the pharmaceutical and industrial importance, basic and applied aspects of cell fusion technology have been extensively investigated but, for the limitations of space, exhaustive coverage has been avoided in this chapter and readers may refer excellent books and reviews available in this field [3,4,44-48].

### 26.5.2 ELECTROTRANSFECTION

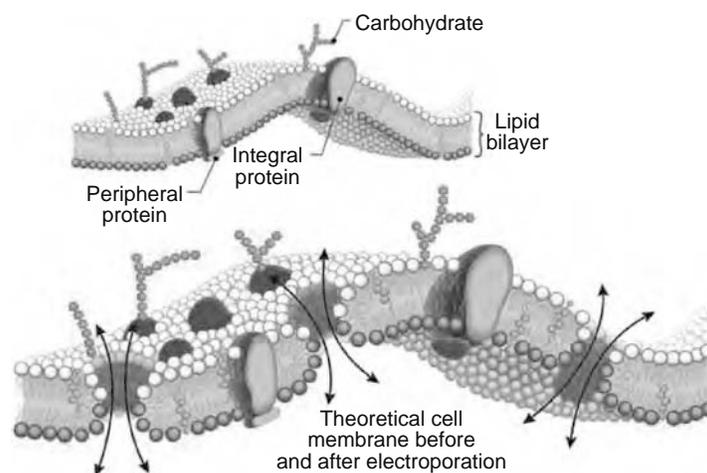

Electroporated cells can be used to transfer DNA in bacterial, plant, and mammalian cells. This method offers rapid and efficient incorporation of plasmid and DNA in cells [49]. The *in vivo* electroporation has been shown to yield enhanced plasmid delivery to a wide range of tissues including muscle, skin, liver, lung, artery, kidney, retina, cornea, spinal cord, brain, synovium, and tumors. The precise mechanisms involved in electroporation applications *in vivo* are uncertain and require further studies, but appear to involve both electropore formation and an electrophoretic movement of the plasmid DNA.

### 26.5.3 THERAPEUTIC APPLICATIONS

Temporary permeabilization of the cells by electric fields provides an opportunity to access the cellular interior in a controlled fashion without seriously compromising the cell viability (Figure 26.4). This technique has the capability to enhance the incorporation of the drug into electroporated cells and has been demonstrated to increase uptake of anticancer drug in cancer cells [42,43,49-52] (ECT). Efforts have also been made by researchers to study the potential of transdermal drug delivery by electroporation. Gene therapy is yet another potential application with considerable promise [42]. Enhanced action of therapeutic drugs after gamma irradiation and electroporation has been demonstrated in normal as well as tumor cells author's laboratory [28,43]. These lines of investigations have generated continued interest and have progressed substantially leading to phase trials for cancer patient treatment in clinics.

### 26.5.4 POTENTIAL FOR OVERCOMING TUMOR RESISTANCE

One of the major problems faced by physicians in clinic is the commonly observed side effects and drug resistance in patients suffering from cancer. The resistance of cancer cells to anticancer drugs, a phenomenon called chemoresistance, is a major

**FIGURE 26.4** Cell electroporation and electrodelivery of therapeutic drug into cells.

hurdle in cancer chemotherapy. The electroporation technique has the potential to overcome the problem of drug toxicity by reducing the dose and making drug-resistant tumor cells to respond. Permeabilization of membrane by electroporation allows incorporation of drugs into cells, which are otherwise impermeant. In vitro studies from our laboratory have shown increased toxicity of resistant tumor cells to doxorubicin when combined with electroporation suggesting possibility of apply this method to treat chemo- and radio-resistance tumors (Table 26.1). Similar results were reported earlier by other investigators using bleomycin and other drugs.

**26.5.5 ELECTRO CELL MANIPULATION**

Fusion of cells by electric pulses is based on electroporation phenomenon and it was first reported by Senda [35]. This technique has become very important in the field of biomedical research. Electroporated membrane acquires fusogenic state due to some structural changes in the membrane surface, which facilitates cell fusion. Usually the cells could be brought in contact with each other by dielectrophoresis using very high frequency and low amplitude AC field. Under suitable conditions, a chain of cells were found to be formed due to the AC field and a subsequent electroporation by DC pulse caused cells to become permeable and fuse. Studies on electric field-induced fusion of fibroblasts and erythrocytes were successfully demonstrated [36]. Using fluorescent probes occurrence of cell fusion involving membranes of participating cells has been reported. Electric field-induced fusion of cells offers advantages in terms of specificity, efficiency, and speed of cell fusion. Author and colleagues have achieved fusion of electroporated human erythrocytes by subsequent centrifugation of cells (unpublished results) [53].

**26.5.6 ELECTROLOADING OF CELLS**

Electroporation methodology offers a novel method to load drugs into cells for controlled release or for targeted delivery of drug. Considerable progress has been made to load enzymes, radioactive molecules, and plasmids in human erythrocytes and

results have demonstrated the usefulness of loaded drugs in enhancing their lifetime in blood circulation. Among the various systems proposed for delivery of pharmacological substances for improvement of their therapeutic potentials, electroporation has been found to have several merits over other methods. An electroporated cell can be allowed to reseal in the presence of the substance to be loaded into cells. The percentage entrapment can be calculated from the substance remaining in the supernatant to that entrapped in resealed cells. The efficacy of electroporation and membrane resealing was investigated by these investigators by monitoring [ $^{14}$ C]-sucrose (sucrose with radiocarbon) uptake by human erythrocytes [40,53–55]. Dextran and human serum albumin protein (MW 65 kDa) were entrapped in electroporated and resealed erythrocytes (Nanda and Mishra, unpublished results).

### 26.5.7 ELECTROCHEMOTHERAPY

Growing demands in anticancer research and biotechnology necessitates research on developing new modalities of treatment. Significant developments have taken place in using electroporation for increasing cytotoxicity of anticancer drugs, a process called ECT. The methodology involves increasing local potentiation of an anticancer drug by permeabilizing electric pulses. These approaches acquire greater significance in clinical situations where the side effect of chemotherapeutic drug is severe or the cost of drug is prohibitive. This has found enormous potential for developing effective anticancer therapy in recent years. Substantial success of ECT has been demonstrated *in vitro* as well as *in vivo* experiments leading to clinical trials of this approach [43,49–52]. The protocol is mainly focused on three aspects: (1) electroporation of cells in living tissues, (2) potentiation of cytotoxic drugs that are nonpermeant to cells, and (3) intrinsic response of the body systems, i.e., immune response and blood flow patterns of the patient. Undoubtedly, this is a growing field of research with an immense potential for clinical applications. The results of the ECT experiments involving anticancer drugs, doxorubicin, bleomycin, and cisplatin appear close to success.

### 26.5.8 RADIO-ELECTROCHEMOTHERAPY

Research has progressed to suggest that electroporation can enhance the radiation effects on mammalian cells especially tumor cells. It has also been found by author and his coworkers that combined effects of anticancer drug and ionizing radiation can be significantly enhanced by electroporation (Figure 26.5). The results have suggested that radiocytotoxicity of tumor cells *in vitro* as well as *in vivo* was enhanced significantly by electroporation methodology, which may offer a potentially improved treatment of cancer [28,29,43]. The research work author's laboratory has investigated the phenomenon of radio-electrochemotherapy (RECT), which points to enormous potential to effectively kill cancer cells including chemo- and radio-resistant tumors (Table 26.2). It is hoped that optimization of protocols appropriately and clinical evaluation of this approach in radiotherapy settings may offer unique and efficient treatment of patients suffering from cancer [41–43,49–51].

## 26.5.9 IN VIVO APPLICATIONS

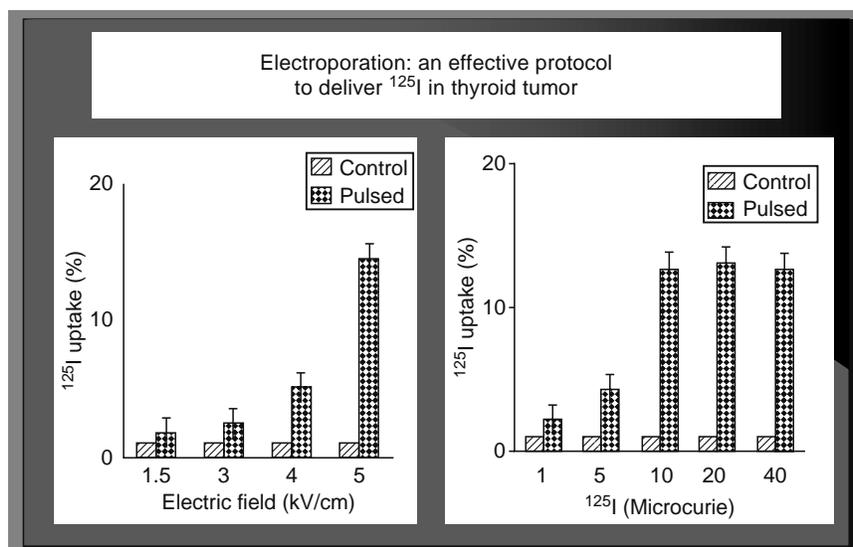

Recent research in the field of ECT had concentrated on the preclinical experiments in animal models. Many laboratories have developed specially designed parallel plate electrodes to carry out in vivo studies. Murine tumors grown in Swiss mice have been considered as suitable system for such studies. In vitro, it has been established that high percentage of permeabilized cells, with less percentage of cell killing, can be achieved by using eight square wave pulses with individual pulse strength of 1.3 kV/cm, duration 0.1 ms. These pulses were also effective in producing electropermeabilization in vivo in tumor tissues. In a recent study, Satkauskas et al. have successfully studied the effectiveness of the ECT as a function of electric pulse strength and duration on C57B1 mice bearing LLC tumors. Their investigations revealed that the largest antitumor efficiency of ECT was attained for 1.5 kV/cm and duration of 1 ms. These pulse conditions used neither significantly suppressed tumor growth nor induced noticeable side effects [38]. Reports also suggested that both square wave and exponential wave electroporations have helped in overcoming tumor drug resistance to bleomycin and cisplatin. After successful experimentations in mouse models, clinical trials have been initiated [49–51]. Effective delivery of beneficial drugs or genes has the potential of greatly improving vascular therapy. Areas of vascular therapy that may benefit the most from improved local delivery technologies include the prevention and treatment of restenosis following angioplasty.

## 26.5.10 ELECTROPORATIVE GENE DELIVERY

Conventional techniques for the gene transfer include DBA precipitation by Ca<sup>2+</sup> treatment of cells with DEAE, dextran, liposomes, viral vectors protoplast fusion, or direct microinjection into the target cells. Electroporation has been found to be superior to other available methods of gene transfer. It was first demonstrated by Neumann et al. that thymidine kinase (TK) deficient mouse L cells were transformed to TK positive cells by treatment with suitable DC electric pulses in the presence of the plasmid DNA containing TK gene [56]. More recently, short interfering RNA (siRNA) is widely used in vitro to study gene functions or to identify and validate new drug targets. Electroporation-mediated delivery siRNA has been highly efficient method for selective gene suppression with siRNA in various established cell lines and primary cells. High-efficiency gene transfer and eliminated transfection-related toxicity were achieved for a variety of established cell lines as well as primary cell [19,57–59]. This line of research is making rapid progress.

## 26.5.11 ELECTRODELIVERY OF PROTEINS

One of the striking applications of electroporation is incorporation of externally added protein into plasma membrane. Protein molecules with amphipathic nature can be stably entrapped in electroporated membrane when they reseal. This phenomenon called electroinsertion has been demonstrated in a number of investigations. For example, electroinsertion of transmembrane protein CD4 receptors [60] and glycophorin [61] was demonstrated, which may prove valuable in surface engineering and studies on transmembrane proteins. In addition, a number of exogenous peptides and protein enzymes have been introduced

**FIGURE 26.6** Electroporative incorporation and retention of radioiodine in thyroid tumor cell line. (From Gopal, R. et al., *Appl. Radiat. Isot.*, 59, 305, 2003. With permission.)

into cell to study their degradation and therapeutic effects. With the possibility to introduce large proteins, there seems to exist enormous new research in applications of transcriptomics, proteomics, genomics, and nanoscale separation science, which hold promise for future.

### 26.5.12 INCORPORATION OF RADIOIODINE INTO TUMOR CELLS

The efficacy of using the electroporation to cancer has been studied by Gopal et al. [62], who have shown uptake of radioiodine  $^{125}\text{I}$  by human thyroid cancer cells which are otherwise recalcitrant. Electroporator designed and developed indigenously giving exponentially decaying voltage pulse in authors' laboratory was used for this study. It has been inferred that applications of the electroporation-mediated drug delivery may potentially help in overcoming the drug resistance of thyroid tumors. Loss of ability to concentrate iodide makes thyroid cancer cells refractory to radioiodine therapy. In this study, the focus of research was on the effects of post pulse incubation temperature on cell viability, incorporation of  $^{125}\text{I}$ , and its retention in the resealed cells. It was observed that the radioiodine was remarkably retained in the cells for up to 24 h. Effects of pulsing and incubation temperature on  $^{125}\text{I}$  uptake were also investigated. Electroporated cells were found resealing efficiently on incubation at  $37^\circ\text{C}$  (Figure 26.6). Results have shown promise and future validation in in vivo needs to be investigated.

### 26.5.13 ELECTROPORATION IN BIOTECHNOLOGY

#### 26.5.13.1 Water Sterilization

Electroporation-based sterilization of drinking water, wastewater, and seawater has been considered an attractive technology option. An industrial-scale system that utilizes PEF (pulsed electric field) technology results in killing of bacteria in water purification applications surmounting the consumer concern for harmful effects of heat or chemical methods of sterilization.

Microorganisms present in water are retained when it is passed through polarized material and in preparation of injection solutions reinforcing the choice of filtering material to be critical for optimization process. Seawater used in mariculture is the potential carrier of pathogenic bacteria, e.g., *Vibrio parahaemolyticus* and related species. Use of PEF, a nonthermal and nonchemical method, has been demonstrated to overcome the technical problems faced in heat and antibiotic methods of sterilization [63]. Optimization of electric field parameters and other experimental conditions is the main determinant of sterilization outcome. Technologies are also under development to use electroporation for wastewater treatment during filtration of water. Bacteria can be substantially killed by exposure of water to high voltage electric field by irreversible damage to their membrane. It seems interesting that electroporation-based sterilizer of water at lower field strengths can be exploited to increase the efficiency of chemical disinfectants, e.g., chlorine due to transient changes in membrane of the organisms while electroporation at higher field strengths is capable of inactivating/killing bacteria and other pathogens without use of chemicals. Hence, electroporation is at least a partial alternative to chlorination. A prototype of an electroporation system for sterilizing wastewater or drinking water has been developed [45]. Electroporation-based sterilization technology is being developed by Bioelectromagnetics, Inc. (Elm Grove, Wisconsin) in United States to reduce cost and achieve optimum efficiency of water sterilization.

### 26.5.13.2 Food Sterilization

Electroporation technology has been developed to kill spoilage microorganisms, e.g., *E. coli*, fungi, etc. providing scope for the development of nonthermal sterilization of food free from the disadvantages commonly encountered with existing physical, chemical, or radiation sterilization. It is hoped that the application of high amplitude PEFs can make food sterilization economical, compact, energy efficient, and environmentally acceptable. Exposing liquid foods to intense electric fields over short periods effectively inactivates spoilage microorganisms, which results due to cell's membrane damage. The damage is governed by the intensity of the electric field, the treatment time, and on the type of microorganisms. Foods that are free of chemical preservatives and having longer shelf life retaining their natural appearance and flavor would make acceptable technologies. Ionizing radiation-based sterilization liquid food suffers from generation of free-radical and possible undesirable effects on the quality and taste of treated foods. Research results suggest that application of high-field electric pulse technology to kill microorganisms for development of industrial-scale nonthermal sterilization of food seems commercially promising food preservation technique with potential to replace or partially substitute for thermal processes. A recent study has reported that PEFs sterilization technique sterilizes liquid foods effectively while maintaining the food quality and reduced the sterilization cost [46]. The method is claimed to be adaptable to liquid foods, such as, syrup, milk, soup stuff, etc. Electrical sterilization of apple juice by high voltage field pulse has been reported, which overcomes some of the problems faced by sterilization by thermal process [47]. Among others, the pilot plant program on liquid food sterilization of the Ohio State University using high voltage PEF has made considerable progress.

### 26.5.14 TRANSGENIC PLANTS AND ANIMALS

Transgenic technology allows transfer of genes between species and prepared clones. Transgenic organisms carry a foreign gene in their cells, which were introduced by laboratory methods. Genes cloned from microbes, plants, are introduced into plant or animal cells. Transgenic animals and plants (agrobacterium) have been produced by microinjection, embryonic stem cell method, retrovirus but electroporation has been used successfully to produce animal and plant transgenic animals and plants [44,48]. Studies have also shown regeneration of shoot after electrostimulation of hypocotyls of plant [64] and pollen for possible plant transformation [65]. These approaches hold great promise for future applications in plant science.

### 26.5.15 TRANSDERMAL DRUG DELIVERY

Application of external electric field to skin results in large increase in molecular and ionic transport [66]. This method has been applied to several drugs and is called transdermal delivery. The transdermal delivery of biomolecules has several important applications to the practice of dermatology and cosmetics. A prototype for the Inovio's transdermal delivery device has been developed and tested in various applications from drug delivery to cosmetics. Pharmaceutical companies are testing several drugs in the use of transdermal delivery. Transdermal delivery offers a wide range of applications: delivery of classical drugs, such as many different organic chemical compounds, delivery of proteins, peptides, and macromolecules DNA and oligonucleotides for gene therapy-related treatments DNA vaccines. Mammalian skin owes its remarkable barrier function to its outermost and dead layer, the stratum corneum. Transdermal transport through this region occurs predominantly through intercellular lipids, organized largely in bilayers. Electroporation is the creation of aqueous pores in lipid bilayers by the application of a short (microseconds to milliseconds) electric pulse. Flux increases up to four orders of magnitude were observed with human skin in vitro for three polar molecules having charges between  $-1$  and  $-4$  and  $MW > 1000$ . Similar flux increases were observed in vivo with animal skin. These results may have significance for drug delivery and other medical applications.

### 26.5.16 EX VIVO APPLICATIONS

Ex vivo therapy is the transfection of cells outside the body. Typically, a small amount of tissue is removed from the patient and the cells within that tissue are put into the culture, which allows clonal expansion of the cells. The approach simplifies the delivery of the genes and allows for post-transfection manipulation of the cells. The genetically modified cells, typically blood, bone marrow, or others, are then returned back to the patient, usually by blood transfusion or direct engraftment. Ex vivo transfection of cells by electroporation can be done using either a discontinuous or a continuous process.

Due to recent trends in cellular therapy, the pharmaceutical companies have put emphasis on the use of ex vivo electroporation for both DNA and drug delivery. Using the flow thru system, employing a pump that moves the cell suspension through an electroporation chamber where cells are porated. The entire operation is aimed to a closed system to minimize contamination and facilitate commercial scale cell-processing operations.

## 26.6 SINGLE-CELL ELECTROPORATION

Most of electroporation methods have adopted total population cell treatments. Total population methods yield information about average electroporative behavior of cells. Since cells are heterogenic cell population, it is important to examine if average

behavior represents individual cells. Recently, microelectrodes that can produce extremely localized electric fields, such as solid carbon fiber microelectrodes, electrolyte-filled capillaries and micropipettes as well as chip-based microfabricated electrode arrays enabling to electroporate single cells and subcellular structures, have been designed. Single-cell electroporation opens up a new window of opportunities in manipulating the genetic, metabolic, and synthetic contents of single-targeted cells in tissue slices, cell cultures, microfluidic channels or at specific loci on a chip-based device. Automated single-cell methods have been developed allowing to differentially manipulate the genetic, metabolic, synthetic contents of single-targeted adherent cells in a population [67]. In addition, high-throughput and real-time study of single-cell electroporation has been achieved using microfluidics. Recently, nucleofection method has been introduced to much resistant neuron cells by electroporation [68]. Subsequently, an elegant improvement has been introduced to mass 96-well electroporation 96 plasmids in neurons in a single step [69].

## 26.7 FUTURE PROSPECTS AND CHALLENGES

Extensive research during past decades has generated considerable new knowledge on biophysical basis of cell membrane electroporation but our present understanding of the dynamics involved in electropore formation and molecular transport is far from satisfactory. It is hoped that future research would provide deeper insight on the precise mechanisms involved, which would show new direction for research in membrane science and applications. It is, however, important to recognize that applicability of electroporation has been demonstrated in a variety of bacteria, yeast, and mammalian cells and some applications are ready for exploitation while many new technologies seem potentially possible. Notably, some of the biomedical applications have reached close to commercialization (e.g., food sterilization, cancer treatment modality, hybridoma technology for antibody production). Cell electroporation phenomenon would continue to be a frontier area of fundamental and applied research with promise in biomedicine and biotechnology. Electroporation-based tumor killing, gene therapy, cell fusion, drug loading for controlled release, and targeted delivery are some of the attractive developing new technologies with considerable implications to human health such as cancer electrotherapy, RECT, electroporative drug and gene delivery, etc. However, further research is highly warranted to optimize various factors that control the electroporative efficiency of the cells. Current state of development provides enough basis to be optimistic as some of the research progress has reached the pilot plant scale and clinical level evaluations. Combination of electroporation with radiation and anticancer drug is proving an effective way to kill cancer cells *in vitro* as well as *in vivo*. Development of user-friendly clinical electroporator with automation and suitable microelectrode devices are among the greatest challenges for medical biotechnology. Considering the immense potential of electroporation technique in research and applications, greater research efforts are needed to achieve comprehensive understanding of molecular processes involved and to apply the new knowledge in realizing the fruits of electroporation technology for innovative applications in food science, industry, and healthcare.

## ACKNOWLEDGMENTS

Author thanks the coworkers whose work has been cited in this article. The help and cooperation of Dr. B.N. Pandey, Dr. S.H. Sanghvi, Amit Kumar of Baba Atomic Research Center, Mumbai and professor P.B. Vidyasagar and Dr. Pratip Shil of Pune University, Pune are duly acknowledged. Part of this article was prepared when the author was a visiting professor at Research Institute for Radiation Biology and Medicine, Hiroshima University, Hiroshima, Japan. Facilities and encouragements provided by professors H. Hoshi, department of radiation biophysics, and S. Matsuura, department of radiation biology at the institute are deeply acknowledged. The author is also thankful to professor F. Suzuki, Director, RIRBM for his support and patronage. The help extended by Dr. Deborshi Bhattacharjee in organizing some of the content material of this article at final stage of preparation is gratefully appreciated. Lastly, he thanks his family members especially his wife, Usha deserves his deep gratitude for her silent support and exemplary tolerance for the long hours of working during preparation of this chapter.

## 27.1 INTRODUCTION

Polymer electrolyte-based fuel cells are emerging as attractive energy conversion systems suitable for use in many industrial applications, starting from a few milliwatts for portables to several kilowatts for stationary and automotive applications. The ability of polymer electrolyte fuel cells to offer high chemical to electrical fuel efficiency and almost zero emissions in comparison to today's prevailing technology based on internal combustion engines (ICEs) makes them an indispensable option as environmental concerns rise [1–6].

Although the basic principles of fuel cells have been known for at least a century, the introduction of solid polymer electrolyte membranes (PEMs) a few decades ago revolutionized fuel cell technology. Initially, poly(styrenesulfonic acid) (PSSA) and sulfonated phenol-formaldehyde membranes were used, but the useful service-life of these materials was limited because of their tendency to degrade in fuel cell-operating conditions [7,8]. A critical breakthrough was achieved with the introduction of Nafion, a perfluorinated polymer with side chains terminating in sulfonic acid moieties, which was invented in the 1960s for the chlor-alkali industry at DuPont. This material and its close perfluorosulfonic acid (PFSA) relatives are currently the state of the art in polymer electrolyte membrane fuel cells (PEMFCs). PFSA-based membranes have good proton conductivity, high chemical and mechanical stability, high tear resistance, and very low gas permeability in fuel cell-operating conditions [9,10].

But some problems associated with PFSA-based membranes have precluded large-scale market adoption of fuel cells. Their relatively high cost, limits to the range of temperature over which they can be reliably used (the upper limit is considered to be somewhat above 100°C, because the glass transition temperature  $T_g$  is around 120°C, at higher temperatures >100°C, membranes have low water content and thus low-proton conductivity), faster oxidative degradation and faster deterioration in mechanical properties at elevated temperatures, and a stringent requirement for external humidification of reactant gases under these conditions make the fuel cell balance of a plant (BOP) more complicated. Additionally for liquid-phase direct methanol fuel cells (DMFCs), the PFSA membrane is permeable to methanol and water, whose presence on the cathode side seriously degrades the DMFC performance.

All these drawbacks have led researchers to make more efforts to discover membranes with improved characteristics on all these accounts. Over the past decade, researchers all around the world have reported success in exploring new concepts for improving the properties of proton-conducting membranes. Companies like DuPont, Dow Chemical, W.L. Gore, PolyFuel, Asahi Glass, Asahi Chemical, Ion Power, and Ballard have brought improved membranes onto the market. The main goal of this chapter is to review some of these new ideas in the field of proton-conducting membranes.

### 27.1.1 BASIC PRINCIPLE OF OPERATION OF POLYMER ELECTROLYTE MEMBRANE FUEL CELLS

A fuel cell consists of two electrodes sandwiched around an electrolyte. Air (or oxygen) is supplied to the cathode and hydrogen to the anode, generating electricity, water, and heat. The electrocatalyst used is either platinum or a platinum alloy, usually supported on high-surface area carbon. The hydrogen atom splits into a proton and an electron, which takes different paths to the cathode. The proton passes through the electrolyte, while the electron passes through the external circuit. At the cathode catalyst, oxygen reduction takes place to produce water molecules. The electrons passing through the external load are available for useful work before they return to the cathode, to be reunited with the proton and oxygen in a molecule of water. The theoretical open-circuit potential for a  $H_2/O_2$  fuel cell is 1.23 V at 25°C and unit activity, but because of kinetic losses in the oxygen reduction process at the cathode and ohmic losses in the electrolyte membrane, the workable potential available from this fuel cell is usually around 0.7 V.

The heart of a fuel cell is the membrane electrode assembly (MEA). In the simplest form, the electrode component of the MEA would consist of a thin film containing a highly dispersed nanoparticle platinum catalyst. This catalyst layer is in good contact with the ionomeric membrane, which serves as the reactant gas separator and electrolyte in this cell. The membrane is about 25–100  $\mu\text{m}$  thick. The MEA then consists of an ionomeric membrane with thin catalyst layers bonded on each side. Porous and electrically conducting carbon paper/cloth current collectors act as gas distributors (Figure 27.1). Since ohmic losses occur within the ionomeric membrane, it is important to maximize the proton conductivity of the membrane, without sacrificing the mechanical and chemical stability.

Existing polymer membranes such as PFSA-based membranes operate most effectively within a limited temperature range and require that the membrane must remain constantly hydrated with water, resulting in complex and expensive engineering solutions (see Section 27.2.1.1). More efficient and better performing polymer membranes are needed for continued advancement of PEMFCs. An additional challenge in developing materials for proton-exchange membranes is that these materials need to endure prolonged exposure to the fuel cell environment. Electrolyte membrane materials must resist oxidation, reduction, and hydrolysis. A further challenge is that the material should be affordable. Finally, it is desirable that the material will permit operation at a higher temperature (>120°C).

Carbon monoxide is formed as a by-product when organic fuels are thermally reformed to produce hydrogen ( $H_2$ ), which can then be used in a fuel cell. For such reformat gas-supplied fuel cell systems, high-temperature membranes offer an

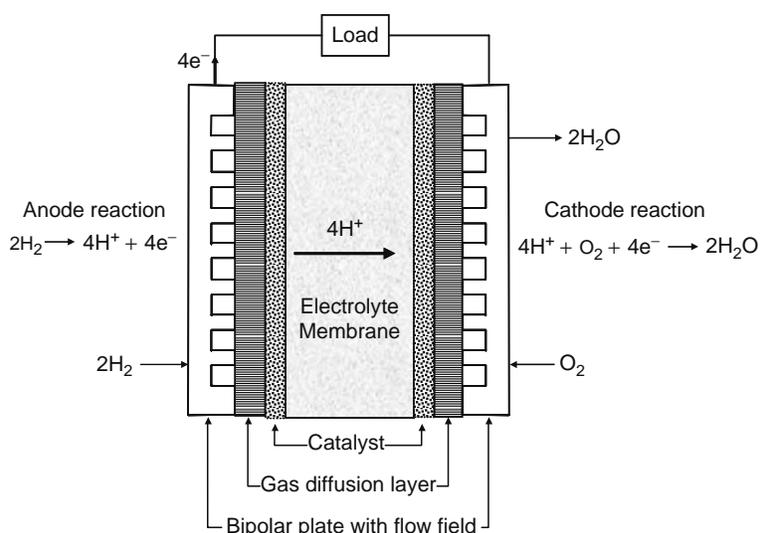

FIGURE 27.1 Diagram of a typical fuel cell.

important advantage because the MEAs based on high-temperature membranes are less susceptible to carbon monoxide (CO) poisoning. Better CO tolerance of high-temperature MEAs results in relatively less stringent demand on purification of the reformat gas to hydrogen. This results in easier and more cost-effective BOP for the fuel cell system. Fuel cells with high-temperature PEMs need smaller and less-expensive cooling systems.

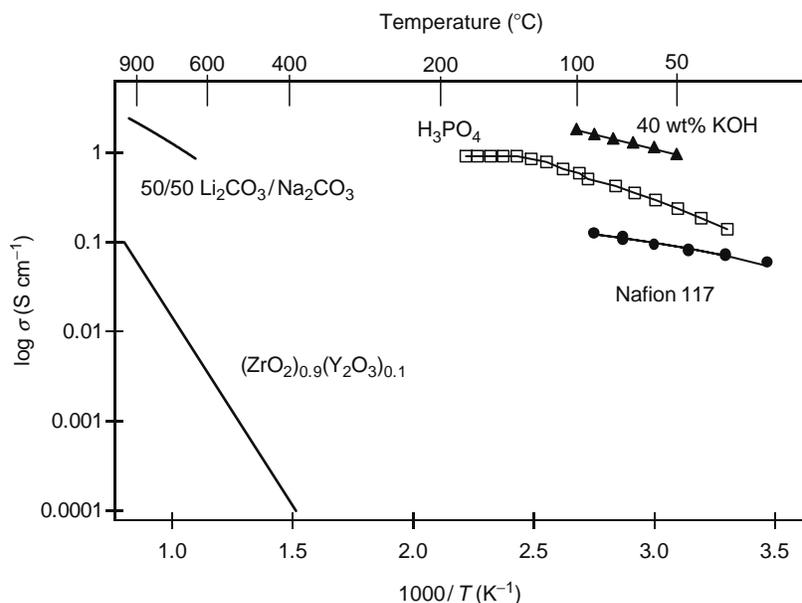

Over the last few years, membrane development has intensified and numerous new developments have been reported [10]. This increase in the interest in novel proton-conducting membranes for fuel cell applications has resulted in several studies and review publications on the overall subject and also on some related topics (e.g., nonfluorinated membranes). The content of these reviews has been used and is cited in the appropriate sections.

Fuel cells, especially PEMFCs, can be used for various applications ranging from portable power supply for use in consumer electronic devices to stationary deployment for combined heat and power generation. Another potential application is transportation, in which fuel cell systems are developed for the propulsion of cars. The performance, operating conditions, costs, and durability requirements differ depending on the application. Transportation applications demand stringent requirements on fuel cell systems. Only the durability requirement in the transportation field is not as rigorous as the stationary application, although cyclic durability is necessary.

## 27.2 PHYSIOCHEMICAL REQUIREMENTS FOR THE MEMBRANES IN FUEL CELL APPLICATIONS

The fuel cell principle is based on the spatial separation of the reaction between hydrogen and oxygen by an electrolyte. An electrolyte needs to conduct either positively charged hydrogen ions (protons) or negatively charged oxygen (or hydroxide or carbonate) ions. For a technical realization, the specific ionic conductivity of the electrolyte has to be in the range of 50–200 mS  $\text{cm}^{-1}$  and the electronic conductivity of the electrolyte should be minimal. It is obvious from the principle of fuel cells that the electrolyte should be mostly gas impermeable to effectively separate the reaction volumes. Furthermore, a high chemical stability is required in oxidizing and reducing atmospheres. Often the MEA made from electrolyte membranes and catalysts has to be pressed against the flowfield/bipolar plates to minimize contact resistance or for sealing purposes. This necessitates good mechanical stability for the membrane. Because of these requirements, only a few systems are suitable for technical applications.

The main requirement—a high specific conductivity of the electrolyte—is illustrated in Figure 27.2, which shows the conductivity of selected electrolytes used in fuel cells. As can be seen in Figure 27.2, suitable materials are available for different operating temperatures and are also quite different ranging from solid-state ceramics to molten salts and aqueous electrolytes. Interestingly, the specific conductivities differ considerably, being higher for the liquids. It should be noted, however, that the important value is the area-specific resistance with a target value of  $<0.15 \Omega \text{ cm}^2$ . Therefore, although the specific conductivity of the oxygen ion conducting yttria-stabilized zirconia (YSZ) is lower compared to the other electrolytes, it can be integrated into a planar fuel cell with a thickness of about 15  $\mu\text{m}$ . To restrict the resistance to  $0.15 \Omega \text{ cm}^2$ , the associated specific ionic conductivity should exceed  $10^{-2} \text{ S cm}^{-1}$ . Figure 27.2 indicates that this value is attained at ca. 700°C for YSZ. The liquid electrolytes generally need a stabilizing matrix and therefore the resulting electrolyte layer is thicker. As a consequence, the specific conductivity has to be higher for these types.

**FIGURE 27.2** Specific conductivities of electrolytes used in fuel cells in different temperature ranges. (Data from Srinivasan, S., *J. Electrochem. Soc.*, 136, C41, 1989; Larminie, J. and Dicks, A., *Fuel Cell Systems Explained*, J. Wiley and Sons, New York, 2000; Carrette, L., Friedrich, K.A., and Stimming, U., *Fuel Cells*, 1, 5, 2001; Metha, V. and Cooper, J.S., *J. Power Sources*, 114, 32, 2003.)

## 27.2.1 SPECIFIC FUEL CELL APPLICATIONS

### 27.2.1.1 Automotive Application

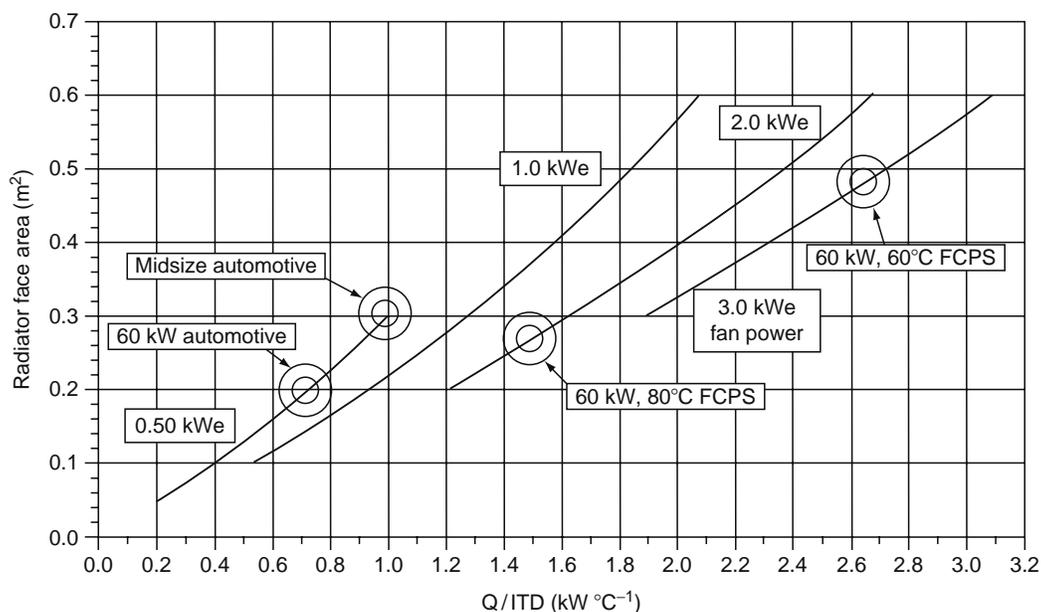

#### 27.2.1.1.1 Cooling Requirements

The main focus in membrane development for automotive applications is the search for membranes, which can operate at higher temperatures and lower relative humidity (RH). The major issues have been published in a series of publications by automotive experts and fuel cell developers [11–13]. The main statements are recapitulated here: assuming the availability of a hydrogen infrastructure, fuel cell-based systems might offer better efficiency than an ICE, which is one of the driving forces behind the development of fuel cells for this application. However, an ICE has the advantage that the waste heat can be removed more efficiently compared to fuel cell stacks. As a rule of thumb, it is stated that in ICEs one-third of the fuel energy is converted into mechanical energy, and two-thirds are converted into heat energy. Half the heat is removed by the coolant and half by the exhaust. Conversely, in a fuel cell system, typically less than 10% of the heat is rejected with the exhaust gases. Although the fuel cell system efficiency of about 50% is higher compared to ICEs, the coolant load is considerably larger. Furthermore, the PEM stack temperature is significantly lower, in the range of 60°C–80°C, as compared to ICE peak coolant temperature of 120°C. Since radiator performance is nearly proportional to the initial temperature difference (ITD) between the coolant and ambient temperatures, an ICE has about 2–4 times the heat rejection capacity during operation at elevated ambient temperatures of 32°C–40°C (an ambient temperature of 38°C is the design value for radiators). The thermal rejection requirements for automotive power trains are shown in Figure 27.3. The necessary radiator face area is plotted versus the ratio of heat power and ITD. The solid line represents the radiator fan's constant electrical power. As can be seen with the present technology, even a modest-sized fuel cell power system in cars requires cooling systems that challenge normal car design. Consequently, stack temperatures coincident with or even higher than normal ICE coolant temperatures would be highly desirable to achieve more efficient cooling. Another aspect is that a well-developed automotive hardware could be used enabling more cost-effective stack sizing and compact packaging.

#### 27.2.1.1.2 Humidification Requirements

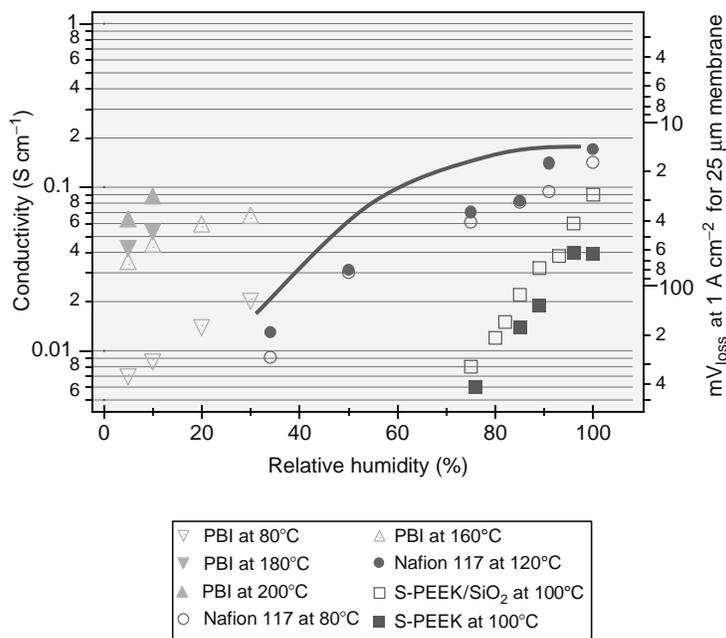

The operating temperature ranges of PEMFCs are determined by the humidification requirement of the electrolyte membranes. Also, current membranes have glass transition temperatures in the range of 80°C–120°C and are thus subject to creep and hole formation at temperatures in this range. The implications of operating PEMFCs at higher temperatures and at 100% relative humidity are discussed in detail in the following section.

The membrane and ionomer humidification requirements are of paramount importance for PEMFC operation since the proton conductivity is a fundamental necessity in the membrane as well as in the electrode for the fuel cell to function. The operating conditions of current PEMFCs are dictated by the properties of the membranes/ionomers. Now, the most important membrane type (e.g., Nafion membranes from DuPont) is based on PFSA ionomers that are used in the membrane

**FIGURE 27.3** Thermal rejection requirements of automotive and fuel cell systems ( $T_{\text{amb}} = 38^{\circ}\text{C}$ ). Solid lines are lines of constant radiator fan power. (Reproduced from Masten, D.A. and Bosco, A.D., in W. Vielstich, H.A. Gasteiger, and A. Lamm (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, Vol. 4, J. Wiley & Sons, Chichester, 2003. With permission.)

and the catalyst layers. Figure 27.4 shows the proton conductivity versus relative humidity for three electrolyte systems, which are either presently available or are being developed for fuel cells. The often used PFSA system is represented by 1100 equivalent weight (EW) Nafion as measured by Alberti et al. [14]. Values at  $80^{\circ}\text{C}$  and  $120^{\circ}\text{C}$  are provided. Further results on sulfonated polyetheretherketone (s-PEEK) membranes are shown; the pure system is compared to an Aerosil-filled membrane. The third system is a high-temperature membrane based on polybenzimidazole (PBI) filled (doped) with phosphoric acid by Ma et al. [15]. The PBI/ $\text{H}_3\text{PO}_4$  conductivity at four temperatures ( $80^{\circ}\text{C}$ ,  $160^{\circ}\text{C}$ ,  $180^{\circ}\text{C}$ , and  $200^{\circ}\text{C}$ ) is given. The minimum

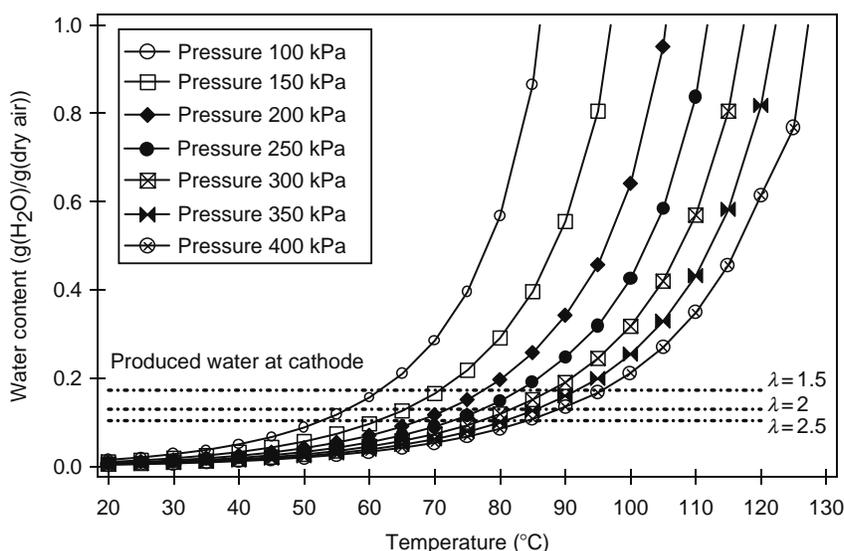

**FIGURE 27.4** (See color insert following page 588.) Conductivity of different membranes as a function of humidity. Requirements for an advanced membrane. (Data from Alberti, G. et al. *Solid State Ionics*, 145, 249, 2001; Ma, Y.L., Wainright, J.S., Litt, M.H., and Savinell, R.F., *J. Electrochem. Soc.*, 151, A8, 2004; Wainright, J.S., Litt, M.H., and Savinell, R.F., in W. Vielstich, H.A. Gasteiger, and A. Lamm (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, J. Wiley & Sons, Chichester, 2003.)

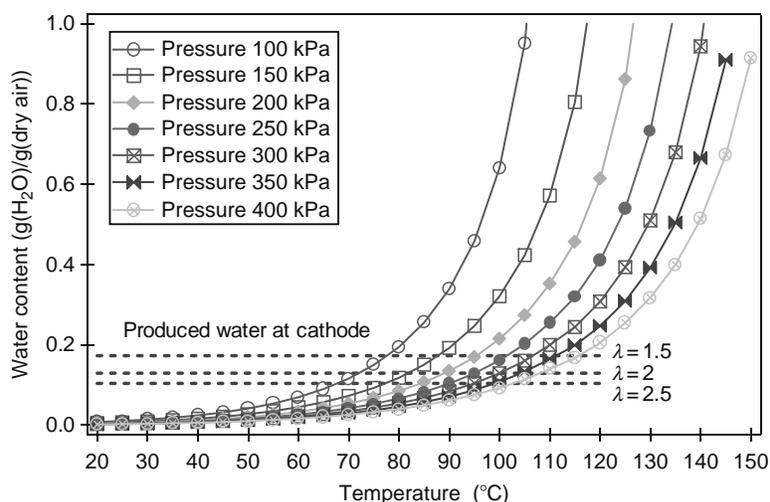

conductivity for fuel cell application was stated earlier in this section as  $50 \text{ mS cm}^{-1}$ . This conductivity is achieved for all membrane systems at different temperatures and different humidification conditions. For Nafion, the conductivity is above  $0.1 \text{ S cm}^{-1}$  for relative humidity (RH) values greater than 90% for both  $80^\circ\text{C}$  and  $120^\circ\text{C}$ , but drops to  $0.01 \text{ S cm}^{-1}$  at 40% RH. Also represented on the right-hand axis of the plot is the ohmic loss for a  $25 \mu\text{m}$  membrane at  $1 \text{ A cm}^{-2}$ . At  $0.1 \text{ S cm}^{-1}$ , the loss is 25 mV, which corresponds to a voltage efficiency loss of about 2%. Although this loss appears relatively small, the overall voltage efficiency is a critical issue and should be kept as high as possible in automotive applications. The problem with the PFSA systems is the need for nearly 100% humidification, which is an important constraint in the system design. An alternative polyarylene membrane system, such as s-PEEK membranes, has the advantage of being potentially more cost effective compared to the fluorinated material but the humidification requirements are similar to or even more stringent than (at least in this example) for the Nafion. A hypothetical-advanced membrane with more suitable properties is represented by the blue line: such an advanced membrane should exhibit conductivity well over  $50 \text{ mS cm}^{-1}$  at relative humidification (RH) of the gases below 50%. A membrane operating in a stable fashion at 50% RH and at  $120^\circ\text{C}$  would be the ideal candidate for a future automotive fuel cell power system. The PBI/ $\text{H}_3\text{PO}_4$  attains appropriate conductivity only above  $160^\circ\text{C}$  at 30% RH. At this high temperature, 30% RH is also critical as discussed below. Furthermore, this membrane system has performance disadvantages in dynamic load and temperature operation as discussed later. As a consequence, this system is better suited to stationary applications.

Figure 27.5 displays the water content of air given as the ratio  $g(\text{H}_2\text{O})/g(\text{dry air})$  for saturation humidity as a function of temperature and pressure. The 100% RH requirement of the membrane means that a low-pressure system is restricted to temperatures below  $100^\circ\text{C}$  since the saturation partial pressure of water increases exponentially with temperature. In addition, it would be highly desirable to have a water neutral situation to obtain a compact and simple system where the water produced at the cathode of the fuel cell as well as the permeated water is collected completely (a condenser would be necessary) to humidify the gases. In this respect, it would be an ideal situation to operate the fuel cell at the intersections of solid and dashed lines, which are the water neutral-operating conditions. The only way to achieve such an operation while maintaining the 100% RH demand at temperatures near  $100^\circ\text{C}$  is to increase the pressure to 400 kPa. However, this means a drastic reduction in system efficiency due to the heavy losses associated with pressurization. These simple relationships exacerbate design complications and have been summarized thus by Masten and Bosco: at higher temperatures and lower pressures, the humidification energy duty and associated condensate water requirements will overwhelm the water and thermal management capabilities of an automotive thermal system. Increased stoichiometry and increased pressure may help in diminishing the water load, but are associated with increased complexity and costs for the compressors and expanders.

Figure 27.6 shows the analogous relationships for 50% RH of the air. If a membrane tolerated such operation conditions over a long time, water neutral operation would be feasible at  $100^\circ\text{C}$  at moderate overpressure of 250 kPa. Ideally, a membrane should operate at 15%–20% RH which would enable water neutral operation at ambient pressure and  $110^\circ\text{C}$ . However, such a membrane would probably be based on a radically different conduction mechanism compared to the present membranes where the proton conductivity is based on the liquid water environment. Such a membrane would be very welcome, but now is far

**FIGURE 27.5** Water content required for membrane saturation versus temperature for different pressures of air. The dashed lines indicate the water produced for different air stoichiometries (ZSW (Zentrum für Sonnenenergie- und Wasserstoff-Forschung) measurements: Internal publication).

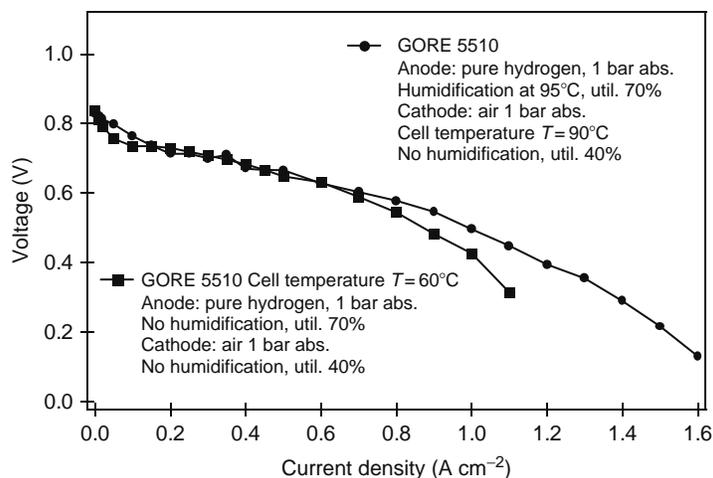

**FIGURE 27.6** (See color insert following page 588.) Water content required for 50% RH in air for advanced membranes versus temperature for different air pressures. The dashed lines indicate the water produced for different air stoichiometries (ZSW measurements: Internal publication).

from being realized. Realistically, it has to be assumed that progress in membrane development will consist of gradually improving membrane humidification and temperature stability.

In this respect, however, it is interesting to examine to exactly what degree 100% RH requirement is really necessary for state-of-the-art MEAs in the anode as well as in the cathode compartment under different operating conditions. Figure 27.7 shows single-cell measurements with GORE 5510 MEAs under low humidification conditions. The membranes in these MEAs have a thickness of about 25  $\mu\text{m}$ , which is a low value for PEMFCs. Therefore, it is possible to efficiently humidify the membrane by back-diffusing the liquid product water into the membrane from cathode to anode side. The normal drying-out effect at the anode is diminished in this case because the membrane is thin and does not represent any significant diffusion resistance. With thin membranes, high current densities are also achievable due to their low ionic resistance. These attributes can be seen in Figure 27.7, which shows  $V$ - $I$  curves at a higher temperature of 90°C at the anode with humidification only at the anode as well as at a lower temperature of 60°C with no humidification at all. The  $V$ - $I$  curves exhibit relatively low open-circuit voltages due to a high crossover of the gases and therefore, the temperature difference does not influence the  $V$ - $I$  curve much at lower current densities. At high current densities, humidification is improved and stable operation is observed over about 12 h due to more water formation at the cathode. However, now it is not clear if this performance can be maintained over prolonged operation of more than 1000 h and if the power density is sufficient for transportation applications.

This example shows that efficient management of the liquid water produced at the cathode can be used to attenuate the 100% RH requirement of the membrane. Besides thin membranes, other strategies (described below) involving wicks or water

**FIGURE 27.7** Performance of a GORE 5510 MEA in a single cell at a temperature of 60°C as well as of 90°C under reduced humidification conditions (ZSW measurements: Internal publication).

produced by catalysts introduced into the membrane are well known. However, all these strategies involve compromising other properties for water management, e.g., thin membranes are not as durable since the mechanical properties are inferior or the performance of the MEAs is reduced in conjunction with reduced humidification.

The common way of improving the water management is to humidify the gases entering the fuel cell. A less common approach is the direct hydration of the membrane by mounting porous fiber wicks within the membrane itself [16]. Membranes with wicks are developed using twisted threads of porous polyester fibers which are then placed between the membrane and a cast thin film of Nafion ionomer and hot-pressed at 150°C. Such membranes with porous fiber wicks are supplied with water directly through the wicks. The parts of the wicks outside the membrane are kept in contact with a water source such as a humidifier or condenser outside the membrane. Water diffuses through the porous fibers into the membrane, thus keeping it humidified. Similar approaches have also been reported by other authors [17,18].

### 27.2.1.2 Stationary Application

Fuel cells are promising candidates for energy conversion systems used for distributed power generation, which can guarantee uninterrupted power supply and thus cut unnecessary dependence on the grid. Fuel cells are quite efficient at around 60% electrical energy conversion efficiency and the use of waste heat from the fuel cells to houses would make them more efficient. The efficiency of such a CHP fuel cell system depends on the operating temperature of the system, which dictates the amount of recoverable heat. A fuel cell-based system makes very low noise and produces almost zero emissions when direct H<sub>2</sub> from nonfossil fuel sources is used. These are important advantages in comparison to conventional systems based on ICEs. But high costs and problems in long-term durability are major obstacles in the path of wide-scale introduction to the market. PEMs contribute a significant cost factor. The membranes are also primarily responsible for the degradation of the performance of the fuel cell system, being one of the most vulnerable components in the fuel cells. An effective heat removal system and a humidification management system are still very important in stationary fuel cell systems. But stationary applications put the strongest demand on the durability of the PEMs. To understand the durability of the membrane, it is imperative to discuss various modes of its degradation.

#### 27.2.1.2.1 Mechanical Degradation

Mechanical parameters related to preparing an MEA contribute significantly to the overall service-life of the membrane [7]. A high degree of cleanliness and quality control must be maintained to ensure that no foreign particles or fibers are introduced that may perforate the membrane during the MEA fabrication process. Generally, perforation can also take place at the fuel cell reactant inlets where mechanical stress may be highest. Care must be taken to design the fuel cell flow field to avoid local drying due to nonuniform distribution of reactant gases in the cell. Uniform contact pressure should also be maintained between the current collector system and the MEA. Excessive penetration of the catalyst layer into the membrane during MEA fabrication or due to high-localized pressure exertion by the current collector can lead to high local current density and stresses. Excessive-localized pressure close to the edge of the electrode/membrane may also lead to perforation and tearing of the membrane. Care must be taken in designing the fuel cell to avoid unsupported regions in the MEA flow field support structure into which the membrane could extrude and ultimately fail. Generally, when a membrane is perforated, hydrogen and oxygen will cross over to the other sides and react chemically on the catalyst producing only heat. The cell potential will decrease because of this mixing of reactants. The excessive heat produced due to the chemical reaction between hydrogen and oxygen may lead to more holes in the membrane [7].

#### 27.2.1.2.2 Thermal Degradation

PEMFCs generally operate at temperatures <100°C. PFSA-based polymer ionomer membranes like Nafion, Gore, Aciplex, and Flemion are not significantly affected by temperatures up to 150°C where most of the water is lost and membranes may suffer irreversible dry out. Chemical degradation of these membranes in the H<sup>+</sup> form usually starts with the loss of sulfonate groups at over 220°C [7].

#### 27.2.1.2.3 Chemical and Electrochemical Degradation

For properly designed and cleanly operated PEMFCs, polymer electrolyte membrane degradation by electrochemical and chemical mechanisms generally occurs relatively slowly over a period of several hundred hours. PEMs are especially sensitive to metal ions, which may get into the fuel cell via dust particles in the air or even rust. Even the platinum ions ever present in the electrode are not completely benign. Metal ions within the fuel cell would exchange with protons, thereby drastically reducing the proton conductivity of the membrane. It is also known that peroxide radicals are produced at very low levels during fuel cell operation and these radicals are responsible for the chemical and physical deterioration of the membrane after extended use [19,20]. On the basis of these findings, methods have been developed to perform accelerated chemical tests to simulate this type of polymer electrolyte membrane (PEM) degradation. Peroxide radical-assisted degradation has been extensively studied for early PSSA membranes [21]. It was shown that oxygen crossing over to the hydrogen side may lead to the formation of peroxide and hydroperoxide radicals, which can slowly deteriorate the membrane. The PFSA membranes are, relatively

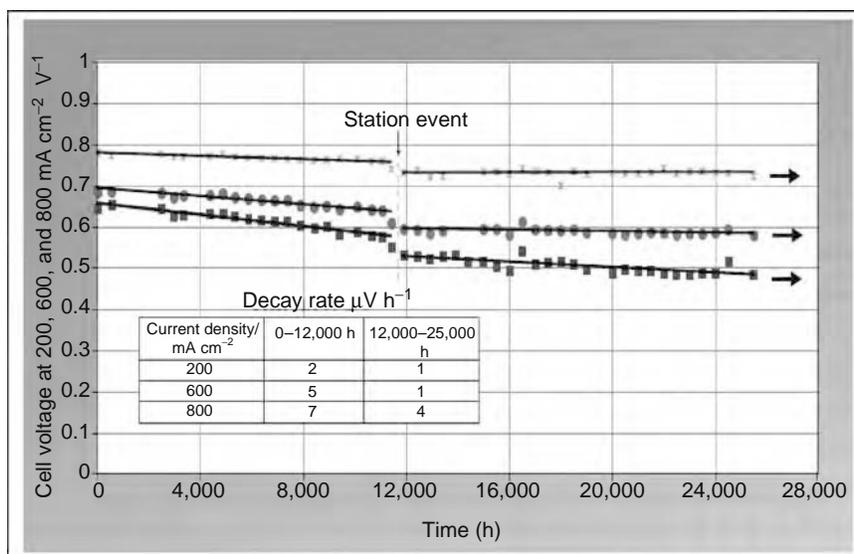

FIGURE 27.8 (See color insert following page 588.) Long-term tests. (From W.L. Gore & Associates, Elkton, Maryland.)

speaking, much better in terms of performance and service-life. But peroxide radicals can still degrade the membrane, albeit to a smaller extent, as the basic backbone  $-\text{CF}_2$  is less susceptible to peroxide attack. The susceptibility to peroxide attack has been attributed to traces of groups such as  $-\text{CHF}_2$ , which are inadvertently introduced into the perfluorocarbon sulfonyl structure during synthesis and can be converted into a carboxyl group by peroxo insertion [22,23].

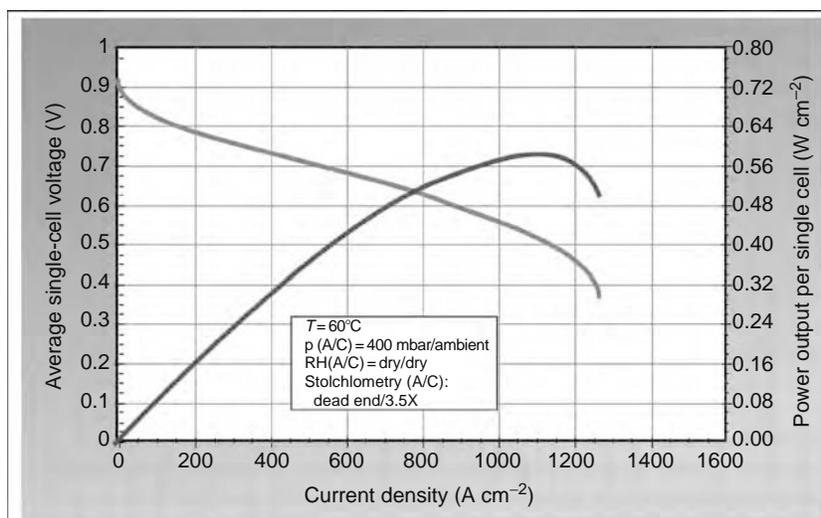

The sum effect of mechanical, thermal, and chemical degradation of the membrane along with the degradation of catalysts will take its toll on the long-term performance of the fuel cell. A lot of effort is being put into improving membrane service-life as well as MEA service-life by many players in this field. For example, W.L. Gore has demonstrated service-lives exceeding 28,000 h for MEAs targeted for stationary fuel cell systems (Figure 27.8).

### 27.2.1.3 Portable Applications ( $\text{H}_2$ -Fuelled PEMFC)

Portable applications are one of the most attractive segments in terms of fuel cell commercialization as the number of possible units required for consumer electronic market is high and cost limitations are much easier to meet than automotive or stationary applications. Fuel cells in the low power range can be used either as a complete substitute for batteries or in fuel cell/battery hybrid power supply systems. Fuel cells for portable applications usually operate under ambient conditions. For portable power supply applications based on hydrogen-fuelled PEMFC, the most important issue is the power to volume/weight ratio, as more and more miniaturized power sources are needed for consumer electronic devices, like laptops, mobile phones, palmtops, video cameras, and a host of military applications. To a large extent, the power to volume/weight ratio depends on the energy density of the fuel from which  $\text{H}_2$  is extracted. Possible options for hydrogen sources could be metal hydride, chemical hydride, or a thermal reformer, e.g., methanol reformer. But the basic size of a fuel cell system also has a fair share in determining the overall energy density of portable fuel cell-based power supply. Thus to meet these miniaturization challenges, passive thermal and water management and also suitable components for hydrogen/air feeding and pressure control must be realized. In meeting these requirements the polymer electrolyte membrane (PEM) has a big role to play, at least in water management. Water management requires the synergetic action of the gas diffusion layer (GDL) and the PEM. To meet the requirement of complete passive water management, the fuel cell should run on dry  $\text{H}_2$  and dry air and retain just enough water in the membrane.

#### 27.2.1.3.1 Membrane Humidification by Cathode Back Diffusion

One such approach employs a microporous layer (MPL) with an average pore size of around  $1 \mu\text{m}$  between the GDL (with an average pore size of  $10 \mu\text{m}$ ) and the catalyst layer. The MPL is made up of conducting carbon and is hydrophobized with a small amount of Teflon. MPLs do not allow the water to escape as liquid drops because of surface tension in small pores. This builds up hydrostatic pressure on the cathode side. This hydrostatic pressure buildup allows back diffusion to the anode side. The positive role of microporous layers in water management in PEMFCs has been investigated theoretically and experimentally [24–28]. For the back diffusion to humidify, the whole membrane requires a thin and obviously stable membrane. With pure PFSA-based membranes, it has not been possible to reduce the thickness without compromising mechanical strength. To achieve this goal, several new ideas have been pursued which are discussed later in this chapter. One such approach is to reinforce the membranes with polytetrafluoroethylene (PTFE) fibers, a technique pioneered

**FIGURE 27.9** (See color insert following page 588.) Performance of the Gore 58 series in completely dry conditions. (From W.L. Gore & Associates, Elkton, Maryland.)

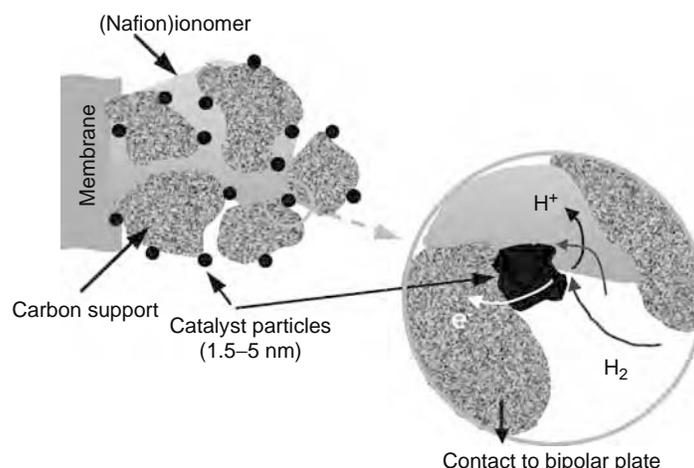

by W.L. Gore, which can reduce membrane thickness to only a few micrometers. Figure 27.9 shows the  $I$ - $U$  (current-voltage) characteristics of a fuel cell using Gore membranes, under completely dry conditions.

### 27.2.2 POROUS STRUCTURE AND PERMEABILITY REQUIREMENTS

The important chemical reactions take place at the interface between an electrode and an electrolyte. Since reactants in fuel cells are mostly gaseous and poorly soluble in the electrolyte, a third phase, the gaseous one, has to be in contact with the interface, leading to a three-phase boundary. Furthermore, a certain solubility and diffusivity of the reactant within the ionomer material in the electrode is needed to achieve greater utilization of the catalyst. This permeability in the ionomer helps to extend the electrochemically active surface area of the catalyst that belongs to the three-phase boundary. A diagram of this zone in a PEMFC is shown in Figure 27.10. Presently, differing opinions exist on the structure of the active layer: It is unclear if the ionomer is present at the interface as a third bulk phase or as a thin film of about 20–50 nm covering the catalyst. Such differences would have considerable implications for the optimization of this interfacial region.

To optimize the kinetics in this area, the following features are required:

- High, electrochemically active surface area of the catalyst
- Good access for the reactants to the electrode-electrolyte interface and sufficient permeability in the ionomer
- Effective water removal from the three-phase zone
- Good electric and ionic contact at the reaction sites

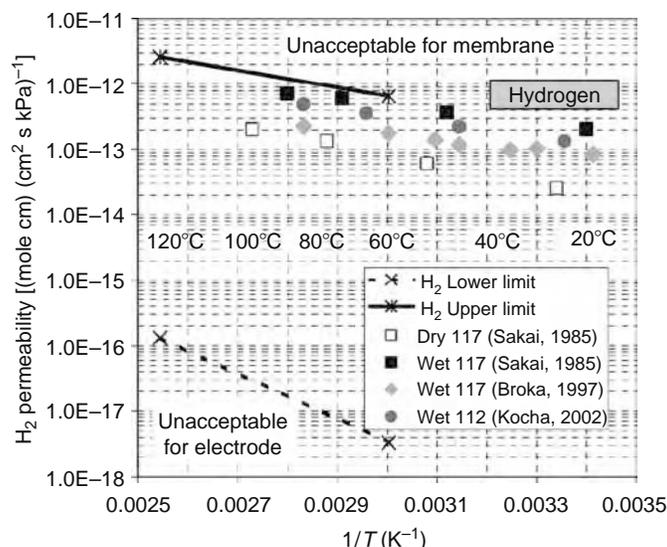

**FIGURE 27.10** Diagram of the active layer of a gas diffusion electrode in a PEMFC.

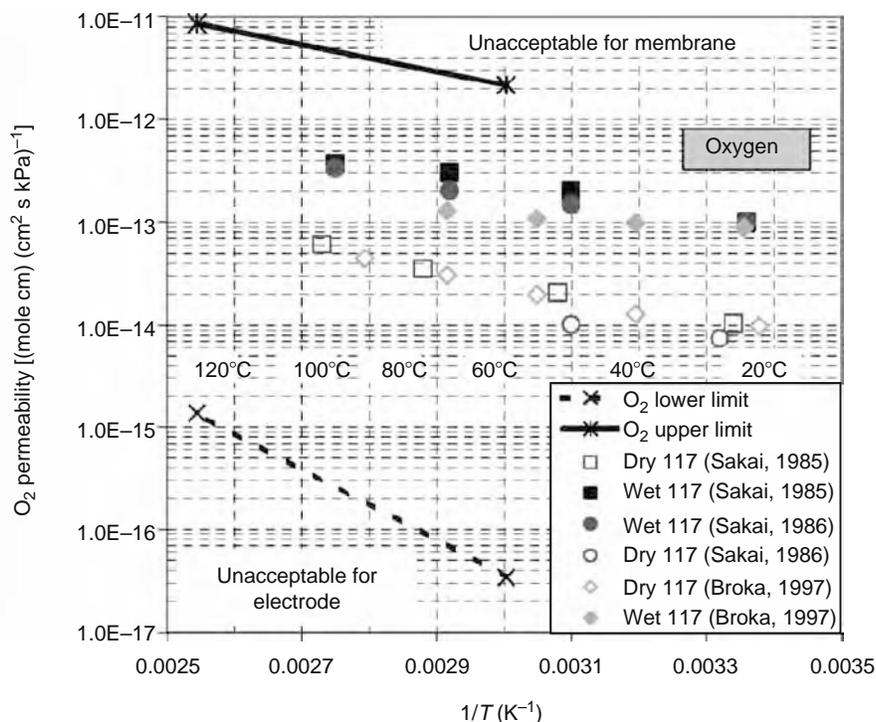

These requirements can be achieved best with a porous structure, but the realization depends strongly on operating temperature. Since costly precious metals (Pt and Pt alloys) are used as a catalyst, high dispersion of these metals is necessary to optimize the surface to mass ratio. Starting from metal salts, various chemical routes are usually used to achieve very small metal catalyst particles and thus high dispersion. The metal particle sizes are of the order of a few nanometers (platinum surface areas in the range of 20–60 m<sup>2</sup> g<sup>-1</sup> are common). In supported catalysts, the metal clusters are supported on larger electron-conducting and porous carbon particles (usually about 50–100 nm in diameter) to achieve better dispersion of the metal catalyst, higher active surface area and to prevent agglomeration of metal catalyst nanoparticles. The catalyst is introduced into the electrocatalyst layer along with the proton-conducting ionomer component. The ionomer content increases the metal catalyst utilization in the catalyst layer, but normally an optimum content is found and further increase in ionomer content leads to lower catalyst surface utilization. Largely varying utilizations of catalyst surfaces (varying between 50% and 90%) in PEMFC electrodes have been reported [29]. Usually, the catalyst layer has a thickness in the range of about 5–30 μm.

Gasteiger and Mathias have analyzed the requirements of membranes for automotive applications and have stressed that in addition to proton conductivity, other critical ionomer properties include the H<sub>2</sub> and O<sub>2</sub> permeability [12]. Of course, the membrane material must not be too permeable to the reactive gases to avoid excessive gas crossover and resulting fuel efficiency loss. In the other extreme, the ionomer in the electrode must have sufficient gas permeability so that the reactant transport through it occurs without significant concentration gradients and associated mass-transfer losses. Standard perfluorinated membranes allow permeation of gases at a rate proportional to the product of a permeability coefficient (dependent on temperature and RH, normalized by membrane thickness) multiplied by a partial pressure driving force and divided by the membrane thickness. This permeation leads to fuel efficiency loss with two components: direct reaction at the anode determined by the O<sub>2</sub> crossover rate and direct reaction at the cathode determined by the H<sub>2</sub> crossover rate. This fuel loss can be expressed in terms of an equivalent current that would be observed externally, if the H<sub>2</sub> consumed by crossover had reacted electrochemically. A tolerable fuel efficiency loss due to crossover was set at <10% for a low load and <1% for a high load of the MEA. Gasteiger and Mathias assumed a thin-film structure of the ionomer of 0.5–2 nm covering the entire solid catalyst surface. Experimental support for this electrode structure comes from double-layer capacitance measurements using cyclic voltammetry and AC impedance techniques. Gasteiger and Mathias observed values that are typical of Pt and carbon interfaces with electrolyte and imply that the entire solid surface was in contact with electrolyte for these electrodes. Under several assumptions regarding structure, diffusion, and reactivity, a minimum permeability was derived for a maximum of 20 mV loss.

These considerations regarding the membrane permeation properties have been summarized by Gasteiger and Mathias in Figures 27.11 and 27.12, with literature data of gas permeation measurements of Nafion membranes. Following their evaluation, the present membranes are close to the upper limit of gas permeation, which is acceptable, but a further increase in these properties at higher temperatures cannot be tolerated.

Besides the traditional methods of measuring gas permeation by way of gas analysis (a volumetric method or gas chromatography), an electrochemical methodology to determine the gas permeability and solubility of membranes is also used, which seems to have become more popular recently. Using microelectrodes, which are pressed onto a membrane in a solid-state electrochemical cell, electrochemical reactions are investigated by chronoamperometry (recording of current transients) of the diffusion-limited potential ranges. From the transients, gas concentrations (solubility) and diffusion coefficients in various proton-exchange membranes can be measured and diffusion-limited current densities can be determined [30–36]. This is an interesting and simple way of measuring permeabilities since it may enable in situ measurement in a running fuel cell and also a local resolution. However, in contrast to the permeation measurement by gas analysis, no driving force in the form of a partial pressure gradient is applied to the membrane. The comparison of both techniques is therefore not straightforward. Under diffusion-limited conditions, the concentration at the microelectrode interface is zero and therefore, a partial pressure gradient corresponding to the pressure in the cell (e.g., 100 kPa for ambient conditions) is assumed. Under this assumption, the results from both measurements should be comparable and a comparison of selected measurements is shown in Figure 27.13.

As can be seen from Figure 27.13, the permeability measurements of Nafion-like membranes do vary considerably, probably because the state of the membranes is difficult to control (e.g., the dryness of the membrane). There is a pronounced difference in the permeabilities for wet and dry membranes, but the method of measurement does not yield consistent variation in the measured values. It can therefore be concluded that the electrochemical method is equivalent to the gas analysis method, even though the measurement conditions are different from those in fuel cell applications.

### 27.2.3 CATALYST UTILIZATION AND INTERFACIAL ASPECTS

The importance of the ionomer in the electrode for the performance of the PEMFC has been well known since the pioneering work of Raistrick et al. [37]. In the PEMFC, the electroosmotic drag of water due to the proton transport from the anode to the cathode leads to the membrane drying out from the anode side (back diffusion of water from cathode to anode compensates partly for the water loss from the anode side of the membrane). Therefore, the loss of conductivity of the ionomer at the anode is also an additional important issue related to the membrane topic, since the ionomer in the electrode needs to connect ionically and chemically to the membrane. In an investigation of the transverse water profile in Nafion in PEMFCs with a

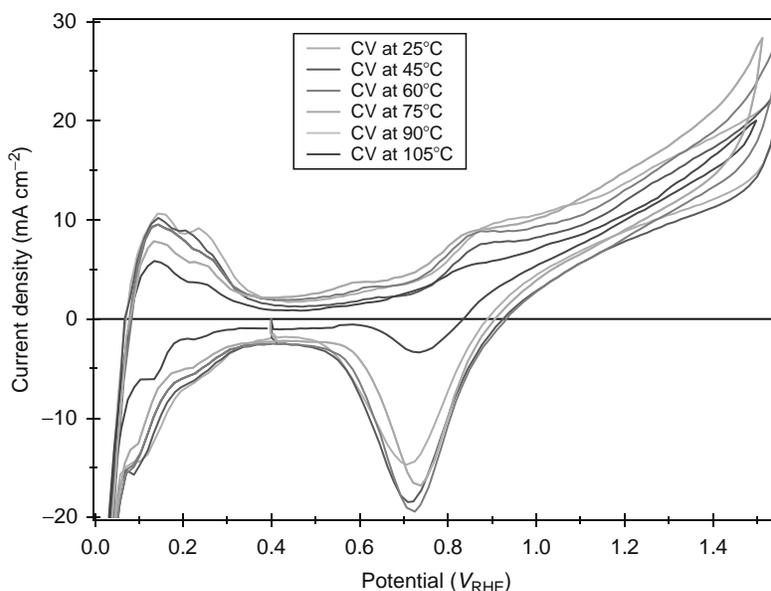

**FIGURE 27.13** (See color insert following page 588.) O<sub>2</sub> permeability as a function of temperature measured using an electrochemical method (microelectrodes, EC) and a gas permeation (gas analysis, GA) method. Permeability calculated for a partial pressure gradient of 100 kPa. (From Vielstich, W., Gasteiger, H.A., and Lamm, A. (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, J. Wiley & Sons, Chichester, 2003; Masten, D.A. and Bosco, A.D., in Vielstich, W., Gasteiger, H.A., and Lamm, A. (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, J. Power Sources*, 127, 162, 2004; Alberti, G., Casciola, M., Massinelli, L., and Bauer, B., *J. Membr. Sci.*, 185, 73, 2001; Ma, Y.L., Wainright, J.S., Litt, M.H., and Savinell, R.F., *J. Electrochem. Soc.*, 151, A8, 2004; Watanabe, M., Satoh, Y., and Shimura, C., *J. Electrochem. Soc.*, 140, 3190, 1993; Ge, S.H., Li, X.G., and Hsing, I.M., *J. Electrochem. Soc.*, 151, B523, 2004; Ge, S.H., Li, X.G., and Hsing, I.M., *Electrochim. Acta*, 50, 1909, 2005.)

sheet-partitioned membrane, Büchi and Scherer found that the increase in resistance is always confined to the membrane sheet contacting the anode [38]. It cannot be excluded that the main contribution to increased resistance of the MEA at high temperatures is from the ionomer in the electrode. To obtain clarification, cyclic voltammograms (CVs) of a commercial MEA with about 25  $\mu\text{m}$  thick membranes were performed as a function of temperature at 100% RH to detect the influence of these interfacial structures on the performance of PEMFCs. Figure 27.14 shows the CVs of the anode as a working electrode (catalyst loading of 0.3  $\text{mg cm}^{-2}$ ) under nitrogen purging. The cathode was used as a combined counter and reference electrode and purged with hydrogen. Due to the small thickness of the membrane, hydrogen permeates the anode leading to an almost linear slope in the CVs. This current was subtracted to obtain more information regarding the interfacial properties of the MEA. The humidification of nitrogen/hydrogen was achieved by gas bubblers, which were invariably kept at 5°C higher than the cell. Condensation of water was avoided by choosing adequate temperatures for the gas distribution system. Interestingly, the features due to hydrogen adsorption/desorption decrease with increasing temperature, indicating a loss of active catalyst surface area.

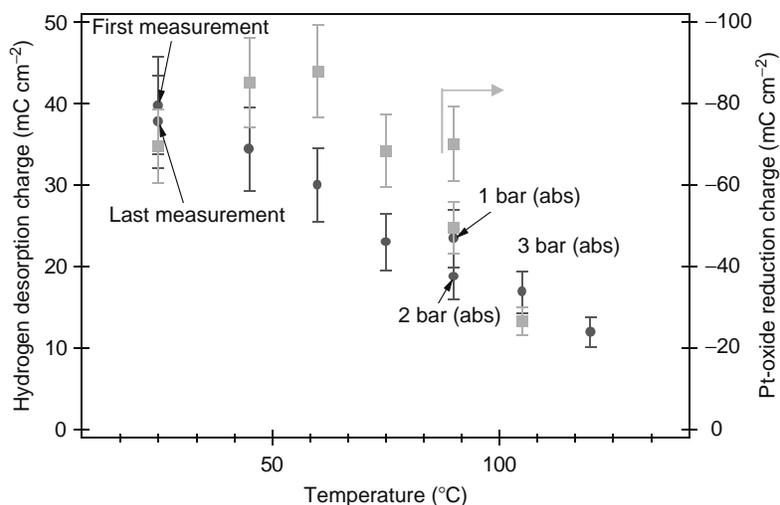

From these CVs, the reduction of Pt oxide in the negative going scan can also be used to estimate the contacted catalyst surface area. The integration of the respective areas is not highly accurate and an integration error of  $\pm 15$  mC is displayed in the charges plotted against temperature in Figure 27.15.

As can be seen from Figures 27.14 and 27.15, the hydrogen desorption charge decreases almost monotonically with increasing temperature, indicating a loss of active surface with increasing temperature. At variance with the linear decrease, the charges from Pt oxide first increase up to 60°C and then a strong decrease is observed at higher temperatures of 90°C. The charges from hydrogen desorption are considered to be of higher significance for the active surface determination, since the Pt oxide reduction may be influenced by kinetic and mass-transport properties of the interface, which are strongly affected by the temperature increase. The form of the CV in the oxide region indicates mass-transport limitations due to diffusion in a polymer film. Especially there is a strong decrease in active catalytic area when the pressure is increased, e.g., at the same temperature. This is demonstrated in Figure 27.16 for the temperature of 90°C where the pressure was increased from 1 to 2 bar(abs).

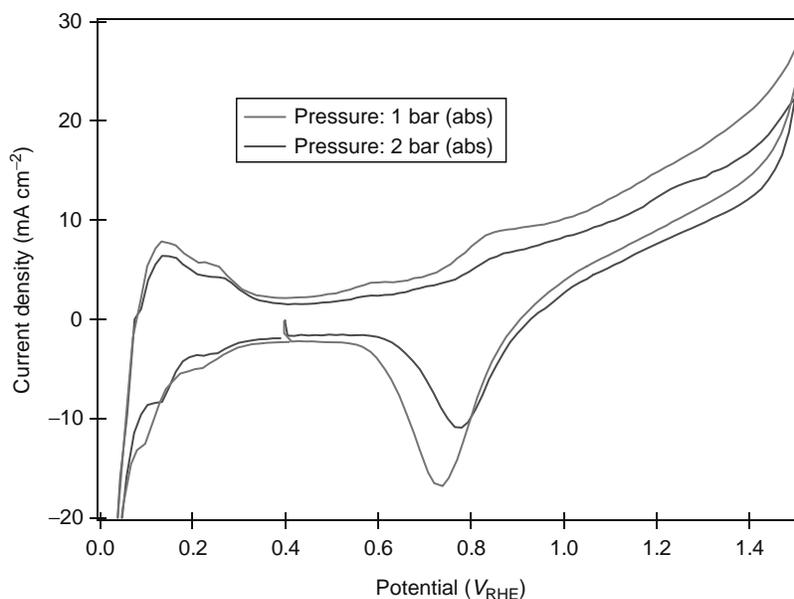

**FIGURE 27.14** (See color insert following page 588.) CVs of a commercial MEA with a 25  $\mu\text{m}$  thick membrane as a function of temperature. Scan rate  $50 \text{ mV s}^{-1}$  (ZSW measurements: Internal publication).

The loss of surface area when increasing the pressure is probably associated with the water content depicted in Figures 27.15 and 27.16. With increasing pressure, the water content decreases and may lead to the ionomer in the electrode drying out. Since the membrane swells considerably with the water content, the higher pressure conversely leads to the ionomer in the electrode shrinking and thereby to reduced catalyst utilization. But then the question remains why the catalyst surface utilization decreases with increasing temperature, although the water content of air/nitrogen increases considerably with temperature. It is well known that the water uptake of Nafion membranes is lower in the gaseous phase compared to the liquid phase (16 versus 22 water molecules per sulfonic acid group). This is an effect that has been discussed for numerous membranes and is termed Schroeder's paradox [39]. Furthermore, Nafion has also been reported by Broka and Ekdunge to adsorb less water with increasing temperature even at constant humidity [40]. The reasons are not yet completely understood, but are associated with the nanoporous structure and the phase-separated hydrous and anhydrous regions of Nafion. This effect is shown in Figure 27.17 for the temperature range of  $20^\circ\text{C}$ – $70^\circ\text{C}$ . If such dependence also exists in the ionomer present in the electrode, it is understandable why, with increasing temperature, the catalyst surface utilization also decreases.

**FIGURE 27.15** Hydrogen desorption charge (left-hand side, circles) and Pt oxide reduction charge (right-hand side, squares) as a function of temperature and pressure (ZSW measurements: Internal publication).

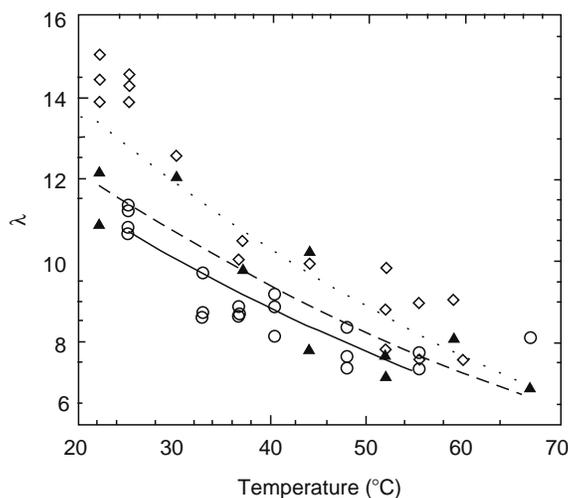

**FIGURE 27.16** (See color insert following page 588.) CVs of a commercial MEA at 90°C for 1 and 2 bar (abs) pressure. Scan rate 50 mV s<sup>-1</sup> (ZSW measurements: Internal publication).

It can be concluded that there are various problems associated with the standard PFSA membranes with increasing temperature:

- Loss of conductivity of membrane
- Loss of conductivity of ionomer in the electrode
- Loss of active catalyst surface area

#### 27.2.4 MEMBRANE REQUIREMENTS FOR DIRECT METHANOL FUEL CELLS

DMFCs have potential near-term applications mainly in the portable power source market, as they are smaller, lighter, simpler, and cleaner than conventional batteries. Liquid methanol is consumed directly in a DMFC, which implies a higher energy density of the fuel cell system. But the power densities achievable with state-of-the-art DMFCs are still smaller in comparison

**FIGURE 27.17** Water uptake from vapor phase (100% relative humidity [RH]) by Nafion 117 membrane and recast Nafion film at different equilibration temperatures: (◇) Nafion 117 membrane, (▲) recast Nafion film, (○) heat-treated Nafion 117 membrane. Fitted curves: second order polynomial;  $\lambda$  is the number of water molecules per sulfonate site. (Reproduced from Broka, K. and Ekdunge, P., *J. Appl. Electrochem.*, 27, 117, 1997. With permission from Springer Science and Business Media.)

to hydrogen-fuelled PEMFCs. One of the major problems lies in the use of liquid methanol solution on the anode of the DMFC, which, on the one hand, keeps the ionomeric membrane water saturated (and thus no humidification is needed), but on the other hand, does not keep fuel (methanol or any other organic fuel, e.g., formic acid, ethanol, etc.) and water from permeating to the cathode side, since the basic PFSA membranes are permeable to both methanol and water [41,42]. The fuel and water crossover from anode to cathode hampers the performance of the air cathode.

#### 27.2.4.1 Methanol Crossover

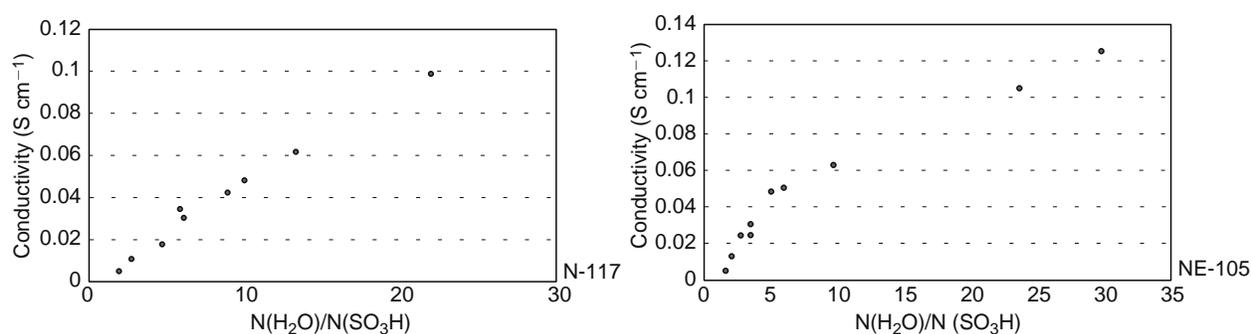

One of the most challenging issues that prevent DMFCs from being used in practical applications is the crossover of methanol fuel through typical PEMs, e.g., Nafion, from the anode to the cathode. It has been found that nearly 30%–40% of methanol can be wasted due to this crossover to the cathode depending on operating conditions like temperature, concentration of methanol in the anode feed, and current density in the cell. The mechanisms responsible for this transport of methanol to the cathode are diffusion due to concentration gradient and electroosmotic drag as moving protons also drag methanol like water, both being polar in nature. Methanol transported through the membrane by diffusion and electroosmotic drag recombines chemically with oxygen at the cathode and therefore, fuel utilization efficiency is lowered. Additionally, methanol present at the cathode depolarizes the oxygen electrode and establishes a mixed potential thus lowering the cathode potential. Methanol competes with the oxygen reduction reaction at the cathode and predominantly reacts with oxygen. This undesired reaction increases the demand for oxygen and therefore requires higher stoichiometric flow rates. To minimize the negative impact of the methanol crossover, fuel cell developers are forced to use thicker membranes which reduce the fuel crossover, but increase the specific cell resistance [8,41,43–46].

#### 27.2.4.2 Water Permeation

Water permeation to the air cathode in liquid methanol solution-fed DMFCs creates a barrier for air diffusion to active sites in the cathode catalyst layer by flooding the electrode. The water transport mechanisms from the aqueous anode to the gaseous cathode are electroosmotic drag and diffusion. The Nafion membrane is saturated with water for DMFCs, which gives rise to high electroosmotic drag coefficients [47] in comparison to partially saturated membranes, as in H<sub>2</sub>/air PEMFCs. At lower current densities, diffusion due to a huge concentration gradient of water between anode and cathode is the dominant water transport mechanism. But with increasing current density, the electroosmotic drag becomes the dominant mechanism as the water transported by electroosmotic drag is proportional to current density. The water transport properties of different types of membranes have been widely investigated by several research groups [45,46,48–54]. The permeated water hampers the performance of the air cathode by flooding the cathode catalyst and GDL and it also makes the self-sustainable high-temperature operation of DMFCs difficult due to excessive heat loss by water vaporization from the air cathode [55,56]. Additionally, it puts a huge demand on the air blower to remove water, making the DMFC's design more complicated and less energy efficient [42,43]. In this vein, DMFCs or any direct liquid oxidation fuel cells using methanol, formic acid, or ethanol, etc. as fuel should have membranes which are more liquid tight and still have sufficient proton conductivity.

### 27.3 MECHANISTIC ASPECTS OF PROTON CONDUCTIVITY (NAFION AND PERFLUORINATED SULFONIC ACIDS)

It is very important that the perfluorinated membrane has sufficient water content to function in fuel cells. The interaction of the perfluorinated membrane with water and the resulting water content of the membrane determine the proton conductivity of the membrane. The mechanistic aspects have been discussed in numerous publications, which cannot be completely recapitulated here [57–67]. When in contact with water vapor or liquid water, Nafion or similar membranes show a pronounced swelling of 20%–50% associated with a considerable water uptake. Due to the ambivalent nature of the polymer, as it has a hydrophobic backbone and hydrophilic head groups, a spontaneous phase separation takes place in the membrane. In a hydrated condition, hydrophilic ionic clusters are formed which are connected through water channels, thereby forming a water network. The hydrophilic clusters contain the solvated SO<sub>3</sub> groups, water, and the cations (normally H<sup>+</sup>, but for cation-exchange membranes Na<sup>+</sup>, K<sup>+</sup>, or Li<sup>+</sup> can naturally also be introduced). This water-filled network in a hydrophobic backbone yields high-proton conductivity, which resembles an aqueous electrolyte (similar conductivities as well as activation energies for the proton conduction are observed). The ambivalent property of the membranes assists their mechanical stability as the strong electrostatic interactions of the ionic clusters are apparently responsible for this stability. Importantly, Nafion can absorb more water from the liquid. For Nafion 117, saturated with liquid water, 22 moles of water are absorbed per mole of sulfonic acid groups. It is detrimental for the applications that Nafion can take up only a maximum of 14 mol of water per mole of sulfonic acid groups from the water in the gaseous phase. As discussed earlier, the conductivity of Nafion membranes is strongly dependent on water content, which is displayed in Figure 27.18 for two different equivalent weights. The membrane with the lower EQ shows the higher conductivity since the concentration of sulfonic acid groups is higher. A dried-out

**FIGURE 27.18** Conductivity of Nafion 117 and 105 as a function of water content expressed as the ratio of water molecules per sulfonic acid group. (From Hodgdon, R.B., Boyack, J.R., and Laconti, A.B., The degradation of polystyrene sulfonic acid. *General Electric Company TIS Report 65DE 5 1966*; Laconti, A.B., Fragala, A.R., and Boyack, J.R., in *Proceedings of the Symposium on Electrode Materials and Process for Energy Conversion and Storage*, J.D.E. McIntyre, S. Srinivasan, and F.G. Wills (Eds.), The Electrochemical Society Inc., Princeton, NJ, 1977, p. 354.)

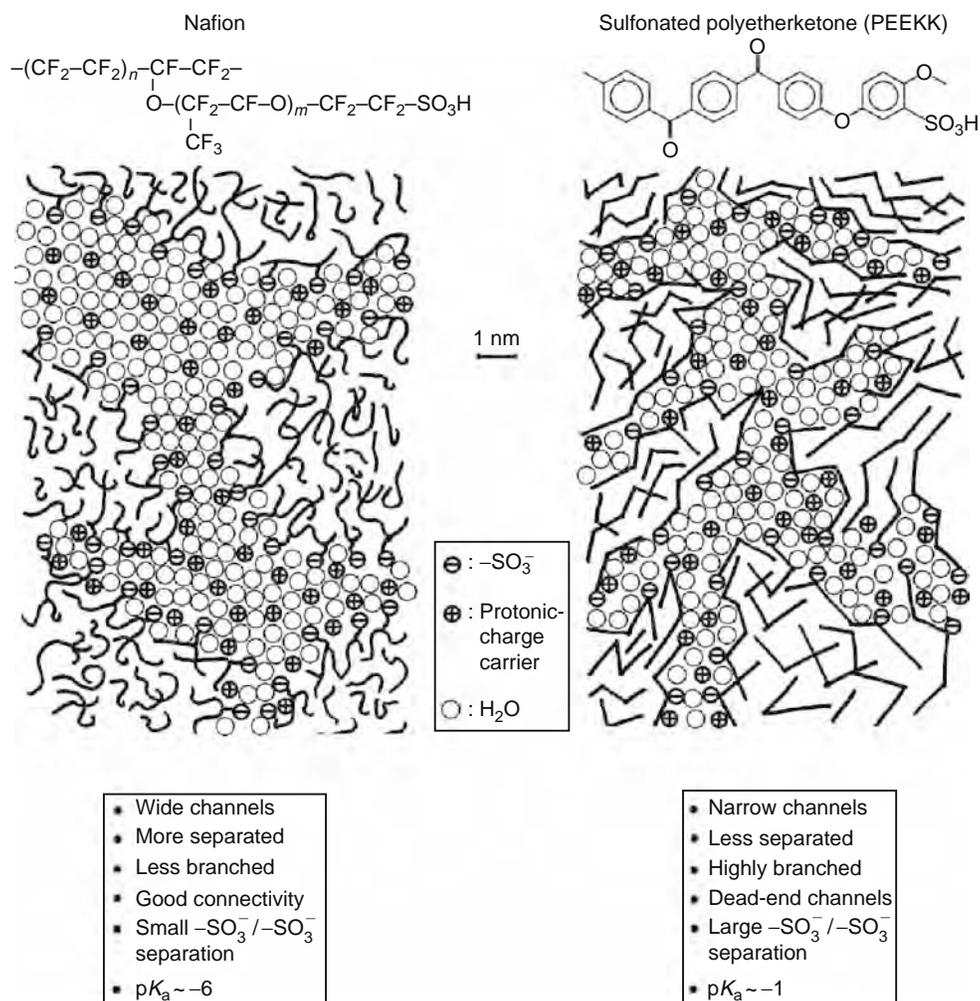

membrane possesses lower proton conductivity. Thus, water management in the membrane is one of the major issues in PEM technology. Processes influencing the water content in the membrane are electroosmotic drag and back diffusion of product water from the cathode into the membrane.

Water in a PEMFC is usually provided by the humidification of the reactant gases or from the cathode reaction. The amount of water fed to a cell by humidifying the reactant gases depends on gas temperature, pressure, and the flow rate. Water production at the cathode is directly proportional to the current density. Water carried to the cathode side by electroosmotic drag combined with the production of water at the cathode results in a gradual accumulation of water at the cathode. The water at the cathode can be carried to the flow channel through the GDL or through the membrane to the anode by back diffusion due to the water concentration gradient between the anode and cathode of the PEMFC. Water transport to the anode by back diffusion, which helps in keeping the membrane humidified, depends strongly on the thickness of the membrane and the properties of the GDL.

### 27.3.1 MICROSCOPIC STRUCTURE

The differences between PFSA membranes and nonfluorinated polyaromatic membranes are discussed on the basis of publications by Kreuer [64]. Perfluorosulfonic polymers naturally combine the extremely high hydrophobicity of the perfluorinated backbone with the extremely high hydrophilicity of the sulfonic acid functional groups in one macromolecule. Especially in the presence of water, this gives rise to some hydrophobic/hydrophilic nanoseparation. The sulfonic acid functional groups aggregate to form a hydrophilic domain. When this is hydrated, protons form within inner space charge layers by dissociation of the acidic functional groups. While the well-connected hydrophilic domain is responsible for the transport of protons and water, the hydrophobic domain provides the polymer with the morphological stability and prevents the polymer from dissolving in water. Kreuer's group found the situation in sulfonated polyetherketones to be distinctly different with respect to both transport properties and morphological stability. In sulfonated polyetherketones, the hydrophilic/hydrophobic difference is less pronounced. This was inferred from the results of small-angle x-ray scattering (SAXS) experiments [64]. For a hydrated sulfonated polyetherketone compared to Nafion, the ionomer peak is broadened and shifted toward higher scattering. This indicates a smaller characteristic separation length with a wider distribution and a larger internal interface between the hydrophobic and hydrophilic domain for the hydrated sulfonated polyetherketone. As schematically illustrated in Figure 27.19, the water-filled channels in s-PEEK are narrower compared to those in Nafion. They are less separated and more branched with more dead-end pockets. These features correspond to the larger hydrophilic/hydrophobic interface and, therefore, also to a larger average separation of neighboring sulfonic acid functional groups. The stronger confinement of the water in the narrow channels of the aromatic polymers leads to a significantly lower dielectric constant of the water of hydration (about 20 compared to almost 64 in fully hydrated Nafion) [59].

The different water interactions of the PEEK membranes are both advantageous and disadvantageous: on the one hand, a disadvantageous swelling behavior and a stronger decrease in water and proton-transport coefficients with decreasing water content are observed; on the other hand, the hydrodynamic flow of the water, i.e., electroosmotic drag and water permeation, is reduced compared to Nafion, which is an essential advantage, especially for DMFC applications [64]. Blending sulfonated polyetherketones with inert or basic polymers (e.g., PBI) significantly improves the swelling behavior without reducing the high-proton conductivity at high water contents. Blending also further reduces the hydrophilic/hydrophobic separation and therefore also hydrodynamic solvent transport (water and methanol permeation). Therefore, polymers based on sulfonated polyarylenes are not only interesting, low-cost, alternative membrane materials for hydrogen PEMFC applications but they may

**FIGURE 27.19** Schematic representation of the microstructures of Nafion and a sulfonated polyetheretherketone illustrating the less-pronounced hydrophobic/hydrophilic separation of the latter compared to the former. (Reprinted from Kreuer, K.D., *J. Memb. Sci.*, 185, 29, 2001. With permission from Elsevier.)

also help to reduce the problems associated with high water and methanol crossover in DMFCs using aqueous solutions of methanol as a fuel. An important drawback is their reduced chemical stability, which may well lead to reduced durability of the membranes [68].

## 27.4 MATERIALS: PHYSIOCHEMICAL PROPERTIES AND FUEL CELL PERFORMANCE

The commercial development of single-ion conducting polymer membranes has changed the field of electrochemical devices in a significant way. Traditional systems such as sulfuric acid and potassium hydroxide combine excellent conductivity and cost effectiveness, but the disadvantages are extreme corrosivity and challenging confinement. In this respect, the ion conducting membranes exhibit excellent stability and processability, allowing the flexible design of electrochemical devices.

### 27.4.1 PERFLUORINATED SULFONIC ACID MEMBRANES

PFSA membranes possess high-proton conductivity in the range of  $0.1 \text{ S cm}^{-1}$  at  $80^\circ\text{C}$  and good chemical as well as mechanical stability. The superior stability of Nafion is a consequence of the PTFE-based structure which is chemically inert in reducing and oxidizing environments. The best-known examples of this class of proton-conducting membranes are the Nafion-type membranes from DuPont de Nemours. The most common commercial perfluorinated ionomer membranes used today in various industrial processes are listed in Table 27.1. Asahi, Dow, and DuPont electro dialysis (ED) membranes have similar compositions and structures based on PFSA. The active ionomer component of the Gore-Select membrane is also a PFSA. In their usual form, these polymer membranes require water for conductivity. As long as these proton-exchange

membranes (PEMs) are kept hydrated, they function well, but when these membranes dry out, resistance rises sharply. A PTFE backbone is supplemented by regularly spaced perfluorovinyl ether pendant side chains terminated by a sulfonic acid group with the chemical structure shown in Figure 27.20.

Hydrated Nafion 117 (175  $\mu\text{m}$  thick) has conductivities in the range of  $10^{-1} \text{ S cm}^{-1}$  at  $80^\circ\text{C}$ . Nafion has a high electroosmotic drag coefficient that can lead to problems with water management in a PEMFC. Nafion has been extensively studied because of its electrochemical applications such as chlor-alkali production and, more recently, fuel cells. Continued research has sought to explain the high level of the ionomer ionic conductivity. Fuel cell membrane developers are focusing on thinner membranes to decrease resistance and to alleviate the water management problems. Popular Nafion membrane products for fuel cells include NE-112, NE-1135, N-112, N-105, N-115, and N-117. In fuel cell applications, Nafion serves as a solid electrolyte to selectively transport protons across the cell junction. Tables 27.2 through 27.5 summarize the presently available product information provided by DuPont for Nafion PFSA polymers.

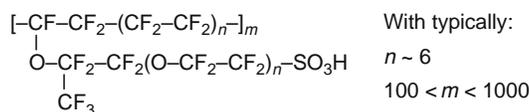

#### 27.4.1.1 Properties of Nafion PFSA Membranes

One activity at DuPont's Fuel Cells Business Center is the development of a thinner membrane with sufficient mechanical stability. Thinner membranes translate into higher current density, which in turn means a higher electrical efficiency. The trade-off is a less mechanically robust membrane. Nafion membranes are nonreinforced films based on Nafion resin, a PFSA/PTFE copolymer in the acid ( $\text{H}^+$ ) form. DuPont is especially marketing Nafion PFSA NR-111 and NR-112 membranes as nonreinforced dispersion-cast films for that purpose. These membranes are delivered as a composite with the membrane positioned between a backing film and a coversheet. This composite is wound on a 6 in. i.d plastic core, with the backing film facing out, as shown in Figure 27.21.

The backing film facilitates transporting the membrane into automated MEA fabrication processes, while the coversheet protects the membrane from exposure to the environment during intermediate handling and processing. In addition, the coversheet (in combination with the backing film) eliminates rapid changes in the membrane's moisture content, and stabilizes the dimensions of the membrane as it is removed from the roll. A roll core leader is attached to the membrane, as shown in Figure 27.21, when this option is desired by the customer. The roll core leader material is the same as the backing film. The properties of these thin membranes are specified in Table 27.5.

#### 27.4.1.2 Performance of DuPont Nafion Membranes

It is assumed that DuPont's Nafion membranes are used in about 80% of all publications on PEMFCs. The simple reason is that this was the only commercially available material for long time. Therefore, it is not possible to present here a complete

**FIGURE 27.20** Structure of Nafion. The characteristic value of proton-conducting polymer membranes is the EW, which is defined as the weight of polymer that will neutralize one equivalent of base, and is inversely proportional to the IEC. The values  $n$ ,  $m$ ,  $n'$  can be varied to produce materials with different equivalent weights.

overview of performance data with Nafion or other membranes. Furthermore, the performance depends strongly on the conditions used as well as MEA preparation (catalyst loading, etc.). As a consequence, only the performance data from the membrane manufacturer itself are reported. Figure 27.22 exhibits performance reports by DuPont in 2002 for a three-layer MEA for neat hydrogen and reformat operation.

According to DuPont, good progress has been made in developing high-temperature operating membranes. Exploratory research membranes in the temperature range of 110°C–140°C have been developed. A further development focus of DuPont membranes is the DMFC application. Beside performance increase, the reduction in methanol permeation is an important aspect of the development. In a presentation, DuPont showed the advantage of using thicker (7 mil) membranes compared to the thinner (2 mil) Nafion 112, which shows good performance for hydrogen/air operation. Figure 27.23 demonstrates this observation.

Another finding reported by DuPont is that the equivalent weight (EW) exhibits a pronounced influence on performance and methanol permeation. Whereas the highest performances were found with low EW membranes, the membranes with high EW had the lowest relative methanol permeation (Figure 27.24). According to DuPont, a 2 mil experimental membrane is in development which exhibits better performance for DMFCs compared to the 7 mil commercial membrane.

### 27.4.1.3 Synthesis of PFSA Monomers and Polymers

The synthesis of the monomers as well as the polymerization of PFSA membranes involve dangerous reactions under conditions of high pressure and temperature. Additionally, the synthesis of the comonomer that is commonly referred to as perfluorosulfonylfluoride ethyl propyl vinyl ether (PSEPVE) involves numerous steps with low yields. These factors contribute to the cost of these materials. The synthesis routes described in detail by Doyle and Rajendran are summarized here. The synthesis of the long-chain PFSA monomers used in commercial systems like Nafion, Flemion, and Aciplex proceeds through

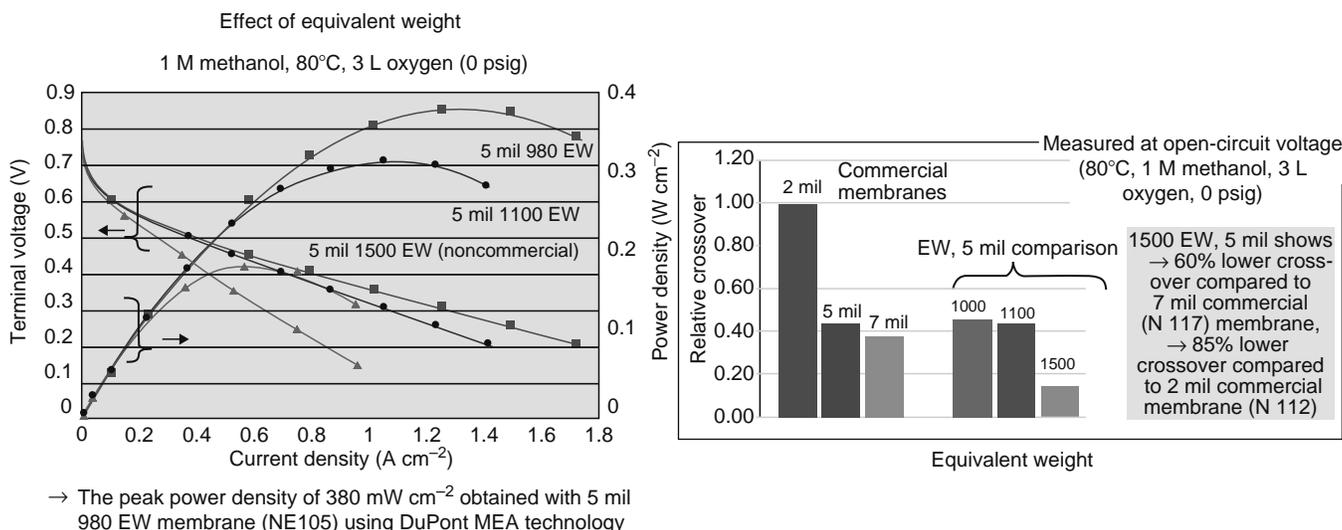

**FIGURE 27.22** Performance for DuPont membrane electrode assembly three-layer (DuPont MEA-3L). (From DuPont 2002, www2.dupont.com.)

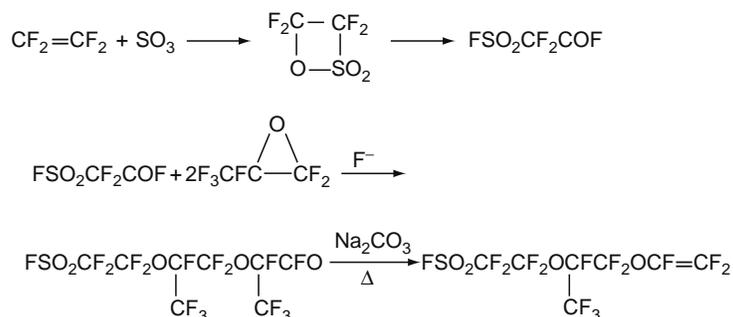

**FIGURE 27.23** (See color insert following page 588.) Comparison of DMFC performance of Nafion 117, Nafion 115, and Nafion 112. (From DuPont 2002, www2.dupont.com.)

the reaction of  $SO_3$  with tetrafluoroethylene (TFE) to form a cyclic sultone. A rearrangement of the cyclic compound yields the so-called rearranged sultone (RSU), which is reacted with hexafluoropropylene oxide (HFPO) to produce sulfonyl fluoride adducts. Heating these compounds in the presence of sodium carbonates yields the comonomer PSEPVE. The synthesis is illustrated in Figure 27.25 from Doyle and Rajendran [8]. Polymerization is typically performed in perfluorocarbon solvents with a perfluorinated free-radical initiator such as perfluoroperoxide.

The short-chain version of the perfluorosulfonyl fluoride vinyl ether monomer is highly desirable for obtaining membranes with improved functionalities. Ionomers with a short chain were intensively developed by Dow Chemical in the early 1990s and almost obtained commercial status. However, the development was abandoned, partly because the synthesis of the short-chain monomer is substantially more challenging. The Dow membrane was based on a copolymer of TFE and  $CF_2=CFOCF_2CF_2SO_2F$ . Since the shorter side chain makes the ionic concentration higher for the same EW, the Dow membrane showed higher conductivity and higher water uptakes under similar conditions. Testing of the Dow polymer in PEMFCs by Ballard in 1987–1988 showed significant improvement in performance compared to Nafion 117 (three times better current density at 0.5 V was reported). The typical functional comonomers of the relevant perfluorinated membranes are given in Figure 27.26 from Doyle and Rajendran.

**FIGURE 27.24** (See color insert following page 588.) Comparison of DMFC performance of 5 mil membranes with different EWs. (From DuPont 2002, www2.dupont.com.)

**FIGURE 27.25** Synthesis process for Nafion membrane comonomer PSEPVE. (Reproduced from Doyle, M. and Rajendran, G., in W. Vielstich, H.A. Gasteiger, and A. Lamm (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, Vol. 3, J. Wiley & Sons, Chichester, 2003. With permission.)

Industrial production of perfluorinated ionomers, Nafion membranes, and all perfluorinated membranes is costly due to several factors: first, the monomers used are expensive to manufacture, since the synthesis requires a large number of steps and the monomers are dangerous to handle. The precautions for safe handling are considerable and costly. Secondly, the PSEPVE monomer is not used for other applications, which limits the volume of production. The most significant cost driver is the scale of production. Today, the volume of the Nafion market for chlor-alkali electrolysis ( $150,000 \text{ m}^2 \text{ year}^{-1}$ ) and fuel cells ( $150,000 \text{ m}^2 \text{ year}^{-1}$ ) is about  $300,000 \text{ m}^2 \text{ year}^{-1}$ , resulting in a production capacity of  $65,000 \text{ kg year}^{-1}$ . When compared to large-scale production of polymers like Nylon ( $1.2 \times 10^9 \text{ m}^2 \text{ year}^{-1}$ ), the perfluorinated ionomer membrane is a specialty polymer produced in small volumes.

DuPont predicted in a communication from 1998 that they consider a price of no more than  $\$10 \text{ kW}^{-1}$  realistic in mass production. This prediction was, however, based on optimistic forecasts for transportation applications. The volumes quoted in the press release were 150,000 midsize vehicles (which corresponds to more than 1 million  $\text{m}^2$  worldwide for economics of scale). In 2002, DuPont's expectation for a production volume of 1 million  $\text{m}^2$  was about  $\$25 \text{ kW}^{-1}$  (Figure 27.27). The rule of thumb is to keep the membrane at 5% of the total fuel cell cost. A fairly common figure presently quoted for Nafion is  $\$500 \text{ m}^{-2}$ , although that varies depending on volume and on customer buying power. Several small-scale users have reported much higher costs. DuPont claims that process improvements combined with increasing market volume have yielded, on average, a 50% reduction in the market price of Nafion over the past 3 years. The company has in place a comprehensive, long-term technology and capital investment plan to continue this trend in price reduction. DuPont has reported a market price of Nafion membranes at about  $\$100 \text{ kW}^{-1}$  for the membrane material in a typical reformed hydrogen fuel cell system.

#### 27.4.1.4 Short Side Chain Perfluorinated Sulfonic Acid Membranes

Dow Chemical tested an experimental membrane named XUS 13204.1 in the late 1990s. These Dow experimental membranes are structurally and morphologically similar to the Nafion ionomers, but have shorter side chains and lower equivalent weights in the 800–850 range [69]. The experimental membrane had a reportedly shorter anion–anion distance, which gave it a slight increase in conductivity and greater water retention capability. A thickness of 50–51  $\mu\text{m}$  was considered possible. The patents and related property were reportedly part of the now terminated licensing agreement between Dow and DuPont. The lower equivalent weight ion-selective membranes decrease resistance and therefore lead to power density increase in PEMFCs. According to several sources, an experimental membrane from Dow reportedly exhibited a fourfold increase in power density compared to the Nafion 117 membrane. The disadvantages of lower EW are high swelling in water and

low durability. More recently, similar performances of the experimental Dow membrane and other membranes have been observed [70] (Figure 27.28).

Investigations on Dow membranes can be found in Refs. [70–82]. Solvay Solexis has started a research and development project to create new ionomer membranes for fuel cells and other applications similar to the Dow concept. The development is based on Solexis's capability for producing sulfonylfluorovinylether by a much simpler route than the original Dow synthesis [83]. The Solexis route is schematically represented in Figure 27.29 and the monomer can be produced on an industrial scale. The SSC monomer and TFE are copolymerized by free-radical polymerization to obtain the polymers in Figure 27.30 (named Hyflon Ion).

Starting from the monomers, ionomers are synthesized by taking advantage of a proprietary microemulsion polymerization process. This technology, broadly applied to the polymerization of other fluoropolymers, is able to give very high polymerization kinetics and high-molecular-weight polymers with accurate control of the molecular structure. This fully fluorinated proton-exchange polymer known as Hyflon Ion short side chain polymer obtains results similar to Nafion in fuel cells. This polymer has been used with success in DMFCs up to 130°C within the framework of the EU DREAMCAR program and tested

**FIGURE 27.28**  $\text{H}_2/\text{O}_2$ , versus  $\text{H}_2/\text{air}$  performances in PEMFCs with alternate membranes; E-TEK electrodes (20% Pt/C,  $0.4 \text{ mgPt cm}^{-2}$ ), 50°C, 1 atm. up to 110°C in hydrogen fuel cells. A solution of Hyflon Ion polymer is also available and will be used as a binder reference polymer in MEAs.

Solvay Solexis has reported composite membranes which have been prepared with EW from 750 to 1100 g mol<sup>-1</sup> and thicknesses from 20 to 80 μm. The ionomer in the acid form, dissolved at ambient or high temperature in water-ethanol mixtures, has been used to impregnate perfluorinated porous supports. These membranes have also shown high conductance as expected considering the low thickness. The casting method, used on a laboratory scale to prepare small membrane samples, was considered by Solexis to be quite complex and is especially susceptible to inconsistency, so not easily industrially viable. Moreover, for the more crystalline higher EW polymers, the limited gain in mechanical stability due to the support is countered by a loss in conductivity due to the presence of a fraction of volume that is occupied by the nonconducting material. Therefore, self-supported semicrystalline membranes have been prepared with an EW higher than 750 g mol<sup>-1</sup> and as slim as 15 μm. These membranes reportedly showed very good conductance and also very good mechanical properties. Furthermore, the ionomer, tuned with the appropriate molecular weight distribution, yielded high-quality and consistent membranes by film extrusion. This last process appeared to be the most viable and low-cost industrial process. Efforts were therefore made to select the ionomer that yielded the best combination of processability, conductance, mechanical properties, and dimensional stability, while also being able to guarantee extremely low membrane thickness and high duration. The reported performance results are presented in Figure 27.31 (no operating conditions were specified). The mechanical properties of Hyflon Ion-FM membranes and other commercial membranes are reported in Table 27.6 and expanding/shrinking characteristics on hydration/dehydration are reported in Table 27.7. Solvay also has access to the polysulfone polymer known under the trade name UDEL. Different grades of this polymer are available and can be supplied to partners on request. Some work on the sulfonation of this polymer in solution has already been carried out within the framework of the EU DREAMCAR project.

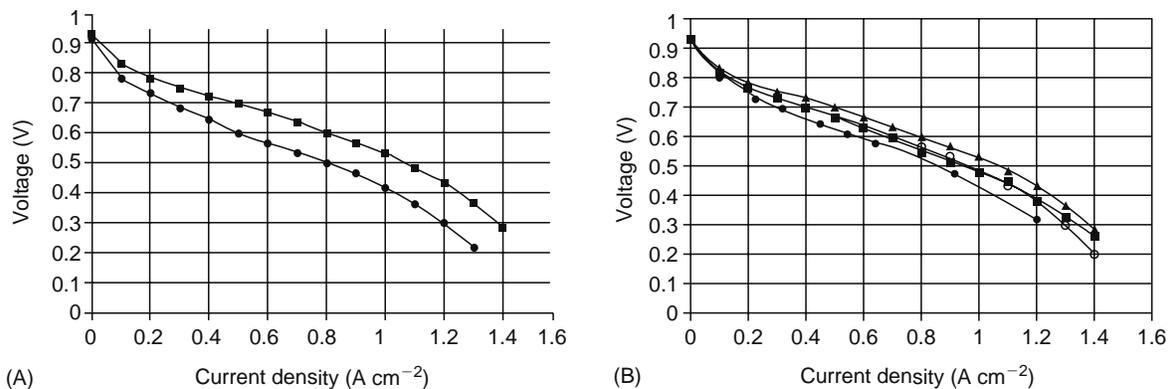

Fully assembled five- and seven-layer (include integrated gaskets) MEAs from matched components have been developed by 3M. A further development activity aims at high-speed precision coating technologies and a proprietary, automated MEA production process with online defect inspection. According to 3M, combining manufacture and component integration ensures product uniformity and low defect levels, resulting in high-quality, durable MEAs. A new PFSA-containing membrane has been developed based on a new perfluorinated monomer developed at 3M. This new membrane is designed to have improved thermomechanical properties at higher temperatures compared to currently available PFSA. The characteristics of the new 3M membrane are summarized below, according to statements by 3M [84]:

- Cast 30-μm membrane
- Equivalent weight of 980
- $T_g = 125^\circ\text{C}$  dry
- High modulus over a wide temperature range
- Equivalent or superior conductivity compared to other commercially available membranes
- Equivalent water absorption characteristics to Nafion-based membranes

The properties are summarized in Table 27.8.

<sup>a</sup> Test results are the average of downweb and crossweb film directions.

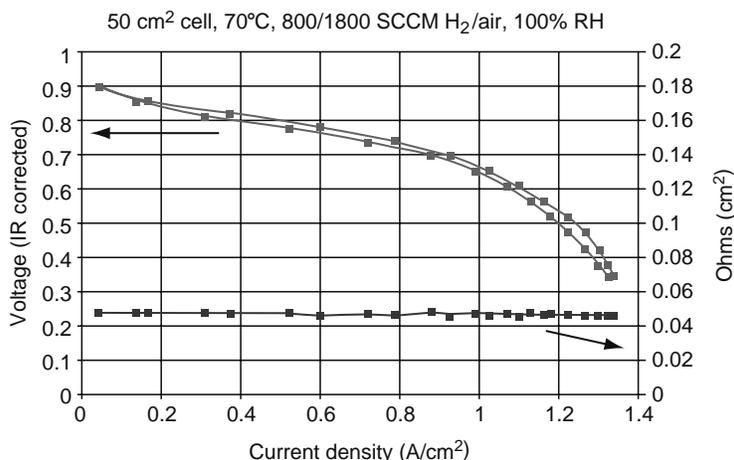

The performance curves given by 3M are presented in Figure 27.32. 3M has further reported performance reproducibility and durability. Figure 27.33 illustrates cell-to-cell variability in a 60-cell stack with 3M MEAs. For this system, the standard deviation in performance across the 60 cells was less than 5 mV. The MEAs in this stack were 3M seven-layer MEAs in which cell compression was limited by the integrated gasket. Figure 27.34 shows the performance durability of a 3M MEA tested at Osaka Gas in a 25 cm<sup>2</sup> single cell. In this single-cell test, the 3M five-layer MEA achieved more than 17,000 h of continuous operation with approximately 2 mV 1000 h<sup>-1</sup> decay. In addition to the single-cell data shown in Figure 27.34, 3M five-layer MEAs have also been tested in short stacks. Figure 27.35 shows performance in an eight-cell short stack at 70°C under simulated reformat fuel with anode airbled. More than 9000 h of operation were achieved with a decay of approximately 5 mV 1000 h<sup>-1</sup>.

In a recent product bulletin, 3M reported the typical performance data for their seven-layer MEAs (Figure 27.36). The 3M MEA is a seven-layer construction consisting of a proton-exchange membrane, an anode electrode, a cathode electrode, two GDLs, and two integrated seals/gaskets. The 3M MEA is produced using high-speed continuous automated assembly equipment.

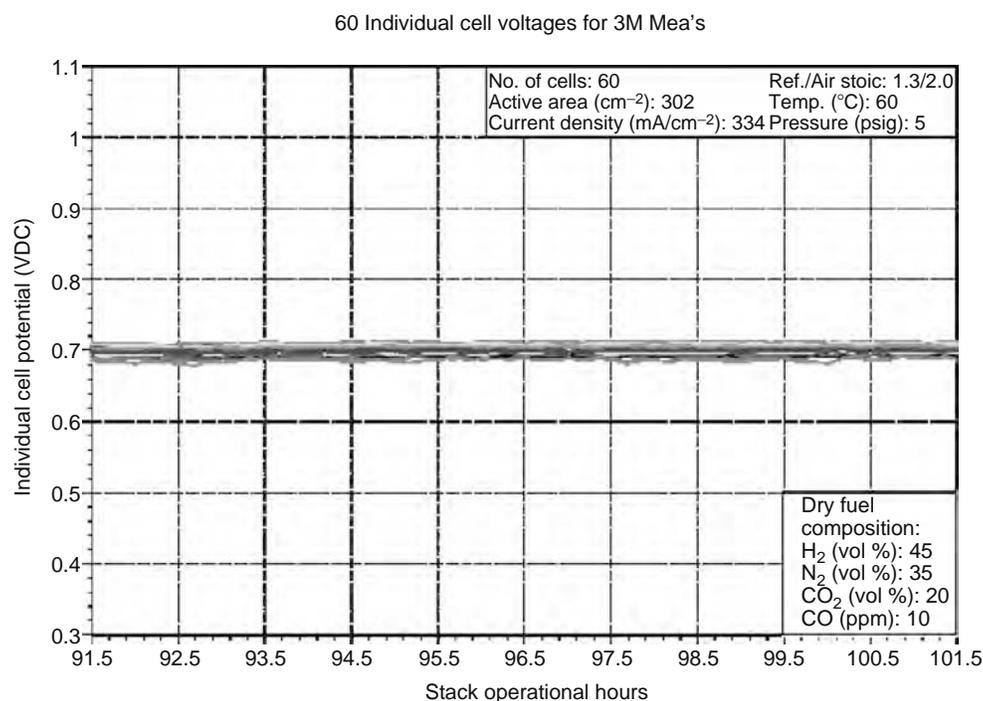

## 27.4.2 MECHANICALLY REINFORCED PERFLUORINATED MEMBRANES

### 27.4.2.1 PFSA Ionomer in Expanded Porous PTFE, Gore-Select Membranes

The company W.L. Gore & Associates (Elkton, Maryland) develops membranes under the name Gore-Select consisting of a microporous stretched PTFE (expanded PTFE porous sheet) membrane filled with perfluorinated ionomer. The microporous PTFE matrix provides the mechanical strength and therefore, the thickness of the membrane can be reduced considerably and a thickness of 20–40 μm is commonly used leading to lower ionic resistances. The specific resistance of Gore-Select membranes is relatively high compared with nonreinforced membranes, but this is compensated by the small thickness and by lower equivalent weight ionomers. The membrane is composed of a micronetwork of nodes and fibrils with a continuous internal void volume in which the ionomer is introduced. The expanded PTFE technology has been refined and applied to a variety of

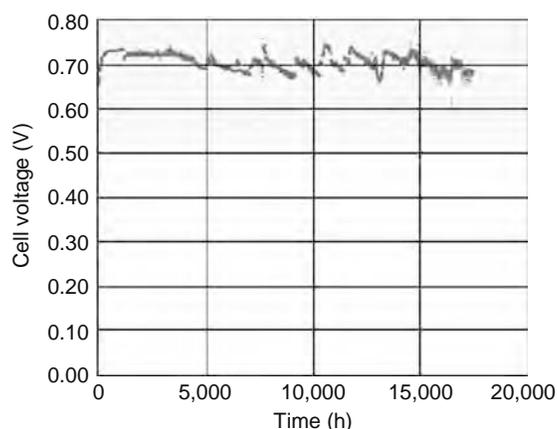

**FIGURE 27.32** Fuel cell polarization curve of a 50 cm<sup>2</sup> MEA made with the new 3M cast membrane (30 μm). (From 3M, www.3m.com.)

**FIGURE 27.33** Cell to cell uniformity from a 60-cell stack using 3M seven-layer MEA. (From 3M, [www.3m.com](http://www.3m.com).)

applications including use as a PEM in MEAs. In the mid-1990s, Gore began to work on expanded PTFE, which was then applied to PEMFCs. Their MEA is covered in U.S. Patent 5,547,551 issued in 1996 [85]. The fabrication of Gore-Select membranes is described in the patent. The important step is the impregnation with ionomer solution by brush (Figure 27.37). The company does not intend to actively market Gore Select, but will use it in its catalyzed PRIMEA MEA. Gore claims to be the highest MEA volume supplier in the world with a capacity for membrane and MEA fabrication of 100,000 m<sup>2</sup> per year. Gore has demonstrated a current density of 1200 mA cm<sup>-2</sup> at 0.6 V at ambient pressure with hydrogen or reformat fuel. Operating temperatures range from ambient to 60°C–80°C. The company is carrying out research to address activation and mass-transport limitations and advance the performance of the PRIMEA power assemblies. A current goal is to achieve 400 mA cm<sup>-2</sup> at 0.8 V. PRIMEA MEAs have been used in many PEM vehicle demonstrations, including vehicles such as the NJDOT Venturer, which operates on compressed hydrogen, and the NJDOT Genesis, which uses Millennium Cell's sodium borohydride as a hydrogen storage medium. Currently, PEMFC stack technology is being targeted at three major market sectors: portable power, residential, and transportation. Each market is driven by a different combination of features, such as power density, size, and life cycle cost. Gore adapts its MEAs to the specific application by optimizing the ionomer for the requirements. In this respect, specifically developed MEAs with increased performance or with improved durability are reported. The names used by W.L. Gore are the PRIMEA series 56x for the next generation of stationary applications

**FIGURE 27.34** Performance stability of a 3M five-layer MEA in single-cell testing at Osaka Gas. (From 3M, [www.3m.com](http://www.3m.com).)

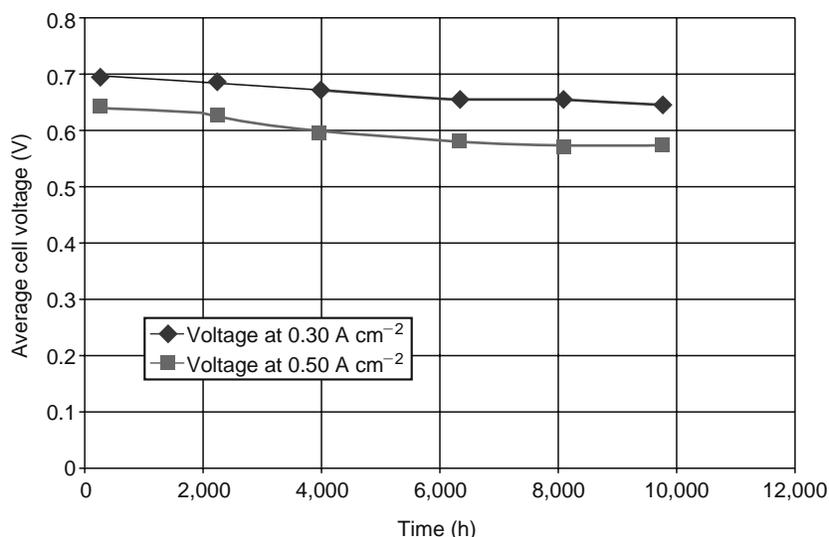

FIGURE 27.35 Short stack durability testing at 70°C with simulated reformat and anode airbled. (From 3M, www.3m.com.)

(presently 5621), the series PRIMEA 57 for transportation systems, and series 58 for portable applications. The reported properties of the MEAs are listed in Table 27.9.

According to Gore, one of the most important criteria in identifying a practical membrane material for MEA manufacturing and membrane service is tear strength or tear resistance. Cleghorn et al. compared reinforced Gore-Select membranes and nonreinforced Nafion 112 and determined the stress required to propagate a membrane tear using (ASTM) test 1922–1994a [86]. The results indicate that both membrane types are anisotropic and have greater tear resistance in the machine direction, and reduced tear resistance when hydrated. However, Gore-Select membranes reportedly show superior tear-resistant properties compared to Nafion 112 membranes. Even the hydrated transverse direction for the Gore-Select membrane is more tear resistant than the dry transverse direction for Nafion 112 membranes (Figure 27.38).

As can be seen in Figure 27.39, the voltage loss at 800 mA cm<sup>-2</sup> of the PRIMEA 56 MEA is in the range of 5 μV h<sup>-1</sup>. The development goal is <1 μV h<sup>-1</sup> to achieve the 40,000 h requirement for stationary applications. In 2003, Gore reported technology status for automotive applications in comparison to their goals (Table 27.10). Surprisingly, a relative humidity below <50% is indicated as already having been achieved in state-of-the-art MEAs with high power density requirements. Gore has reported intensive activity regarding accelerated life test procedures [86,87].

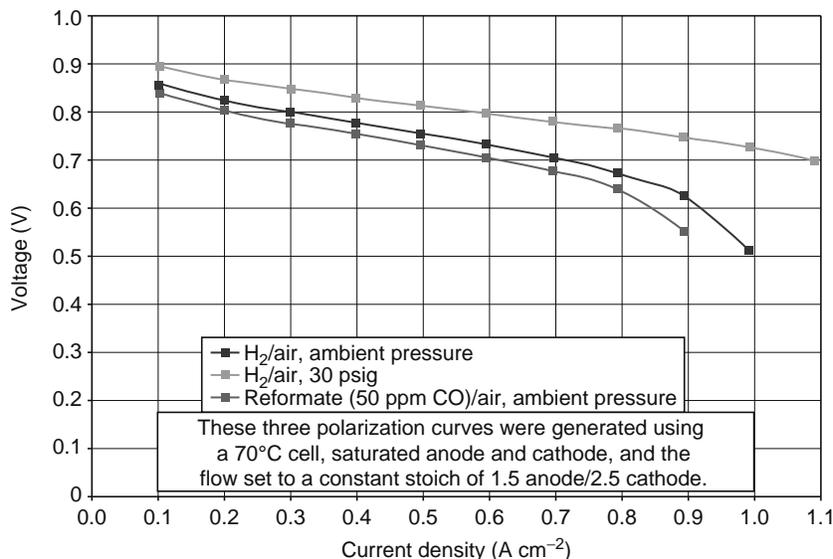

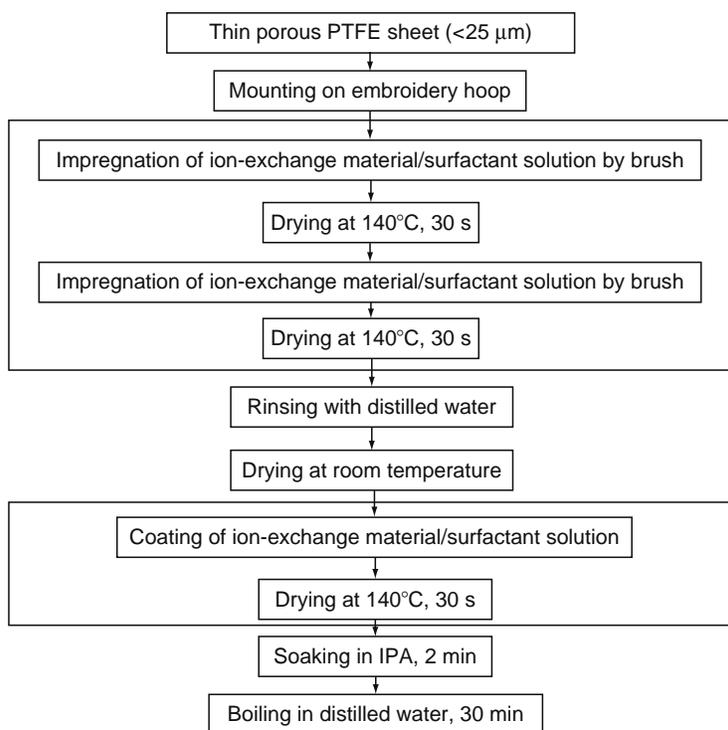

FIGURE 27.36 (See color insert following page 588.) Typical performance data for 3M seven-layer MEAs. (From 3M, www.3m.com.)

**FIGURE 27.37** Fabrication scheme of Gore-Select described in U.S. Patent 5,547,551. (Reproduced from Nakao, M. and Yoshitake, M., in W. Vielstich, H.A. Gasteiger, and A. Lamm (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, Vol. 3, J. Wiley & Sons, Chichester, 2003. With permission.)

Figure 27.40 shows the efforts to reduce noble metal content in MEAs under conditions, suitable for transportation applications. Although a significant reduction in Pt has been achieved in the series 57 MEA, further reduction in platinum is required. Gore's low-loading development still shows good performance, but it is markedly lower compared to the 57 series.

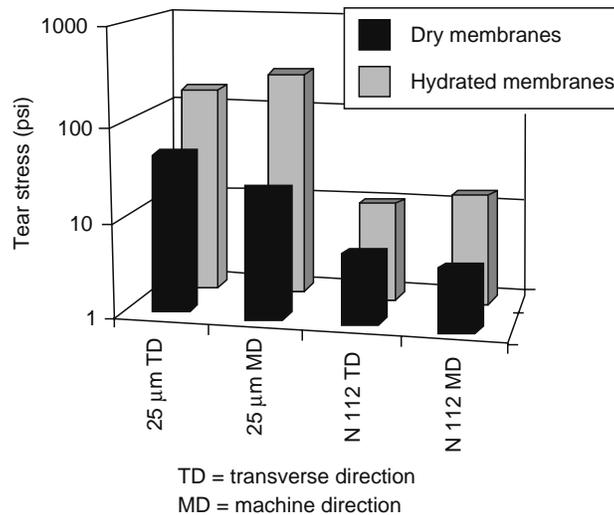

#### 27.4.2.2 PFSA Ionomer with PTFE Fibril Reinforcement; Asahi Glass; Flemion

Asahi Glass Co., Ltd. (AGC) manufactures Flemion, which is based on a PTFE fibril reinforcement which was originally developed for chlor-alkali electrolysis. AGC has participated in the NEDO's PEMFC R&D programs and has developed ion-exchange membrane technologies for PEMFCs since 1992. In the first phase of the NEDO's program, various chemical/physical properties of Flemion membranes were investigated. In the second phase, fundamental properties required for practical use of PEMFCs were evaluated for Flemion membranes that have various thicknesses and ion-exchange capacities, and AGC successfully developed a new technology for membrane reinforcement. In the third phase of program, AGC has been developing some basic technologies for high power density-type MEAs and for high-temperature-type MEAs.

*Reinforcement of Membranes:* AGC's fabrication method consists of dispersing a small amount of PTFE fibers in a polymer matrix consisting of a perfluorosulfonic resin with high-ion-exchange capacity (IEC) (EW 909). In addition (according to Asahi Glass), a novel stretching method is used which leads to an evenly enlarged film with less than  $50 \mu\text{m}$ . The structure of the fibril-reinforcement is shown in Figure 27.41. Nearly 2%–5% of the PTFE microfiber weight is dispersed in the perfluorosulfonic resin. Various mechanical properties are controlled by optimizing the fibril content, length and radii of PTFE fibrils, and other parameters. The trade name for Asahi Glass membranes is Flemion. The Flemion FR30 is  $30 \mu\text{m}$  thick and the SH50 is  $50 \mu\text{m}$  thick [88].

**TABLE 27.9**  
**Properties of W.L. Gore Membrane Development**

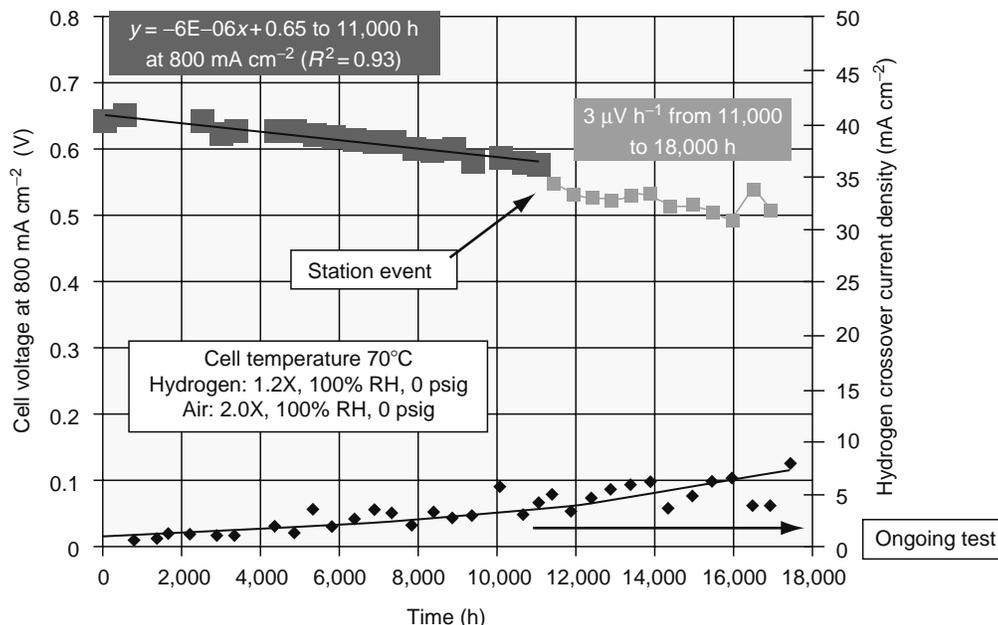

Stationary Applications, 56x	Transportation Applications, 57	Portable Applications, 58
Highest durability	Highest power density	Highest power density for dry gas operation
Lowest cost per kilowatt hour	Lowest cost per kilowatt system	Lowest cost per kilowatt system
Commercially available	Highest operational flexibility	Simplified system design

**FIGURE 27.38** Comparison of tear strength for hydrated and dry Gore-Select membranes (25 μm) and Nafion 112 membranes in MD and TD. (Reproduced from Cleghorn, S., Kolde, J., and Liu, W., in W. Vielstich, H.A. Gasteiger, and A. Lamm (Eds.), *Handbook of Fuel Cells: Fundamentals, Technology and Applications*, Vol. 3, J. Wiley & Sons, Chichester, 2003. With permission.)

The key parameter in the preparation of a thin and flat membrane with fibril reinforcement is the uniform dispersion of the fibrils in the matrix. Furthermore, the overall flatness of the membrane is important for coating the electrodes. Asahi Glass's new preparation method is disclosed in European Patent EP1,139,472 [89,90]. A precursor polymer and PTFE powder are kneaded, pelletized, and subsequently extruded to make a thicker base film. This base film is stretched (using a supporting film) to form a thin cationic film. This film then undergoes alkali and acid treatment. The process is schematically illustrated in Figure 27.42. Table 27.11 lists the properties of reinforced and nonreinforced Flemion membranes. The reported durability of the Flemion membranes is also relatively good (Figure 27.43).

Asahi Glass's developments concerning high power density-type MEAs are represented in Figure 27.44, which shows the structure of an MEA at the cathode side, whereby the cathode is fabricated from catalysts and ionomers. Asahi Glass is trying to accommodate all the electrode requirements with improved ionomers and hydrophobic components in the electrode structure.

They are developing high-performance MEAs using candidate materials for improving power density such as high IEC ionomers, new ionomers with high oxygen solubility, and soluble fluoropolymers (Cytop) [91].

Asahi Glass is developing an undisclosed new polymeric ionomer with a superior oxygen solubility and permeability especially for electrodes [91]. Table 27.12 gives the values reported by Asahi Glass. A somewhat better performance is achieved with the new polymer in the electrode (Figure 27.45).

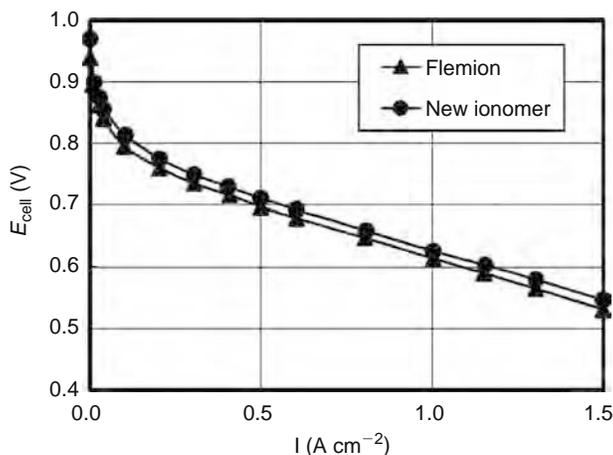

**FIGURE 27.44** (See color insert following page 588.) Pictorial depiction of the development activities of Asahi Glass. (From Yamada, K. et al. *Abstracts of the 2003 Fuel Cell Seminar*. 2003.)

**FIGURE 27.45** Effect of ionomer in the cathode on cell performance. Cell temperature: 80°C. (From Yamada, K. et al. *Abstracts of the 2003 Fuel Cell Seminar*, 2003.)

Hydrogen and oxygen permeabilities of Flemion membranes have been reported in two publications, one from 1998 concerning nonreinforced membranes with different thicknesses and a more recent publication concerning the comparison of nonreinforced and reinforced 50  $\mu\text{m}$  thick membranes [88,92]. The trade names, IECs, and further remarks on the membranes investigated are summarized in Table 27.13. The hydrogen and oxygen permeabilities of these membranes are given in Figure 27.46.

In the development of high-temperature membranes, Asahi is experimenting with different polymer backbones leaving the side chain unchanged. It was found that the softening temperature of the new membrane is 40°C higher than that of conventional Flemion. However, mechanical properties are reported to be insufficient and no performance data with

**TABLE 27.13**  
**IEC and Thickness of Membranes as Reported by Asahi Glass**

	Membrane IEC (mequiv g <sup>-1</sup> )	PTFE-Fibril Content (%)	Thickness (mm)	Remarks

the new membrane have been reported so far. Figure 27.47 shows the  $I-U$  curves of the MEAs using FlemionRf2 and FlemionR, both having the same membrane thickness. The cell performances are nearly equal to those using a nonreinforced membrane.

### 27.4.2.3 PFSA Ionomer and PTFE Reinforcement at Asahi Kasei; Aciplex Membranes

Asahi Kasei develops membranes mainly for chlor-alkali electrolysis technology with Aciplex F PFSA membranes. The Aciplex F membrane is employed in plants with a total production capacity of over 5 million tons of sodium hydroxide

**FIGURE 27.46** (See color insert following page 588.) Oxygen and hydrogen permeabilities of Flemion membranes in comparison with Nafion membranes. (From Pasaogullari, U. and Wang, C.Y., *Electrochim. Acta* 49, 4359, 2004; Stonehart, P., *Berichte der Bunsengesellschaft für Physikalische Chemie* 94, 913, 1990.)

**FIGURE 27.47** Cell performance of an MEA using FlemionRf2 and FlemionR in a single cell (gas: H<sub>2</sub>/air, pressure: 0.15/0.15 MPa, electrode area: 25 cm<sup>2</sup>, cell temperature: 80°C, Pt loading: 0.4/0.4 mg cm<sup>-2</sup>). (Reprinted from S Hommura, S. et al. *J. Fluorine Chem.*, 120, 151, 2003. With permission from Elsevier.)

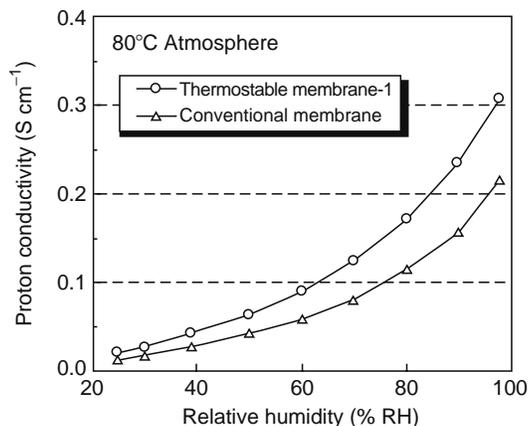

per year. Since 1996, Asahi Kasei has been developing Aciplex membranes for PEMFCs under a grant from NEDO in view of the rising expectations for the adoption of PEMFCs as an alternative energy source in both transportation and stationary applications and with the specific purpose of identifying the membrane properties required for durable fuel cell stacks. Asahi Kasei is also focusing its activities on reinforced membranes. Reinforced membranes namely Aciplex-S-AH and Aciplex-S-H-EH of 100, 150, and 200 μm thickness have been reported which use reinforcing webs of 150 and 200 denier PTFE, respectively. These membranes have been modified for the conditions of their hydration to increase their water content in comparison to conventional nonreinforced membranes. The dimensional stability of the reinforced membranes, in terms of dimensional change between their wet and dry states, was considerably improved. Shrinkage in drying is reportedly <10% for each of the reinforced membranes, and 14.9%–18.8% for the nonreinforced membranes. As with the previous reinforced membranes, the tensile strength of the reinforced membranes is about twice that of nonreinforced Aciplex-S membranes. The reinforced membranes also show considerably less creep under stress than the other membranes [93].

A new effort by Asahi Kasei involves the development of thermostable membranes for high-temperature cell operation (Table 27.14), based on perfluorocarbon material to satisfy both high performance and high durability by focusing on the design of the polymer structure (Figure 27.48). They are probably modifying the polymer backbone to improve thermal stability. They have achieved a 20°C–30°C higher glass transition temperature  $T_g$  for this new polymer material compared to that of conventional membranes [93]. The performance of the new thermostable membrane as compared to that of Aciplex S1002 (Figure 27.49), is significantly improved [93].

**TABLE 27.14**  
**Overview of Membranes Reported by Asahi Kasei**

Membrane Type	Membrane Equivalent Weight (EW) (g equiv <sup>-1</sup> )	Thickness (mm)	Remarks
Thermostable membrane-1	710	25, 50	New polymer material
Thermostable membrane-2	970	25	New polymer material
Aciplex SF-1001, Aciplex SF-1002	950	25, 50	Highly durable membrane
Aciplex SF-1003	1020	25	Highly durable membrane
Aciplex S1001X	950	25	Conventional membrane, new polymerization, and film formation process

**FIGURE 27.48** Proton conductivity of Asahi Kasei membranes at 80°C. (From Wakizoe, M., Kodani, T., and Ota, T., *Abstracts of the 2003 Fuel Cell Seminar*, 2003.)

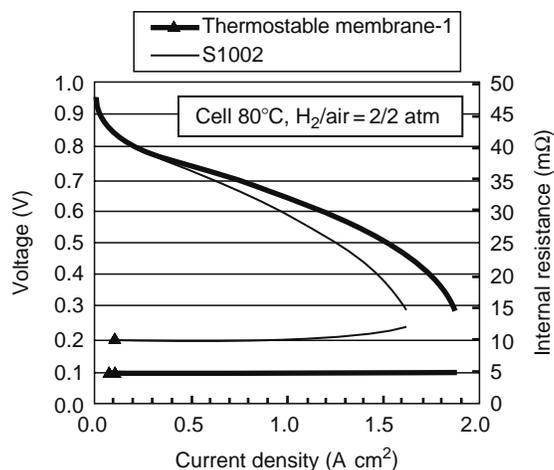

An independent study by the Dalian Fuel Cell R&D Center, Dalian Institute of Chemical Physics, China, investigated several perfluorinated membranes, namely Nafion, Flemion, Shanghai (Shanghai Institute of Organic Chemistry), and Aciplex membranes [94]. The performance of Aciplex 1002, 1004, 1104 is presented in Figure 27.50. The conditions for the comparison are as follows: The electrodes were prepared according to a Dalian procedure (20 wt% carbon-supported-platinum [Pt/C] catalyst, carbon paper, PTFE suspension [Teflon T-30, DuPont]), and a Nafion solution (Aldrich, 5 wt% in 15%–20% water/low aliphatic alcohol, 1100 equiv wt) was used for electrode preparation. The catalyst layer (Pt loading of  $0.4 \text{ mg cm}^{-2}$ ) of the electrodes was impregnated with Nafion solution with Nafion loading  $1 \text{ mg cm}^{-2}$ . Two electrodes with an active area of  $5 \text{ cm}^2$  were hot-pressed to one piece of membrane at 135°C to form the MEA, which was then tested in a single cell. Pure hydrogen (99.9%) and pure oxygen (99%) were used for fuel and oxidant with gas pressures 0.30 and 0.50 MPa, respectively. The fuel cells were operated at 80°C.

This chapter also presents a comparison between Nafion 112 and Aciplex 1002 membranes, showing almost indistinguishable performance in the lower current density region (Figure 27.51). At higher current density, the superior behavior of Aciplex was attributed to the lower EW of the Aciplex membranes [94].

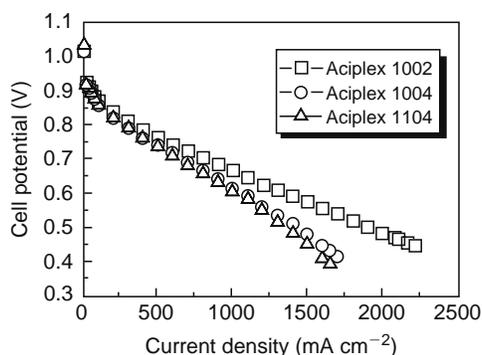

### 27.4.3 PARTIALLY FLUORINATED IONOMERS

#### 27.4.3.1 FuMA-TECH Membranes

FuMA-Tech is an established manufacturer of ion-exchange membranes and belongs to the (Best Water Technology) BWT Group based in Austria. With 65 group companies and some 2700 employees, the BWT Group is the leading water

**FIGURE 27.49**  $V$ - $I$  curve of Aciplex membranes. Cell performance was evaluated with a single cell of  $10 \text{ cm}^2$  electrode area. The Pt loadings of anode and cathode were about  $0.1$  and  $0.2 \text{ mg cm}^{-2}$ , respectively. *Source:* Asahi Kasei. (From Wakizoe, M., Kodani, T., and Ota, T., *Abstracts of the 2003 Fuel Cell Seminar*, 2003.)

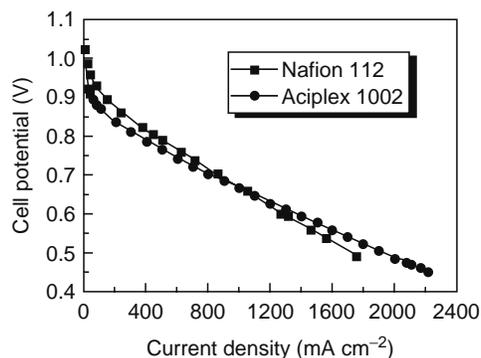

**FIGURE 27.50** Performances of PEM fuel cells with Aciplex according to Du et al. (Reproduced from Du, X.Z., Yu, J.R., Yi, B.L., Han, M., and Bi, K.W., *Phys. Chem. Chem. Phys.*, 3, 3175, 2001. With permission from the PCCP Owner Societies.)

technology company in Europe. FuMA-Tech GmbH develops membranes for PEMFC. FuMA-Tech is the only supplier to offer both fluorinated and nonfluorinated membranes for PEMFCs and DMFCs with application temperatures of up to 130°C. Catalyzed membranes for fuel cells and water electrolysis are manufactured as well. FuMA-Tech offers two membrane families for fuel cell applications. For standard applications in hydrogen/air or oxygen environment, the partially fluorinated (highly conductive and chemically stable) FKH series ranging from 950 to 1500 equiv wt is offered. The membranes are available in two thicknesses and two configurations (not specified). It is stated that membrane electrode processing by way of a standard hot-pressing protocol is possible and that reliable and reproducible results have been obtained. A second class of partially fluorinated membranes consists of glass fiber reinforced FKH/60GF, which was developed to avoid wrinkling and uncontrolled membrane swelling caused by the solvents in most catalyst ink or paste formulations. Besides this feature, the membrane is reported to be insusceptible to mechanical stress. The FKE membranes using polyketone-type sulfonic acids are a completely different type of membrane, being nonfluorinated and intended for medium-temperature applications above 100°C and DMFCs (Table 27.15). According to FuMa-Tech these membranes are offered in standard sheets measuring 30 cm by 30–200 cm. Other dimensions and rollware have to be requested. Curves reported by FuMA-Tech are presented in Figure 27.52.

#### 27.4.3.2 Poly( $\alpha,\beta,\beta$ -Trifluorostyrene) and Copolymers; Ballard Advanced Materials

Ballard Advanced Materials (BAM) ionomers are sulfonated copolymers of trifluorostyrene and substituted trifluorostyrene monomers. BAM, a subsidiary of Ballard Power Systems, investigated the conducting polymers based on polyphenylquinoxaline (PPQ). These can be sulfonated in a wide range and were referred to as BAM1G (Ballard first generation) membranes, but these membranes were found to have short durability. To overcome this problem, BAM developed a second generation of advanced membranes based on two distinct material types. The first material type consisted of a series of sulfonated poly(2,6-diphenyl 1,4-phenylene oxide). The second material type consisted of a series of sulfonated poly(arylether sulfone). But the durability of these membranes was also insufficient. Since the durability of previous membranes was limited, Ballard produced a novel family of sulfonated membranes based on  $\alpha,\beta,\beta$ -trifluorostyrene monomers and a series of substituted trifluoro-comonomers

[95,96]. This family of membranes was named BAM 3G (Figure 27.53). Condensation polymerization techniques were used that did not involve fluoridation technologies. These polymers have low equivalent weights ranging from 375 to 920. Because of this low equivalent weight, these membranes exhibited high water uptake as well as long durability.

Furthermore, in 2001, Ballard entered an alliance with Victrex to produce two new membrane alternatives. One membrane is based on sulfonated poly(arylether) ketone (a variant of PEEK) supplied by Victrex, which may be better suited to PEMFC fabrication applications. In March 2002, U.S. Patent 6,359,019 was issued to Ballard Power for a graft-polymeric membrane in which one or more trifluorovinylaromatic monomers are radiation graft polymerized to a preformed polymeric base. The structures of BAM membranes have been studied by way of small-angle neutron scattering (SANS) [97]. The study of the ionomer peak position suggests the existence of relatively small ionic domains compared to Nafion, despite large water content. Phase separation in the polymer matrix is possibly crucial for the membrane's mechanical and transport properties.

Within the realm of BAM2G membranes, a series of partially fluorinated bisphenol A-type poly(arylether) sulfones were synthesized. As mentioned above, these materials initially exhibited acceptable, useful service-life performance, but were unable to provide more than 500 h of continuous running time. This led to the decision that a perfluorinated backbone would be most beneficial in achieving fuel cell longevity in performance and efficiency. Therefore, the  $\alpha,\beta,\beta$ -trifluorostyrene monomer was chosen as the most suitable platform on which to build BAM3G polymers [98]. The BAM3G has demonstrated over 100,000 h of cumulative performance in a wide variety of Ballard fuel cell hardware. The BAM3G membranes have

**FIGURE 27.52** Performance curves for FT-PKH950/40 and Ft-PKH/757/45. (From FuMa-Tech, www.fumatech.com.)

**FIGURE 27.53** Chemical structures monomers of BAM membranes. (From Zhang, L., Ma, C.S., and Mukerjee, S., *Electrochim. Acta*, 48, 1845, 2003; Basura, V.I., Chuy, C., Beattie, P.D., and Holdcroft, S., *J. Electroanal. Chem.*, 501, 77, 2001.)

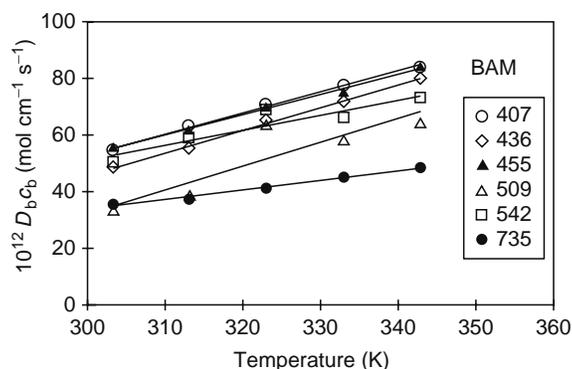

successfully achieved longevity in various Ballard multistack configurations. BAM reported that a multicell stack has exceeded 3200 h of continuous performance in an ongoing evaluation. Ballard stated that with higher volume production, the BAM3G membranes would meet cost target requirements for automotive PEMFC applications. Ballard Power Systems is developing manufacturing methods for its BAM-grafted proton-exchange membranes for fuel cells. BAM membranes use a commercially available base substrate, to which trifluorovinyl aromatic monomers derivatized via radiation graft polymerization, are added, which are then modified to incorporate ion-exchange groups.

Several publications have investigated mass-transport properties for oxygen in BAM membranes [32,33,99]. These studies have mainly been carried out by the Holdcroft group (Vancouver, British Columbia, Canada) and have determined the permeability, solubility, and diffusion coefficients in BAM membranes by electrochemical chronoamperometric detection with microelectrodes. As an example of the extensive measurements carried out, the dependence of permeability on temperature for different BAM membranes with various equivalent weights is shown in Figure 27.54 [33]. As can be seen and is expected, lower EW membranes exhibit higher permeabilities. Therefore, it is possible to design the ionomer for the electrode to have advantageous permeation properties.

Not many publications report performance data with BAM's membranes. The only publication we are aware of is by Stone et al., which also discusses the possibility of introducing a phosphonic acid functionality [98]. Figure 27.55 shows the performance data from this source.

### 27.4.3.3 Radiation-Grafted Membranes

Partially fluorinated membranes prepared by radiation grafting are under active research, for example, in the groups at the Paul Scherrer Institute (Villigen, Switzerland) and the Helsinki University of Technology (Espoo, Finland) [95,100–113]. The preparation of the membranes involves a  $\gamma$ -irradiation or e-beam step to produce radical sites in perfluorinated polymer membranes, partially fluorinated polymer membranes, and nonfluorinated based membranes [114]. Typically, the membranes are swollen with suitable solutions of polymer network forming compounds (e.g., styrene/divinylbenzene). An interpenetrating polymer grafting network is formed at the radical sites normally by heating up the sample. These membranes are then sulfonated. The preparation process is depicted in Figure 27.56. The advantages of this preparation method are stated as enabling low-cost starting materials, simple chemical reactions, and the possibility to form a cross-linked material directly in its final form. PTFE, poly(tetrafluoroethylene-co-hexafluoropropylene) (FEP), poly(ethylene-tetrafluoroethylene) (ETFE),

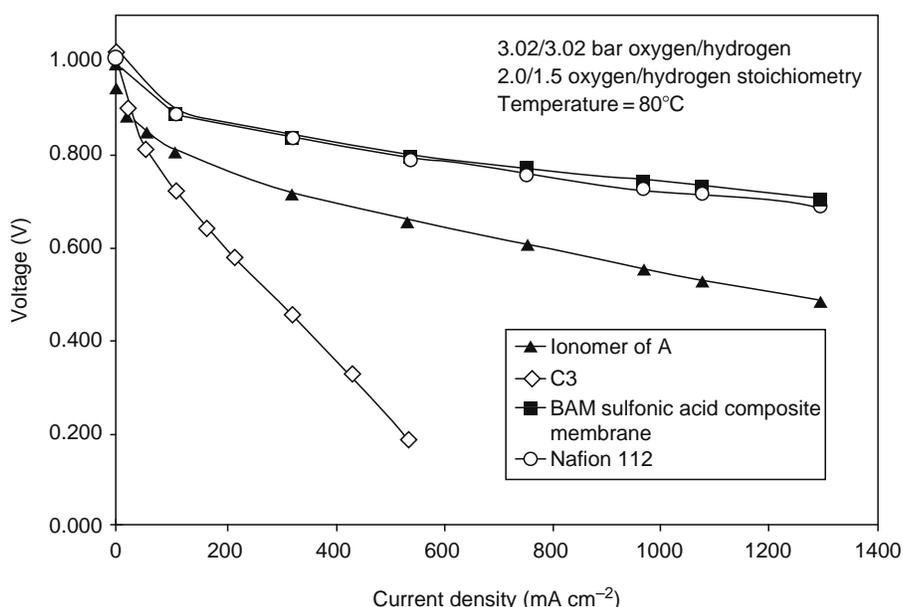

**FIGURE 27.54** The effect of temperature on the permeability  $D_{bc_b}$  for BAM membranes. Conditions: 100% RH and 3 atm oxygen. (Reprinted from Basura, V.I. et al., *J. Electroanal. Chem.*, 501, 77, 2001. With permission from Elsevier.)

poly(vinylidene fluoride) (PVDF), and poly(tetrafluoroethylene-*co*-perfluorovinylether) (PFA) have all been used as host materials for PSSA grafts. Less-investigated alternatives to PSSA include grafting glycidyl methacrylate and methyl styrene with subsequent sulfonation. The exact properties of the membranes may be determined by way of numerous reaction parameters like irradiation dose, thickness of the base polymer film, styrene/divinylbenzene composition, and graft level (determined by ratio of graft material to base material). From the published work it can be derived that there are two main obstacles to realizing technical radiation-grafted membranes. The interface between electrodes and membranes has often shown insufficient bonding and delamination has often been reported. Durability seems to be a critical issue with these membranes [95].

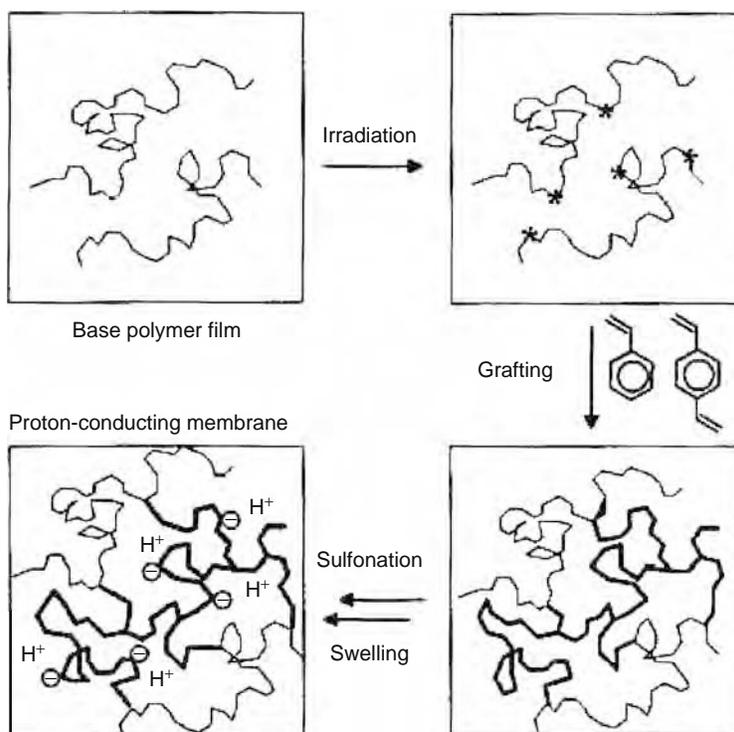

Decent performance curves in short-term operation have been reported for radiation-grafted membranes in DMFC (Figure 27.57). An advantage versus Nafion has been observed by Geiger et al. and Scott et al. (for higher current densities) but so far, all-reported DMFC measurements have been performed for short operating times [115,116].

A publication by the Paul Scherrer Institute reports progress in preparing membrane/electrode assemblies for polymer electrolyte fuel cells based on radiation-grafted FEP PSSA membranes [95]. Hot-pressing with Nafion was used to improve the interfaces. These improved MEAs showed performance data comparable to those of MEAs based on Nafion 112 (Figure 27.58) and an service-life in  $H_2/O_2$  fuel cells of more than 200 h at 60°C and 500 mA cm<sup>-2</sup>.

The long-term performance was found to be stable up to 2000 h (Figure 27.59)—an important improvement on the reported service-lives in the range of 500 h.

#### 27.4.4 INORGANIC/ORGANIC (FLUORINATED) COMPOSITE IONOMER MEMBRANES

##### 27.4.4.1 Hydrophilic Fillers ( $\text{SiO}_2$ , $\text{TiO}_2$ , $\text{ZrO}_2$ ) and Ormosil Networks

Over the last decade, extensive results have been reported regarding the improvement in the characteristics of known ionomeric membranes by dispersing inside their polymeric matrix, the acids with low solubility (e.g., heteropolyacids) or particles of insoluble solids such as metal oxides, lamellar zirconium phosphates, or phosphonates. A second strategy aims at developing membranes obtained by filling a non-proton-conducting polymeric matrix with ionomers or inorganic particles of high-proton conductivity. The degree of dispersion inside the membrane may vary considerably, leading to nano or microcomposites or even macrocomposites.

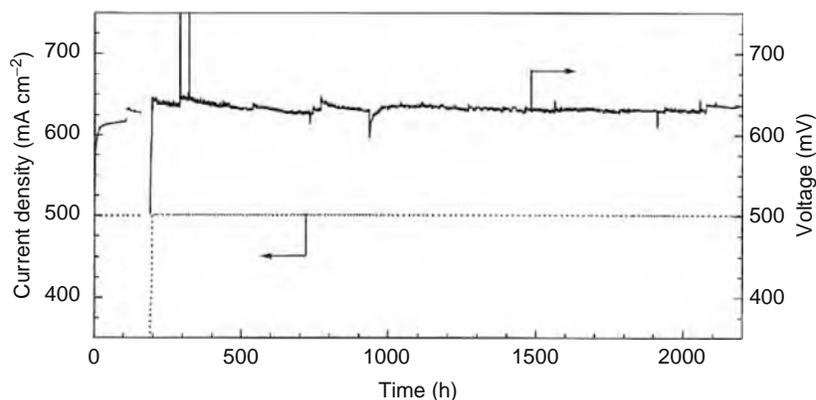

**FIGURE 27.57**  $V$ - $I$  curve of a cross-linked FEP 25 membrane for a 0.5 M aqueous methanol solution at a cell temperature of 110°C. The anodic flow rate was about 37 mL min<sup>-1</sup> and the air stoichiometry was 2. (Reproduced from Geiger, A.B., Rager, T., Matejek, L., Scherer, G.G., and Wokaun, A., in *Proceedings of the 1st European PEFC Forum*, Büchi, F.N., Scherer, G.G., and Wokaun A. (Eds.) 2001. With permission.)

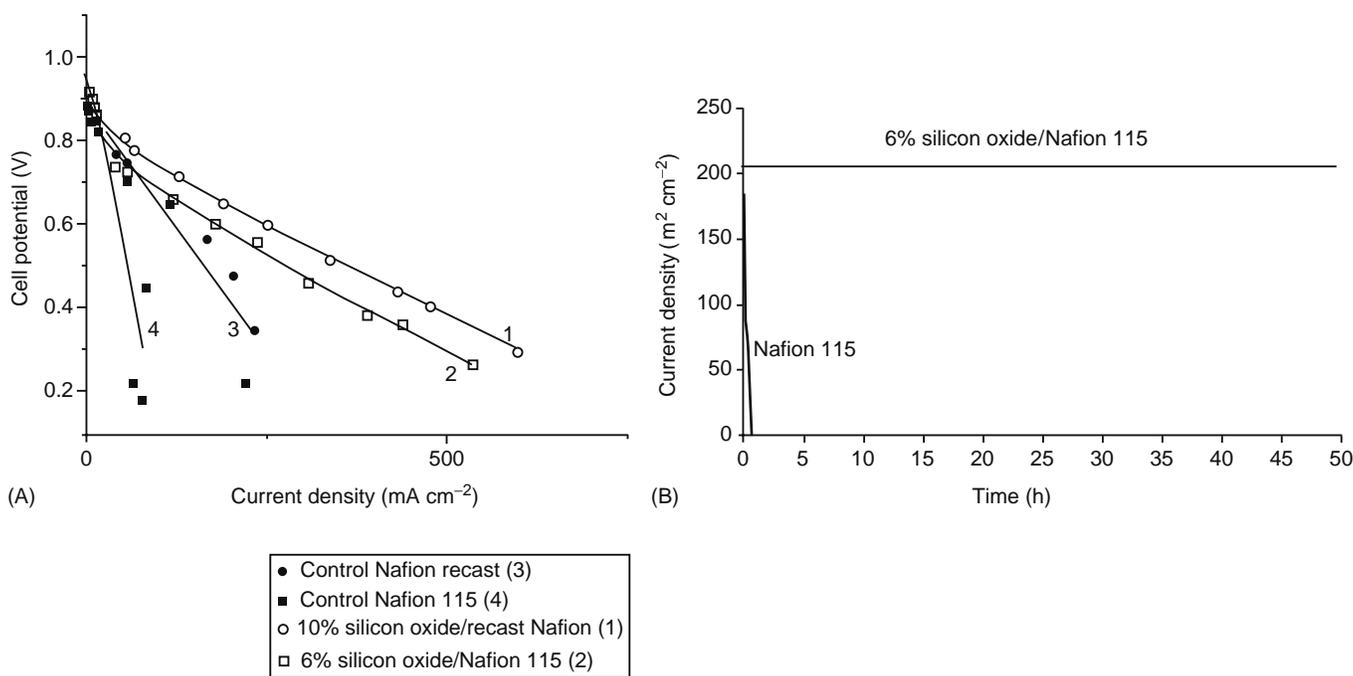

**FIGURE 27.58** Current/voltage and power density curves for MEAs based on Nafion 112 (+: without hot-pressing) and radiation-grafted membranes; influence of hot-pressing on the performance of membrane RG 1 (●, without hot-pressing; ◇, hot-pressed); influence of additional Nafion coating on the performance of membrane RG 2 (□, hot-pressed; ○, Nafion-coated and hot-pressed). (Reprinted from Huslage, J. et al., *Electrochim. Acta*, 48, 247, 2002. With permission from Elsevier.)

The oldest concept in this respect is Nafion-based membranes, which are prepared by recasting Nafion solution and introducing inorganic hydrophilic additives, quite frequently silica or titania particles. This concept was introduced by Stonehart and Watanabe and is protected and disclosed in U.S. Patent 5,523,181 [117]. Clearly, the silica and titania particles (e.g., nanoporous, highly hydrophilic  $\text{SiO}_2$  from Degussa, Aerosil) are completely nonconductive. However, the composite recast Nafion-based membranes containing hydrophilic  $\text{SiO}_2$  or  $\text{TiO}_2$  particles as well as other inorganic material are expected to increase the water retention and therefore to lead toward increased ionic conductivity at elevated temperatures. The interpretation of improved water retention is backed by the experimental result of a higher water uptake of the membranes. The second concept which is supposed to lead to better distribution of the particles in the membrane is based on producing the particles by hydrolysis in preformed membranes by introducing a precursor (e.g., tetraethoxylane [TEOS]) into the swollen membrane [118–122]. The hydrolysis is catalyzed by the sulfonic groups forming an inorganic network in the membranes. Such structures are named organically modified silicate (ORMOSIL). The Mauritz group has prepared different membranes using this route, namely Nafion with  $\text{SiO}_2/\text{OH}$ , Nafion with  $\text{ZrO}_2/\text{OH}$ , and Surlyn with  $\text{SiO}_2/\text{OH}$ . The disadvantage is that the inorganic content cannot be varied over a large range, but these membranes are nevertheless promising for application at temperatures over  $100^\circ\text{C}$ , and therefore also for DMFCs. However, structural changes in the membrane during preparation have also been observed. Differing results have been reported: whereas the Watanabe group found a significant improvement in

**FIGURE 27.59** Courses of voltage and current during long-term testing of the Nafion-coated and hot-pressed membrane RG 2. Constant current mode. (Reprinted from Huslage, J. et al. *Electrochim. Acta*, 48, 247, 2002. With permission from Elsevier.)

(B) Time performance test of Nafion 115 and Nafion 115/silicon oxide at a pressure of 3 atm H<sub>2</sub> and O<sub>2</sub> humidifier temperature 130°C; cell temperature 130°C. Potential 0.65 V. (Reproduced from Adjemian, K.T., Lee, S.J., Srinivasan, S., Benziger, J., and Bocarsly, A.B., *J. Electrochem. Soc.*, 149, A256, 2002. With permission from The Electrochemical Society, Inc.)

membrane performance without humidification of gases, the Savinell group found no improvement in proton conductivity (although the water content was higher) for nanomodified Nafion prepared following the procedure from Mauritz et al. [123]. Recently, Adjemian et al. reported significant improvement in silicon oxide-modified recast Nafion (Figure 27.60) as well as Nafion 115 [124,125].

Alberti et al. have pointed out that it is unlikely that the improved conductivity of composite ionomer membranes is just due to the improved water absorption and retention properties, because the content of the SiO<sub>2</sub> is in the range of 3–10 wt% [126]. The reported increased water uptakes in the range of 20 wt% if only absorbed in the inorganic particles would lead to a molar ratio nearly equal to 27. Since water is only absorbed on the surface of the nanoparticles, the hydration number of the silanol groups (H<sub>2</sub>O/SiO<sub>2</sub>) would be much higher than 27. This is unrealistic, as it would mean that the hydration of silanol groups is higher than that of the superacid (–SO<sub>3</sub>H) groups. However, as mentioned before, the structure of the membrane is changed upon metal oxide modification leading, for instance, to a large degree in crystallinity of the polymer backbone. Therefore, the increased water content of metal oxide-loaded Nafion is probably associated with structural changes in the polymer matrix induced by the presence of the inorganic nanoparticles.

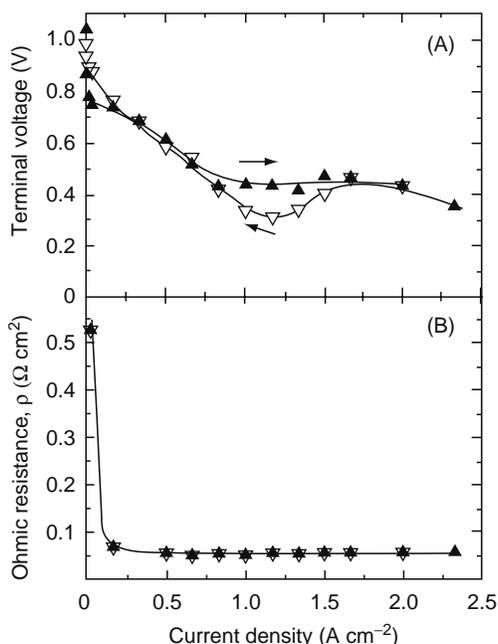

Several groups have reported increased performances for such membranes in DMFC applications due to a decrease in methanol permeation. A maximum power density of 240 mW cm<sup>-2</sup> at 0.4 V was obtained by Arico et al. and Antonucci et al. [127,128]. The reduced methanol permeation of such membranes is, however, controversial [129]. The Watanabe group proposed a further self-humidifying composite membrane with highly dispersed nanoparticles of Pt and TiO<sub>2</sub> (or other metal oxide particles) [130–133]. The idea is represented in Figure 27.61 and consists of generating water by permeating hydrogen and oxygen with the catalytic active Pt in the membrane and a water storage function of the hydrophilic particles in the membrane.

This concept enables the operation of PEMFCs without any humidification, which should also be interesting for higher temperatures. The corresponding *V–I* characteristics are displayed in Figure 27.62. The disadvantage to this concept, however, is that the cost of the membrane is significantly increased by adding noble metal particles. Composite membranes with nonfluorinated polymer matrices have also been investigated. For instance, high-surface amorphous silica, precipitated from a solution of tetrapropylammonium oligosilicate, was used as a filler of s-PEEK with 1.6 mequiv g<sup>-1</sup> IEC [134]. In this work, microcomposite membranes containing up to 20 wt% silica were prepared by bulk mixing the finely prepared powder with the polymer solution. The membrane containing 10 wt% silica exhibited the best electrical (conductivity rises to 3 × 10<sup>-2</sup> S cm<sup>-1</sup> at 100°C for relative humidity in the range of 75%–100%) and mechanical characteristics.

**FIGURE 27.61** Operation concept of a PEMFC using self-humidifying Pt-oxide-PEM. (Reproduced from Uchida, H., Ueno, Y., Hagihara, H., and Watanabe, M., *J. Electrochem. Soc.*, 150, A57, 2003. With permission from The Electrochemical Society, Inc.)

According to a similar synthetic approach reported by Nunes et al., nanocomposite membranes loaded with  $\text{SiO}_2$ ,  $\text{TiO}_2$ , and  $\text{ZrO}_2$  were prepared by way of hydrolysis of silanes and metal alkoxides in solutions of s-PEEK and s-PEK [135]. While homogeneous dispersions of  $\text{TiO}_2$  and  $\text{ZrO}_2$  particles were obtained starting from  $\text{Ti}(\text{OEt})_4$  and  $\text{Zr}(\text{OPr})_4$ , the hydrolysis of  $\text{Si}(\text{OEt})_4$  led to the formation of larger particles and cavities in the polymeric matrix. However, smaller and better-dispersed silica particles (about 100 nm) were formed by using either silanes covalently bonded to the polymer chain or organically modified silanes-bearing imidazole groups. A loading of 14–33 wt% metal oxide resulted in a decrease in the membrane permeability to water and methanol by a factor of 30–60, but also resulted in reduced proton conductivity at 25°C. A good balance of low permeability and high conductivity ( $3.5\text{--}4.5 \times 10^{-3} \text{ S cm}^{-1}$  against  $5 \times 10^{-3} \text{ S cm}^{-1}$  for the unmodified polymer) was achieved by incorporating a mixture of 10–15 wt%  $\text{ZrO}_2$  and 20–14 wt% amorphous ZrP in s-PEEK.

**FIGURE 27.62** (A)  $V$ - $I$  curve and (B) ohmic resistance of a PEMFC using Pt- $\text{TiO}_2$ -PEM operated at 80°C and ambient pressure with no external humidification at the reactant utilization of  $\text{H}_2$  56% and  $\text{O}_2$  54%. An open-circuit voltage (OCV) was measured at a flow rate of  $7 \text{ mL min}^{-1}$  for both dry  $\text{H}_2$  and dry  $\text{O}_2$ . The amount of Pt dispersed in the PEM =  $0.1 \text{ mg cm}^{-2}$ , the amount of  $\text{TiO}_2$  =  $0.42 \text{ mg cm}^{-2}$  (4 wt%). Full symbols measured on increasing current density and open symbols measured on decreasing current density. (Reproduced from Uchida, H., Ueno, Y., Hagihara, H., and Watanabe, M., *J. Electrochem. Soc.*, 150, A57, 2003. With permission from The Electrochemical Society, Inc.)

### 27.4.4.2 Properties of Recast Membranes with Inorganic Fillers

Preparation of membranes using the recast method with inorganic hydrophilic ingredients has proved to be a promising approach to manipulate the membrane properties with respect to liquid permeation (water and methanol), ionic conductivity, and water uptake. This approach was introduced by Stonehart and Watanabe to improve the water management of Nafion membranes in PEMFCs [136]. Several investigations by Antonucci et al. [137] have also reported an advantage to such composite membranes for DMFC applications due to a decrease in methanol permeation induced by a structural change in the polymer associated with a higher crystallinity. Dimitrova et al. [138,139] reported a detailed characterization of a recast ionomer composite membrane with 4.3% Aerosil A380 (silicon dioxide).

#### 27.4.4.2.1 Water Uptake of Composite Membranes

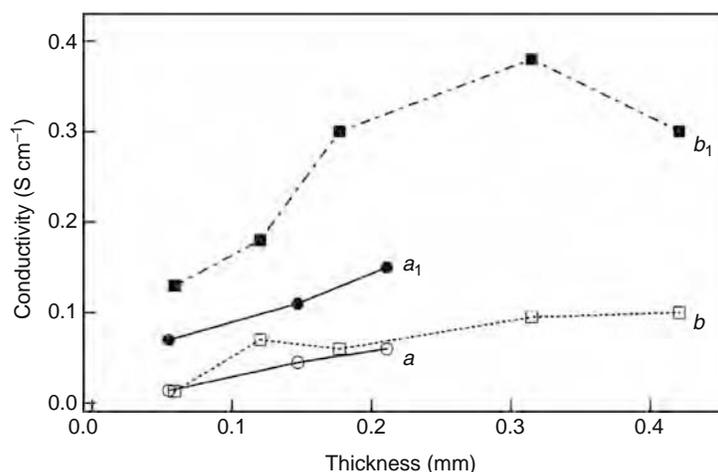

Recast Nafion-based samples with and without fillers absorb more water compared to the commercial Nafion 117, 115, and 112 membranes. It is observed that the water content rises slightly with the thickness of the membranes investigated. Nafion 112 indicates unexpectedly low water content in the swollen state. It is noted that even after many repetitive drying-rehydration treatments, the composite membranes contain more water than the commercial membranes. This finding might be explained by the hydrophilicity of the filler, by the altered physical structure of the ionomer backbone, or possibly by the stronger interactions between the absorbed water and the modified matrix. In particular, the silica nanoparticles retain water even at high temperatures and this property may help to prevent the membrane drying during fuel cell operation. Easier water management during fuel cell operation can be anticipated for the composite membranes.

#### 27.4.4.2.2 Proton Conductivity

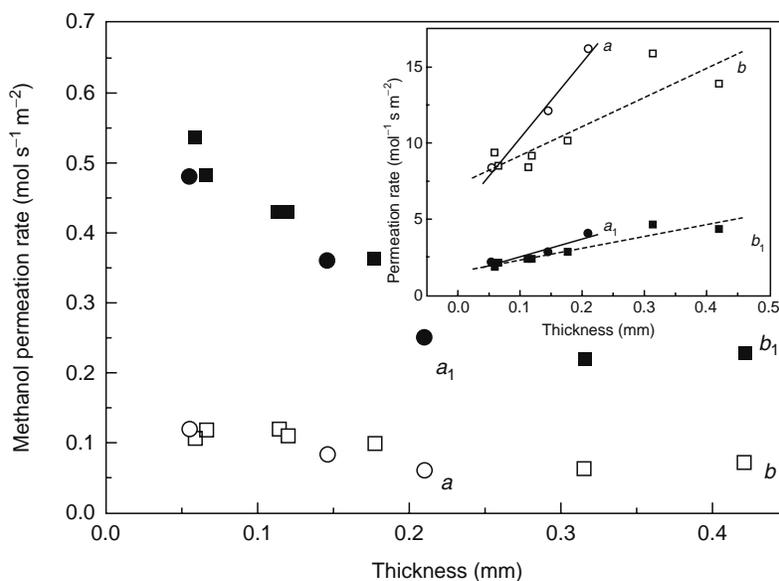

Figure 27.63 shows the conductivity as a function of thickness of the commercial membranes and the modified recast Nafion membranes for temperatures of 15°C and 90°C. A proton conductivity for composite recast membranes higher than or comparable to commercial membranes is measured at 15°C. At 90°C, this difference becomes significant. These results manifest that the hydrophilic particles assist in humidifying the membrane, leading to higher proton conductivity. It should be noted that the conductivity is not constant with thickness, but increases in most samples. The increase in conductivity with thickness, which should not occur for homogeneous material, suggests that the properties of the membrane change with the thickness.

#### 27.4.4.2.3 Methanol Permeation Rate

The methanol permeation measurement illustrates the relationship between the methanol permeation rate and the temperature versus the thickness of the membrane. For thinner samples, the permeation rate changes by a factor of 4 or 5 with a temperature change from 25°C to 65°C, while in the thicker membranes this factor is about 3. At lower temperatures, the variation of the methanol flux through the membranes versus thickness is small compared to that at 65°C, where this dependence is pronounced. As anticipated, a strong decrease in permeation with thickness is observed in all cases. For the reciprocal quantity, a linear relationship between permeation rate and thickness can be derived approximately as shown in the inset of Figure 27.64. The comparison between the composite membranes and the commercial Nafion (Nafion 112, 115, and 117) reveals a similar methanol permeation rate at elevated temperature with slightly higher values of the composites.

**FIGURE 27.63** Conductivity of the membranes as a function of thickness and at different temperatures: (a, a<sub>1</sub>, ○, ●) commercial samples N 112, N 115, and N 117 (b, b<sub>1</sub>, □, ■) composite membranes. Temperature at 15°C, plots a and b (open symbols) and at 90°C, plots a<sub>1</sub> and b<sub>1</sub> (close symbols). Lines are for guidance.

**FIGURE 27.64** Methanol permeation rate of the membranes as a function of thickness and at different temperatures: (*a*, *a*<sub>1</sub>, ○, ●) commercial samples N 112, N 115, and N 117 (*b*, *b*<sub>1</sub>, □, ■) composite membranes. Temperature at 25°C, plots *a* and *b* (open symbols) and at 65°C, plots *a*<sub>1</sub> and *b*<sub>1</sub> (close symbols).

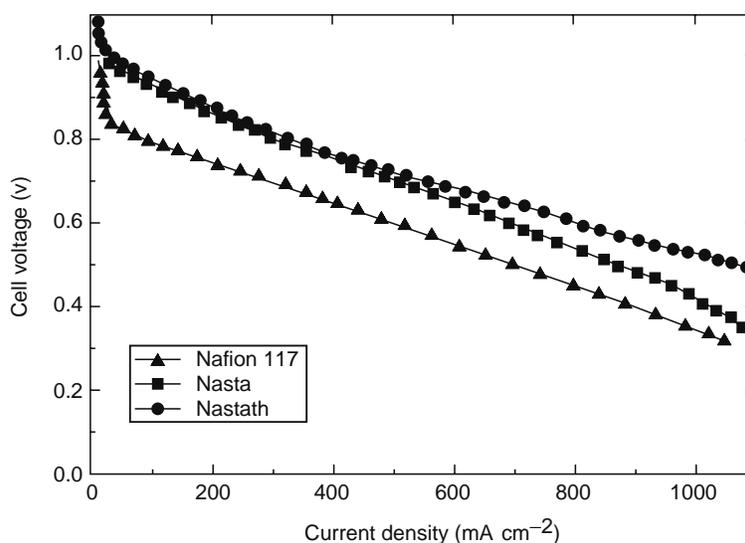

#### 27.4.4.2.4 Water Permeation

It is favorable for fuel cell operation when reduced methanol transport across the membrane is accompanied by proper water management. In particular, a low water crossover from the anode to the cathode is necessary to avoid flooding of the cathode. The dependence of water permeation on the membrane thickness is weak. Only a small decrease in water permeation is observed for the commercial Nafion membranes, whereas the thickness of the recast membranes has no significant influence on the water transport rate. In contrast, the effect of temperature on water permeation is strong. At 65°C, the rates are higher by a factor of 5 compared to those at 25°C.

#### 27.4.4.3 Heteropolyacid Additive

Heteropolyacids possess a relatively high inherent proton conductivity, which increases the overall ionic conductivity of the membrane. Owing to these characteristics, heteropolyacids are suitable membrane fillers for increasing the number of protonic carriers and thus improving the hydrophilic character of the membranes. The major problem with modified membranes is the hydrosolubility of heteropolyacids. Composite Nafion membranes containing heteropolyacids were obtained by simply impregnating preformed membranes with a heteropolyacid solution and mixing a Nafion solution with an appropriate amount of heteropolyacid followed by casting [140,141]. Nafion recast membranes loaded with silicotungstic acid (STA), phosphotungstic acid (PTA), and phosphomolybdic acid (PMA) were investigated regarding ionic conductivity, water uptake, tensile strength, and thermal behavior [140]. In comparison with Nafion 117, all these membranes exhibited higher proton conductivity and greater water uptake, but exhibited a decreased tensile strength. Water uptake, determined by dipping dried membranes in boiling water, increases from 27% for Nafion 117 to a maximum of 95% for the PMA-based membrane. At 80°C, the heteropolyacid-loaded membranes show a better fuel cell performance than unmodified Nafion 117. The current density at 0.600 V increases from 640 mA cm<sup>-2</sup> for Nafion 117 up to a maximum of 940 mA cm<sup>-2</sup> for PMA-Nafion 117. Composite PTA-Nafion 117 membranes, impregnated with PTA solutions in acetic acid or in molten tetra-*n*-butylammonium chloride, were tested in H<sub>2</sub>/O<sub>2</sub> fuel cells working at 1 atm up to 110°C [141]. In comparison with unmodified Nafion 117 (Figure 27.65), these membranes showed a much improved performance that increased with increasing temperature.

Composite membranes with nonfluorinated polymers and heteropolyacid were also prepared. A series of nanocomposite membranes made of s-PEEK and 60 wt% PTA or PMA were prepared by Homna et al. by mixing the heteropolyacid with a polymer solution in dimethylacetamide [142]. In comparison with the pure sulfonated polymers, the composite membranes are characterized by a higher glass transition temperature, probably because of the intermolecular interaction between the sulfonic groups and the heteropolyacids, and by much greater hydration at room temperature (up to five times for PTA-loaded s-PEEK with 80% degree of sulfonation). Conductivity was determined in the range of 20°C–150°C by using an open cell with concomitant water loss (therefore, lower limit of the membrane conductivity). The composite membranes are generally more conductive than the pure polymer, but the conductivity enhancement decreases with an increasing degree of sulfonation. In

**FIGURE 27.65** Potential–current polarization curves of  $\text{H}_2/\text{O}_2$  fuel cells using Nafion 117 (thickness: 180  $\mu\text{m}$  and 30% water uptake) and STA with and without thiophene (termed NASTATH and NASTA, respectively) (thickness about 175  $\mu\text{m}$  and 60% water uptake). Anode and cathode based on 0.35  $\text{mg cm}^{-2}$  Pt from 20% Pt:C catalyst; pressure ratio  $\text{H}_2/\text{O}_2$  3:5 atm; gas flow rates  $\text{O}_2 = 0.8 \text{ L min}^{-1}$ ;  $\text{H}_2 = 1.2 \text{ L min}^{-1}$ . (Reprinted from Tazi, B. and O. Savadogo, O., *Electrochim. Acta*, 45, 4329, 2000. With permission from Elsevier.)

all cases, the conductivity dependence on temperature shows a maximum around 120°C. In the investigated temperature range, the highest conductivities were found for the PTA-based membranes (at 120°C from  $2 \times 10^{-2}$  to  $0.1 \text{ S cm}^{-1}$  with an increasing degree of sulfonation from 70% to 80%).

#### 27.4.4.4 Phosphate and Phosphonate Additives

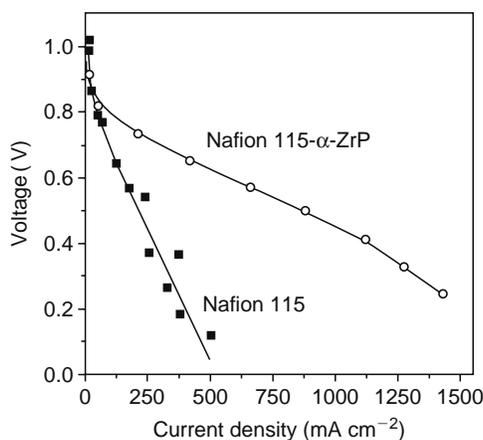

This class of composite membranes is strongly favored by the Alberti group [14,126,143–145]. The Alberti group has developed an in situ method for formation of layered metal(IV) phosphonates or phosphate–phosphonates. These compounds can be considered organic derivatives of  $\alpha\text{-ZrP}$  and have the general formula  $\text{M(IV)(O}_3\text{P-G)}_{2-x}(\text{O}_3\text{P-ArX})_x$ , where  $\text{-G}$  may be an inorganic (e.g.,  $\text{-OH}$ ), organic (e.g.,  $\text{-CH}_2\text{OH}$ ) or an inorgano-organic group (e.g.,  $\text{-CF}_2\text{PO}_3\text{H}_2$ ). Ar is an aryl group (e.g., phenyl); X is an acid group (e.g.,  $\text{-SO}_3\text{H}$ ,  $\text{-PO}_3\text{H}_2$ , or  $\text{-COOH}$ );  $x$  is a coefficient that can vary between 0 and 1.5. Important in this respect is that, because of the presence of the electronegative  $\text{O}_3\text{P}$ -group attached to the same ring, the  $\text{-SO}_3\text{H}$  group acquires superacid properties. In Table 27.16, the conductivity of some zirconium phosphonates is reported and compared with that of  $\alpha$  and  $\gamma$ -zirconium phosphates of varying crystallinity. The conductivity of the sulfophenylene derivatives is much higher than that of the best amorphous ZrP and for some compositions, is comparable or even greater than that of Nafion 117. The in situ formation of these insoluble-layered compounds is based on the experimental observation that their soluble precursors can be formed in proton-acceptor solvents commonly used for the solubilization of proton-conducting ionomers

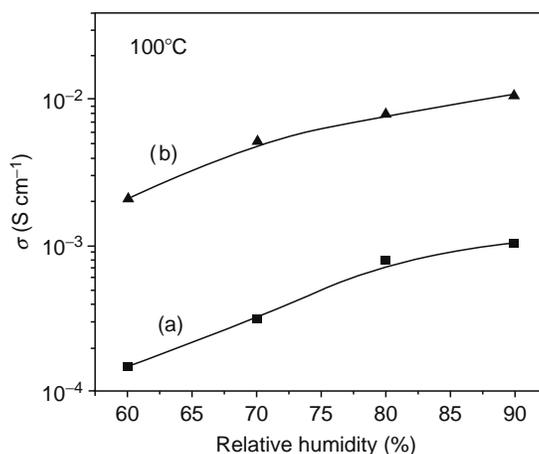

**FIGURE 27.66** Polarization curves of PEMFCs based on Nafion 115 and Nafion 115: 23 wt%  $\alpha$ -ZrP at 130°C and 3 atm with reactants humidified at 130°C. (Reprinted from Costamagna, P. et al., *Electrochim. Acta*, 47, 1023, 2002. With permission from Elsevier.)

(e.g., DMF, NMP, alkanols, etc.). The special property of these compounds is that they can easily be transformed into the final insoluble zirconium phosphonates just by drying at 110°C–130°C.

A composite Nafion 115 and recast Nafion with  $\alpha$ -ZrP nanoparticles were investigated by Costamagna et al. [146]. At 130°C, cell temperature with  $H_2$  and  $O_2$  humidified at 130°C, the nanocomposite membranes displayed much better performance than unmodified Nafion (Figure 27.66). In particular, the polarization curve of a nanocomposite recast membrane at 130°C and 3 atm was equivalent to that of the unmodified recast film at 80°C and 1 atm. Moreover, the composite membranes showed stable behavior over time at 130°C, whereas Nafion was irreversibly degraded under the same conditions. Yang et al. also investigated a Nafion,  $\alpha$ -ZrP nanocomposite membrane in a DMFC which exhibited good performance up to about 150°C, with maximum power densities of 380 and 260  $mW\ cm^{-2}$  under oxygen and air feed, respectively.

Composite polyarylene membranes modified by using organic solutions of zirconium phosphonate precursors were investigated by the Alberti group in combination with FuMA-Tech membranes [126]. Preliminary results from Alberti's group showed that the conductivity of s-PEK membranes of high-molecular weight (FuMA-Tech) is enhanced to a great extent in the presence of nanoparticles of zirconium phosphate sulfophenylphosphonates (Figure 27.67). Taking into account that much lower enhancement was instead obtained with  $\alpha$ -ZrP nanoparticles, these results seem to confirm the importance of the high-proton conductivity and acid strength of the filler. Thus, according to Alberti, superacid zirconium phosphonates deserve further attention as fillers of nanocomposite membranes [126].

**FIGURE 27.67** Conductivity as a function of relative humidity for (a) a high-molecular-weight s-PEK membrane (FuMA-Tech; thickness 50  $\mu m$ ) and (b) the same membrane filled with 35 wt% of  $Zr(O_3P-OH)(O_3P-C_6H_4SO_3H) \cdot nH_2O$ . #### 27.4.4.4.1 Ammonium Polyphosphate

Ammonium polyphosphate composite-based proton conductors for the intermediate temperature range (200°C–300°C) have been found to possess good proton conductivity ( $0.1 \text{ Scm}^{-1}$  at 300°C) under humidified conditions [147]. This temperature range would not have any kinetics or CO poisoning problem, but improving stability of the proton conductor in fuel cell conditions is still a challenge [148–151].

#### 27.4.4.5 Proton-Conducting Membranes Based on Electrolyte-Filled Microporous Matrices/Composite Membranes

Composites enable the mechanical and electrical properties of the membrane to be separated. In most cases, they consist of a matrix (mechanical support) filled with a protonic electrolyte. Varying the electrolyte and optimizing the structure of its mechanical support enable the working conditions of the cell to be adapted. This implies an improvement in the performance of the cell, along with a possible reduction in the cost of the membrane. Successful efforts have been made by some groups in this direction. Haufe and Stimming [152] prepared and characterized composite membranes made by soaking polysulfone fleece and microglass fiber fleece in 5 M sulfuric acid and ionomer electrolytes.

Figure 27.68 shows the conductivity for the various samples in the form of an Arrhenius plot  $\log(\sigma T)$  versus  $1/T$ . This figure reveals that all samples exhibit similar activation energies (0.10–0.19 eV), which correspond to those commonly measured for acids in the liquid state. Moreover, in the investigated temperature regime, the polysulfone fleece soaked with  $\text{H}_2\text{SO}_4$  had a slightly higher specific conductivity than Nafion 117 membranes. This fact might be considered surprising, since, on the basis of the specific conductivity obtained for the free acids and on the basis of the porosity of the fleece (83%), a much higher conductivity is to be expected. This leads to the conclusion that the pores of the fleeces were not completely filled with  $\text{H}_2\text{SO}_4$ .

**FIGURE 27.68** Arrhenius plots  $\log(\sigma T)$  versus  $1/T$  of the proton conductivity of  $5 \text{ mol dm}^{-3} \text{ H}_2\text{SO}_4$  (●) according to Ren, X., Springer, T.E., and Gottesfeld, S., *J. Electrochem. Soc.*, 147, 92, 2000, (○); experimental data;  $15 \text{ mol dm}^{-3} \text{ H}_3\text{PO}_4$  (▲); polysulfone fleece filled with  $5 \text{ mol dm}^{-3} \text{ H}_2\text{SO}_4$  (◇); polysulfone fleece filled with  $15 \text{ mol dm}^{-3} \text{ H}_3\text{PO}_4$  (▽) or with  $19 \text{ mol dm}^{-3} \text{ H}_3\text{PO}_4$  (▼); polysulfone fleece filled with Nafion (◆); microglass fiber fleece filled with  $5 \text{ mol dm}^{-3} \text{ H}_2\text{SO}_4$  (■); microglass fiber fleece filled with Nafion (□) and Nafion 117 membrane (dotted line, according to Ren, X.M., Springer, T.E., Zawodzinski, T.A., and Gottesfeld, S., *J. Electrochem. Soc.*, 147, 466, 2000.)

On the basis of a simple geometric consideration, a comparison between the conductivity of the acid and that of the impregnated fleeces results in only 7% of the volume of the polysulfone fleece and 11% of the volume of the microglass fiber fleece contributing to the proton conductivity of the composite. Similarly, the filled volume for  $\text{H}_3\text{PO}_4$  and the fleece impregnated with it amounts to 13%. The difference between the conductivity of Nafion 117 and that measured for the fleeces impregnated with Nafion ionomer is, however, smaller, revealing a filled volume of 34% for the polysulfone fleece and 53% for the microglass fiber fleece. These observations suggest that the surface treatment of the fleece may help in optimally impregnating the matrix.

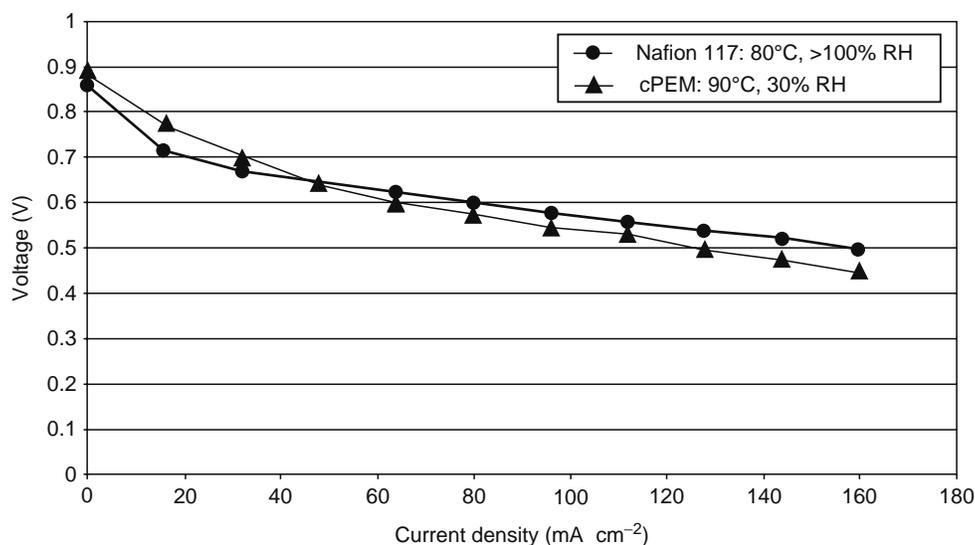

$\text{H}_2/\text{O}_2$  fuel cell performance using a polysulfone fleece filled with  $\text{H}_2\text{SO}_4$ , microglass fiber fleece filled with Nafion, and a Nafion 117 were found to be comparable. The same kind of composite membranes was also suggested to be a good alternative to Nafion for liquid feed DMFCs. Peled et al. [153,154] reported a family of nanoporous proton-conducting membranes (NP-PCMs). These membranes consisted of electronic nonconductive nanosize ceramic powder ( $\text{SiO}_2/\text{TiO}_2$ ), a polymer binder (PVDF), and an acid. They have the appearance of plastic, good mechanical properties, nanosize pores (typically smaller than 1.5–3 nm) filled with the acid, and room-temperature conductivity of up to  $0.21 \text{ S cm}^{-1}$  (twice that of Nafion) at  $25^\circ\text{C}$ . Their thickness ranges from 40 to 400  $\mu\text{m}$ . Their insensitivity to heavy ion impurities and reduced methanol crossover (by order of magnitude) makes them good low-cost candidates for liquid-feed DMFCs.

#### 27.4.4.6 Other Concepts

Creavis's concept is based on ceramic membrane foils already marketed under the trade name CREAMFILTER. They reportedly combine the characteristics of flexible polymeric membranes and ceramic membranes in a favorable way. The basis of the membrane is a woven or nonwoven support of stainless steel or temperature-tolerant glass fibers. Due to their better chemical stability, stainless steel supports are preferred for filtration applications, whereas nonconducting glass supports are needed for batteries and fuel cells. This support is coated with ceramic materials, e.g., alumina or zirconia, and a flexible membrane with microfiltration (MF) properties is realized. The thickness of the membrane is about 80  $\mu\text{m}$ . This is thin enough for the membrane to retain the flexibility of the support. The pore size of the membrane is in the range of 50–500 nm, depending on the particle size of the ceramic materials. This microfiltration (MF) membrane can be modified by superimposing additional layers with smaller particles or active particles onto the first layer. Coating the MF membranes once results in ultrafiltration (UF) membranes with pore sizes between 5 and 50 nm, while coating them twice produces nanofiltration (NF) membranes with pore sizes smaller than 5 nm. To use the CREAMFILTER membranes in a low-temperature fuel cell, the nonconducting MF membrane has to be transferred into a PEM. This can be achieved in a very similar way to the production process of the filtration membrane described above. The MF membrane is infiltrated with a solution, suspension, or sol of a proton-conducting material. After this impregnation step, the proton-conducting material is immobilized by thermally treating the membrane. From a theoretical point of view, all kinds of proton-conducting materials can be used as active materials for infiltrating CREAMFILTER membranes. Due to the inorganic nature of the support, inorganic compounds are preferably used as active materials. Candidate materials for proton conductors are zirconium phosphates, sulfuric acids based on triethoxy silane compounds, or other Bronsted acids, such as  $\text{H}_3\text{PO}_4$  or  $\text{H}_2\text{SO}_4$ . To immobilize these acids, an inorganic sol is typically prepared which contains the acids. The MF membranes are infiltrated with sols that comprise additional metal oxide compounds. During the thermal treatment, the gelation of the sol occurs and the acids are fixed in the gels. The membranes reportedly do not have pores and are absolutely gas tight. The proton conductivity of the membranes is comparable to Nafion membranes. Due to the inorganic nature of the CREAMFILTER PEMs, these membranes show no swelling and need only a reduced relative humidity to reach high conductivities. Figure 27.69 shows a typical  $V$ - $I$  behavior of the membranes. The CREAMFILTER PEM in Figure 27.69 comprises a  $\text{H}_3\text{PO}_4$ -doped silica gel as the proton-conducting material. Typical working conditions for Nafion are  $80^\circ\text{C}$  and a relative humidity of up to 100%. In contrast, the CREAMFILTER membrane works at temperatures of at least  $90^\circ\text{C}$  and relative humidities of about 30%. With this membrane (Figure 27.69), power densities of more than  $50 \text{ mW cm}^{-2}$  can be achieved (low conductivity of phosphoric acid at  $90^\circ\text{C}$ , slow kinetics). Creavis claims that with other proton-conducting membranes the CREAMFILTER PEM reaches power densities of up to  $200 \text{ mW cm}^{-2}$  under the same conditions.

#### 27.4.5 POLYMER MEMBRANES WITH INORGANIC ACID IMPREGNATION

Aromatic PBIs are highly thermostable, with melting points  $>600^\circ\text{C}$ . The PBI commercially available is poly(2,20-[mphenylene]-5,50-benzimidazole) (PBI) (Figure 27.70). PBI has a tendency to take up water, thus explaining the low-proton conductivity (in the range  $\sim 10^{-7} \text{ S cm}^{-1}$ ) that is observed even for the neat polymer [155]. PBI is basic ( $\text{p}K$  value of  $\approx 5.5$ ), and it readily forms complexes with organic and inorganic bases. It has long been known that PBI can be treated with sulfuric and phosphoric acid, which leads to stabilization as well as to a significant increase in conductivity. The acid uptake reaches 5 mol  $\text{H}_3\text{PO}_4$  per PBI repeat unit. This quantity is much too large to use the term "doped," yet this is the term often inappropriately used to describe PBI-acid complexes. The properties of such impregnated (doped) membranes and their

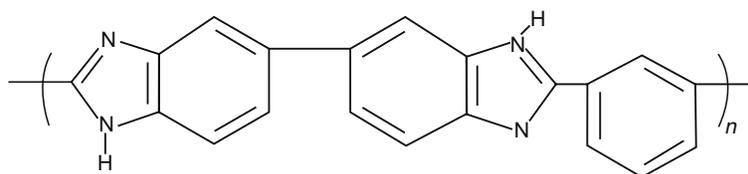

**FIGURE 27.69**  $V$ - $I$  behavior of a CREAMFILTER PEM, compared to Nafion 117. Note the different working conditions of the membranes. (Reprinted from Augustin, S. et al. *Desalination*, 146, 23, 2002. With permission from Elsevier.)

application in PEMFCs and in cells using hydrocarbons and methanol as fuels have been investigated systematically since 1994 by Wainright et al. [15,156–167]. Celanese Ventures is the largest (and for a long time the only) producer of PBI and developed this membrane for fuel cell applications. In 2004, their fuel cell activities were spun off into a new and independent company, PEMEAS, which continues to develop MEAs. These MEAs are based on phosphoric acid-doped PBI. A pilot plant for fuel cell MEAs has been established in Höchst, Frankfurt am Main, Germany. The main advantage of this system is high-temperature operation over 150°C. Doping the membranes with other acids like hydrochloric acid, perchloric acid, or nitric acid leads to high conductivity [163]. Different methods are used to form the PBI/acid complex: immersing a PBI membrane in an acid solution of a given concentration for a given length of time is the most popular method. A second possibility is direct casting from a solution of PBI and phosphoric acid in trifluoroacetic acid. A recent variant of this approach uses polyphosphoric acid as the condensing agent for polymerization and as a membrane casting solvent. Absorption of water after casting leads to in situ hydrolysis of polyphosphoric to phosphoric acid in the membrane [155].

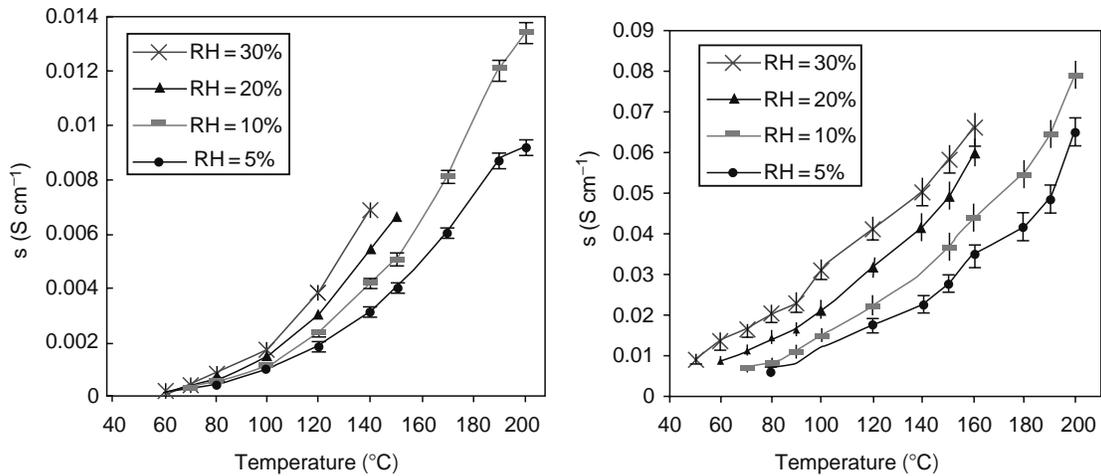

Whether humidification of PBI in fuel cells is necessary remains an open question. Short-term fuel cell tests yielded no or small performance losses when dry fuels were used or humidification was reduced [167,168]. However, membrane conductivity does depend on the water activity: as can be seen in Figure 27.71 taken from a presentation by Savinell, the conductivity of PBI (3 H<sub>3</sub>PO<sub>4</sub>/PBI repeat unit and 6.3 H<sub>3</sub>PO<sub>4</sub>/PBI repeat unit) depends considerably on relative humidity [169]. However, Celanese (PEMEAS) in their publications state that no humidification is required for their PBI systems.

#### 27.4.5.1 PEMEAS (Celanese) Membranes

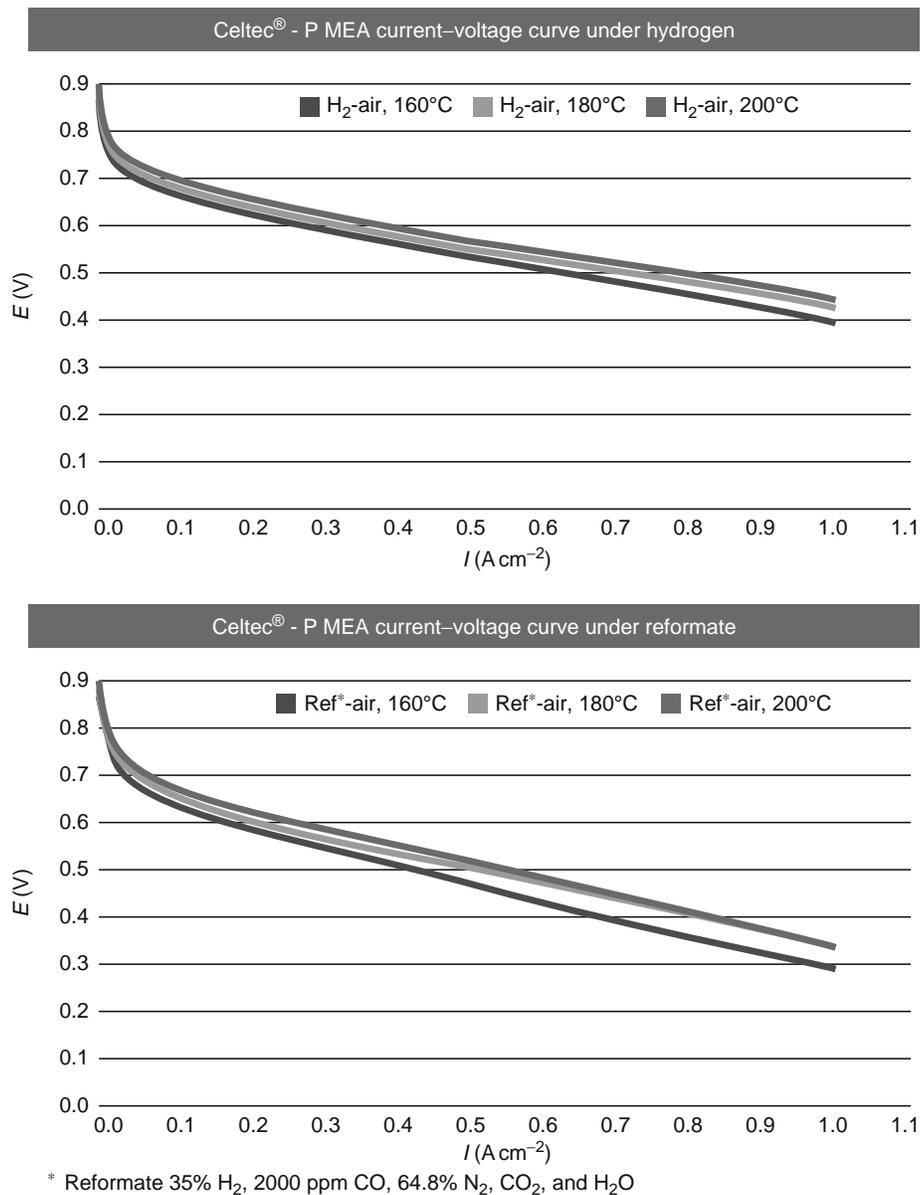

PEMEAS, a 2004 spin-off from Celanese AG, has developed a membrane made from the heat-resistant polymer PBI. The PBI membrane marketed by PEMEAS under the brand name Celtec enables a fuel cell to operate at temperatures of up to 200°C (392°F), while more conventional technologies allow PEMFC-operating temperatures of up to 100°C (212°F). Due

**FIGURE 27.71** Conductivity of PBI versus temperature for various RHs. Left: doping level 300%, right: doping level 630%. (From Ren, X., Zawodzinski, T., and Gottesfeld, S., *Abstr. Pap. Am. Chem. Soc.*, 217, U490–U490, 1999.)

**FIGURE 27.72** (See color insert following page 588.) Celtec P MEA, active cell area:  $45\ cm^2$ , air: $\lambda = 2$ ; 0 bar,  $H_2$ : $\lambda = 1.2$ ; 0 bar, humidification: none. (From Celanese AG, www.celanese.com.)

**FIGURE 27.73** Service-life test of Celtec P MEA, active cell area:  $45 \text{ cm}^2$ , cell temperature:  $160^\circ\text{C}$ , current density:  $0.3 \text{ A cm}^{-2}$ , air:  $\lambda = 2.5$ ; 0 bar,  $\text{H}_2$ :  $\lambda = 1.2$ ; 0 bar, humidification: none. (From Celanese AG, www.celanese.com.)

to the operating temperature, PBI is resistant to carbon monoxide (CO) poisoning of the catalyst and at least 100 ppm CO can be tolerated at  $150^\circ\text{C}$ . The need for higher fuel cell-operating temperatures, according to Celanese AG, is outlined below:

- Higher operating temperature PEMFCs operate with smaller cooling elements. This is especially good for automotive applications.
- Higher operating temperature membranes enable more efficient heat recovery for stationary applications of PEMFCs.
- Higher temperature-tolerant membranes are more tolerant to CO poisoning. This reduces the need for ultrapure hydrogen feed.

The performance curves reported by Celanese are shown in Figure 27.72. The interfacial bonding of electrode and membrane is also accomplished using PBI/ $\text{H}_3\text{PO}_4$ .

Celanese AG has reported reasonable long-term durability and operational stability for Celtec P MEAs (Figure 27.73). The properties of Celtec P MEAs, according to Celanese, are given in Table 27.17.

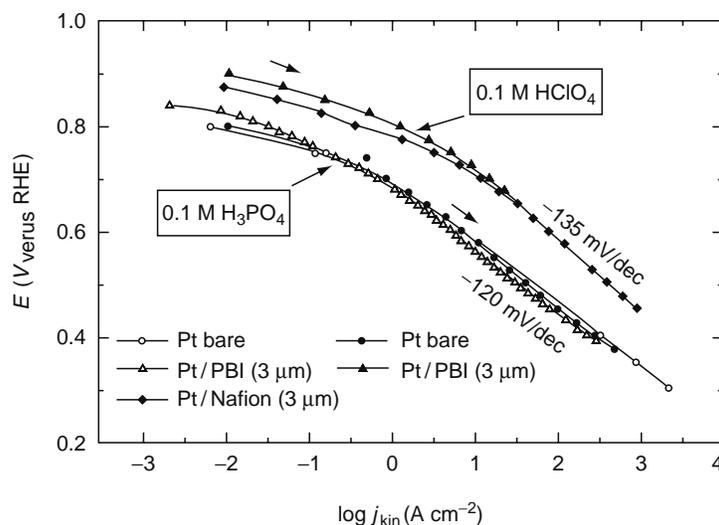

According to Celanese, the MEA and its individual components can be customized in size and shape to meet customer requirements.

Taking the high temperature into account, it is astounding (at least for the authors of this study) that the current densities at high single-cell voltages are comparatively low for PBI. Large losses in the kinetically dominated region of the PBI  $V$ - $I$  curve are observed. This is due to the strong adsorption of phosphoric acid on Pt electrocatalyst and may be difficult to avoid. This effect has been investigated regarding the oxygen reduction reaction by the Savinell group and is summarized in Figure 27.74 for solid Pt electrodes with and without polymer films [165]. PBI and Nafion films do not influence the reactivity appreciably, but in nonadsorbing perchloric acid current density is much higher than in phosphoric acid.

## 27.5 SUMMARY

A lot of research has been carried out in past decade to develop membranes for the whole spectrum of applications, namely automotive, stationary, and portable applications. PFSA-based membranes have played the most prominent role until now. Much research has been conducted into the details of proton transport through different polymers and into methods of improving their properties, but a viable and inexpensive substitute to Nafion has yet to be developed. On the other hand, different approaches using PTFE fibril reinforcements have been successfully applied to PFSA-based membranes to make them more mechanically and thermally stable and thus to enhance durability. Such membranes are also reported to have better humidity and heat management characteristics besides lower specific protonic resistance and high power densities. Alternative approaches to modify the properties of PFSA-based membranes by impregnating inorganic fillers have also been reported to produce favorable results. But such membranes still await wide adoption. For liquid-phase operation (as in DMFCs), very inexpensive membranes based on nanoporous inorganic support matrices filled with liquid electrolytes have also shown good potential. PFSA-based membranes cannot be used in the high-temperature range. A good alternative for the high-temperature range critical to automotive applications is the inorganic, acid-doped PBI-based membrane from Celanese AG. In spite of all these improvements, a lot of work is still needed to improve various membrane characteristics which would make designing fuel cell-based systems much simpler and would eliminate the need for several BOP components, which adds to the complexity of the fuel cell systems.

# 28 Membrane Applications in Industrial Waste Management (Including Nuclear), Environmental Engineering, and Future Trends in Membrane Science: Introduction

*Ana Maria Sastre and Anil Kumar Pabby*

## CONTENTS

28.1 Industrial Effluent Generated by the Chemical Industry .....	823
28.2 Waste Generated by the Nuclear Industry .....	824
References .....	825

Industrial development in this century will be characterized by technologies that allow not only less consumption of raw materials and energy but also permit recovery and reuse of all process streams with least damage to the environment. Membrane science and technology has a big role to play in this changing industrial environment. Membrane-based separation technology has now reached to full-fledged commercial environmental friendly technology to answer the multifarious demands of industry. The growth of membrane science is largely due to the impressive developments in the field of membrane material science and the evolution of different membrane-related equipment.

This section deals with the application of membranes in the treatment of industrial effluent generated by the chemical industries and waste generated by the nuclear industries. Also, this section focuses on important perspectives on environmental engineering with respect to chemical and nuclear waste processing. Before going into the details of the processes used for this purpose, one should understand the background of these types of waste.

### 28.1 INDUSTRIAL EFFLUENT GENERATED BY THE CHEMICAL INDUSTRY

As a result of the growing world population and rapid industrial development, an increasing amount of wastewater is produced worldwide. Wastewater contaminants may eventually enter the food chain and cause severe health and environmental problems. As a result, many countries have been introducing increasingly stringent wastewater regulations to minimize wastewater-related pollution. Current and impending legislation on wastewater effluent discharge has led to the need for enhanced treatment processes that are capable of removing toxic metal ions, high percentages of BOD, suspended solids, nitrogen, phosphorus, bacteria, and other contaminants.

Many conventional wastewater treatment processes that have long been in use are now considered impractical because they require a large amount of space, a large number of unit operations, and are affected by problems associated with odor and other emissions. Recent years have seen an increasing trend toward process intensification, which has led to the development of advanced membrane processes that are simple to construct and operate, have well-defined flow patterns, better dispersion effects, relatively low power consumption, lower emissions, and high mass-transfer performance, which are compact and recyclable.

The treatment and safe disposal of waste is equally important whether it be waste generated by the pulp and paper industry, by the leather industry or gaseous waste. Recently, in addition to other membrane-based processes, demand has grown in the wastewater treatment industry for a process that uses both a biological stage and a membrane module, known as the membrane bioreactor (MBR) process. The bioreactor and membrane module each have a specific function: (1) the biological degradation

of organic pollution is carried out in the bioreactor by adapted microorganisms and (2) the separation of microorganisms from the treated wastewater is performed by the membrane module. The membranes constitute a physical barrier for all suspended solids and therefore enable not only the recycling of the activated sludge in the bioreactor but also the production of a permeate that does not contain suspended matter, bacteria, or viruses.

## 28.2 WASTE GENERATED BY THE NUCLEAR INDUSTRY

The nuclear industry generates a broad spectrum of low and intermediate level liquid radioactive wastes (LRWs). These liquid wastes may be produced continuously or in batches and may vary considerably in volume, radioactivity, and chemical composition. A wide range of treatment methods have been used throughout the industry to treat these wastes. Treatment methods for LRWs have tended to use the same conventional processes found in industrial and municipal water treatment. These processes typically include chemical treatment, adsorption, filtration, ion exchange, and evaporation. They are limited by either their inability to remove all contaminants or, in evaporation, the high operating costs involved and the large quantities of secondary solid waste produced, which means that satisfactory processing of LRWs is difficult to achieve.

It has been demonstrated that membrane separation processes can be successfully used in the removal of radioactive substances, with some distinct advantages over conventional processes. Following the development of suitable membrane materials and their long-term verification in conventional water purification, membrane processes have been adopted by the nuclear industry as a viable alternative for the treatment of radioactive liquid wastes [1]. In most applications, membrane processes are used as one or more of the treatment steps in complex waste treatment systems, which combine both conventional and membrane treatment technologies. These combined systems have proved more efficient and effective for similar tasks than conventional methods alone.

This section aims to explain the unique features of membrane separation methods, their superior performance in contaminant removal, and their operational sensitivities and limitations. We focus particularly on the factors that need to be carefully assessed when the membrane technology to be used in the treatment of liquid radioactive waste is being considered. These include membrane configuration and arrangement, process application, operational experience, data related to key performance parameters, and plant and organizational impacts.

The use of liquid membranes for the separation of actinides in the nuclear industry is still in its infancy [2]. In the past few decades, exotic reagents such as crown ethers and calixarenes have been used for the selective complexation and removal of actinides from solutions containing complex mixtures of metal ions. However, a recently developed, nondispersive solvent extraction method using a hollow fiber membrane contactor has been used successfully at pilot plant scale with no stability problems. In this method, an organic extractant dissolved in the diluent is passed directly through the shell side of hollow fiber contactors [3]. This technique continuously fills the pores of the membrane with extractant. However, it should be noted that hydrophobic membranes are only impregnated in the liquid membrane technique before the experimental run and the feed and strip solutions are passed through the tube and shell sides, respectively. Another improved technique was to use microporous hollow fiber contactors as an alternative to the direct dispersion of ELMs to minimize membrane swelling and leakage. Hollow fiber contactors do not have the high shear rates that are typical of the agitators used in direct dispersion. This technique has been successfully applied in the removal and recovery of strategic and precious metals from wastewaters and process streams (Chapter 39) and is variously known as supported liquid membrane with strip dispersion (SLMSD), pseudo-emulsion based hollow fiber strip dispersion (PEHFSD), or emulsion pertraction technology (EPP). In this case, the organic (extractant dissolved in diluent) and back-extraction phases are emulsified before injection into the HF module and can be separated at the module outlet. PEHFSD has the following advantages over standard extraction and other membrane processes: (1) extraction and stripping can be carried out in a single operation; (2) there is no possibility of emulsion formation in the water phase; (3) the volume of extractant is relatively small and the process parameters are very flexible; (4) phase separation is not necessary; (5) the hollow fiber membranes and short diffusion paths provide a large specific surface area; and (6) the modular equipment is compact and energy consumption is low.

The membrane separation processes listed are at different stages of development and implementation. While some processes have been widely adopted, others are still under development and some are currently making the transition to industrial use. This section contains chapters that describe the use of various membrane techniques for the treatment of nuclear waste generated by the chemical industry. This chapter gives an introduction to all the chapters in the section. Chapter 29 focuses on the introduction, fundamentals, and scope of membrane processes for the treatment of nuclear waste from various sources. Chapter 30 details advances in membrane processes for nuclear waste processing and describes the current global situation of membrane processes for the treatment of nuclear waste. This chapter also covers the future role of membrane processes in nuclear technology and the advantages and limitations of applied membrane processes. Chapter 31 deals with advances in the field of liquid membranes and their application in the separation of actinides. The present review is a compilation of literature reports on liquid membrane-based separation studies dealing mainly with those actinides that are a long-term environmental hazard. Chapters 32 and 33 present case studies on the treatment of radioactive waste generated in a hospital and in a reprocessing plant, respectively. Chapter 34 presents selective coagulant recovery using the Donnan

membrane process (DMP). A non-pressure-driven DMP, also referred to as Donnan dialysis, is analyzed as a technique for alum recovery. This process is based on the Donnan exclusion principle, according to which negatively charged cation-exchange membranes are impermeable to anions and positively charged anion-exchange membranes are impermeable to cations. Unlike pressure-driven processes such as reverse osmosis, nanofiltration, and ultrafiltration, authors claim that DMP is free from surface fouling by natural organic matter (NOM). The process is able to recover alum that is virtually free of dissolved organic carbon, in which trihalomethane can be formed during the chlorination step in water treatment.

Membrane technology may become essential if zero-discharge mills become a requirement or legislation on water use becomes very restrictive. The type of membrane fractionation required varies according to the use that is to be made of the treated water. This issue is addressed in Chapter 35, which describes the application of membrane processes in the pulp and paper industry for treatment of the effluent generated. Chapter 36 focuses on the application of membrane bioreactors in wastewater treatment. Chapter 37 describes the applications of hollow fiber contactors in membrane-assisted solvent extraction for the recovery of metallic pollutants. The applications of membrane contactors in the treatment of gaseous waste streams are presented in Chapter 38. Chapter 39 deals with an important development in the strip dispersion technique for actinide recovery/metal separation. Chapter 40 focuses on electrically enhanced membrane separation and catalysis. Chapter 41 contains important case studies on the treatment of effluent in the leather industry. The case studies cover the work carried out at pilot plant level with membrane bioreactors and reverse osmosis. Development in nanofiltration and a case study on the recovery of impurity-free sodium thiocyanate in the acrylic industry are described in Chapter 42.

The early membranologists have always been optimistic about the possibilities of membrane operations, but the scientific and technical results reached today are even superior to the expectation. A variety of technical challenges must be overcome to permit the successful industrial application of new membrane solutions. Chapter 43, on the same theme, presents the future scenario of membrane processes covering chemical, biotechnological, pharmaceutical applications, etc., and also focusing future progresses in membrane engineering.

## 29.1 INTRODUCTION

Since the breakthrough in synthesis of semipermeable membranes for seawater desalination by reverse osmosis (RO) process in the early 60s, research and development work on membrane technology has been growing steadily. Novel polymeric membrane systems and compact module designs with better performance and newer applications for membrane technology are continuously being reported. The application of membrane technology to the treatment of process streams generated in chemical industries is a subject matter deserving serious attention in the context of rapid industrialization. Nuclear industry covers a wide spectrum of complex chemical operations and hence membrane technology finds several suitable areas of applications, particularly in the field of management of radioactive wastes.

A typical nuclear industry may consist of mining and milling of uranium ore, thorium extraction, fuel fabrication, nuclear reactor operation, and production and application of radioactive isotopes for various industrial medical and research purposes. Almost, in all these steps, waste is generated that needs proper management. Radioactive wastes differ from other industrial wastes due to its radiation exposure and its radiological toxicity to human beings and their environment. Management of radioactive wastes is an important step in a nuclear industry and the objective is to effectively isolate radionuclides from the

**TABLE 29.1**  
**Categorization of Radioactive Wastes**

Category	Solid Surface Dose (mGy/h)	Liquid Activity Level (Bq/m <sup>3</sup> )	Gaseous Activity Level (Bq/m <sup>3</sup> )
I	<2	<3.7 × 10 <sup>4</sup>	<3.7
II	2–20	3.7 × 10 <sup>4</sup> to 3.7 × 10 <sup>7</sup>	3.7 to 3.7 × 10 <sup>4</sup>
III	>20	3.7 × 10 <sup>7</sup> to 3.7 × 10 <sup>9</sup>	>3.7 × 10 <sup>4</sup>

V	—	>3.7 × 10 <sup>14</sup>	—

environment to ensure adequate safety and welfare to the public. Since the advent of nuclear power, the search for more effective and efficient technology for the treatment of radioactive wastes has continued.

## 29.2 SOURCES AND CHARACTERISTICS OF RADIOACTIVE WASTES

The main sources of radioactive waste are generated from operation of nuclear reactors and fuel-reprocessing plants. These wastes contain, in varying concentrations, a wide spectrum of fission products, which are beta–gamma active, and actinides possessing alpha activity. Most of the radioactivity is in the form of radioactive cations and complex anions. The liquid wastes from nuclear reactors have high volumes of dilute chemicals with low radioactivity, while reprocessing plants contain almost 99% of the total inventory of radioactivity in the whole fuel cycle that is contained in a relatively small volume. Radioactive wastes are conventionally classified as belonging to various categories depending upon the level of radioactivity. Table 29.1 gives the categories of radioactive wastes [1]. Effluents containing significant quantities of alpha-active isotopes (actinides) in addition to some beta–gamma activity are specified as alpha wastes. Reprocessing plants generate all types of wastes whereas effluents generated in a nuclear reactor have generally low to intermediate level radioactivity with insignificant amount of alpha-active actinides. In both these waste streams, the concentration of two fission product isotopes, namely, <sup>137</sup>Cs and <sup>90</sup>Sr is generally high. With their long half-lives (30 and 28 years, respectively), these elements are important in the treatment of wastes. Actinides have still longer half-lives, of the order of 10<sup>4</sup> to 10<sup>6</sup> years and demand attention because of their sustained radioactivity over much longer period.

## 29.3 PROCESSES FOR TREATMENT OF RADIOACTIVE WASTES

A typical high-level waste contains radioactivity of the order of 3.7 × 10<sup>9</sup> to 3.7 × 10<sup>14</sup> Bq/m<sup>3</sup> in molar concentration of nitric acid. Corrosion products, alloying elements, fission products, actinides, and chemicals introduced during fuel reprocessing are the major constituents of high-level wastes. In addition to the high levels of radioactivity, there is substantial solution heating from radionuclide decay. The combination of heat generation and radioactivity requires quite selective treatment. The treatment of high-level radioactive wastes involves conversion of these wastes into inert matrix such as glass or ceramics with the help of suitable additives. In vitrification, immobilization of radioactivity together with volume reduction is achieved.

For the treatment of low and intermediate level wastes, three processes are generally adopted, namely, chemical precipitation, ion exchange, and evaporation. The efficiency of the treatment scheme is judged by the values of decontamination factor (DF) and volume reduction factors (VRFs), which are defined as follows:

$$\text{Decontamination factor} = \frac{\text{Concentration of radioactivity in the waste before treatment}}{\text{Concentration of radioactivity in the waste after treatment}}$$

$$\text{Volume reduction} = \frac{\text{Initial volume of the waste}}{\text{Final volume of the waste}}$$

### 29.3.1 EVAPORATION

Among the processes mentioned above, evaporation is an efficient process providing very high DFs (10<sup>3</sup>–10<sup>4</sup> typically, with enhancements up to 10<sup>6</sup>) in the distillate, which is suitable for release to the environment. The concentrate exists as a thick liquid of small volume and contains most of the activity together with concentrated salts. The process is nonselective, concentrating all the constituents that are in solution. Evaporation is costly, as it is energy intensive and is used only for the treatment of low volumes of wastes (10–100 L/min) containing moderate levels of radioactivity with low or high concentration of salts.

### 29.3.2 CHEMICAL TREATMENT

Chemical treatment is a well-proven technique and is less expensive. Generally, specific chemical precipitation is carried out in situ in big tanks holding the radioactive waste stream to remove radionuclides while permitting nonradioactive ions to be released in the effluent from the process. The radionuclides present in the waste are precipitated, co-precipitated, carrier precipitated, or adsorbed by insoluble compounds. A clariflocculator is used for flocculation and clarification. This technique is used as a batch or a semibatch process for large volumes of effluents containing only low concentrations of activity. It provides lower DF values (10–100) than evaporation.

### 29.3.3 SORPTION AND ION EXCHANGE

Sorption is a general term commonly used to describe the uptake of radionuclides (ionic or nonionic) by certain materials (sorbents). Ion exchange, specifically, refers to the process of reversible exchange of ions having charges of the same sign between an electrolyte solution and the ion exchanger. Conventional organic ion-exchange resins are not very selective as they remove both radioactive and nonradioactive materials. In many waste streams originating from nuclear installations, the concentrations of nonradioactive constituents are many times ( $>10^6$ ) greater than the radioactive contaminants. Hence, these are normally suitable for decontamination of relatively clean solutions with low salt content. Once resins are loaded with contaminants, they can be regenerated, washing off the collected contaminants into a small volume that may then be immobilized or further volume reduced by evaporation before solidification. The resin can be reused.

Synthetic ion-exchange resins based on phenolic resins have shown promise in radioactive liquid waste treatment containing high inactive concentrations of ions. In alkaline solutions, these resins show very high uptake of cesium due to the ionization of phenolic hydroxyl groups at high pH. Resorcinol-formaldehyde polycondensate resins have also been successfully tested for efficient removal of radioactive cesium from alkaline-reprocessing wastes containing large concentrations of sodium ions. Incorporation of iminodiacetic acid functional groups into the phenolic polymer matrix gives it the additional feature of strontium uptake by chelation. These resins are presently being used on a large scale [2]. Inorganic sorbents/ion exchangers have higher thermal, radiation, chemical stability, and higher selectivity for certain ions and they are more compatible with various immobilization matrices. Vermiculite, a naturally occurring aluminosilicate mineral, is well known for its selective uptake of cesium followed by irreversible trapping due to lattice contraction. Among other promising irreversible sorbents potassium cobalt(II) hexacyanoferrate(II), ammonium molybdophosphate (AMP), resorcinol-formaldehyde polycondensate resin are noteworthy.

### 29.3.4 MEMBRANE PROCESSES

A major deficiency of conventional treatment systems is their inability to make use of a single-process separation for all the dissolved constituents on a molecular or ionic level. Membrane processes operate at ambient temperature and offer one-step separation for all the dissolved constituents on molecular or ionic level without any need for further chemical addition. Table 29.2 gives the application of different membrane processes for diverse contaminants.

Among the disadvantages, the fouling and degradation of membrane surfaces of the polymeric membrane systems under adverse chemical and thermal conditions are often cited. However, these problems may be partly overcome by proper pretreatment of the effluents, optimizing the process variables and selecting suitable membrane materials. The radioactive wastes most suited for membrane separation are characterized by chemically insignificant amounts of radionuclides and small amounts (few hundred parts per million) of inactive ionic species.

In membrane processes, a solute is defined as the chemical species which does not selectively permeate through the membrane barrier and thereby getting enriched on the high-pressure side of the membrane. Permeate refers to the chemical

**TABLE 29.2**  
**Membrane Process for Diverse Contaminants**

Species	Membrane Processes
Particulates	Microfiltration
Colloids	Microfiltration
High-molecular-weight organics	Ultrafiltration (UF)
Middle-molecular-weight organics large ionics	UF/NF
Low-molecular-weight organics ionics	NF/RO
Ionic contaminants	Electrodialysis/RO
Acids	Diffusion dialysis

**TABLE 29.3**  
**Characteristics of Principal Membrane Separation Processes**

Process	Driving Force	Objective
Gas, vapor, and organic liquid permeation	Concentration gradient (pressure, temperature assisted)	Product enriched in a desired component
Dialysis	Concentration gradient	Solution of macromolecules free of microsolutes
Electrodialysis	Electric potential	Solvent free of ionic solutes Concentration of ionic solutes Ion replacement Fractionation of electrolytes
Microfiltration	Pressure	Sterile, particle-free solution
UF	Pressure	Solution of macro solutes free of microsolutes
NF	Effective pressure	Removal of organics, dyes from effluents Fractionation of electrolytes
RO	Effective pressure	Solvent free of all solutes Concentration of solution

species, which selectively permeate through the membrane barrier and thereby getting enriched on the low-pressure side of the membrane. Recovery refers to the quantity of the permeate obtained by the membrane process for a given quantity of feed sent through the system and it is often expressed as either a fraction or in percentage.

The basis design objectives in these systems aim at high VRFs, corresponding to permeate recovery factor of more than 0.9 and a decontamination factor of at least 10 corresponding to solute rejection of more than 90%. Membrane processes are used in radioactive waste treatment primarily to reduce the volume of the waste that is achieved by redistributing the activity in two phases: one depleted of radioactivity having the majority of the original volume and the other concentrated in a lesser volume. The dilute phase depleted in radioactivity (permeate) may be released to the environment if the permeate meets the regulatory guidelines set for its discharge. The concentrated stream (retentate) must be subjected to secondary treatment. Preconcentration by membrane processes is considered desirable from the point of view of generating low volumes of final waste that can be further processed before it is sent for safe disposal. Membrane separation processes offer the possibility of treatment at the point of generation, leading to a much smaller volume of concentrate that has to be transported to a centralized treatment plant.

Membranes are synthetic barriers across which selective permeation of the desired species can be effected by employing appropriate driving force like electric potential, hydrostatic pressure, or concentration gradient. Characteristics of principal membrane processes are given in Table 29.3.

Membrane processes are classified according to the nature of the membrane and the driving force employed. A number of different types of polymeric/inorganic membranes have been developed in recent times in basically four types of modular assemblies, namely, plate and frame, spiral, tubular, and hollow fine fiber. Table 29.4 gives the application of various membrane processes for the separation of different types of contaminants encountered in effluents.

For radioactive effluent treatment, the relevant membrane processes are microfiltration, ultrafiltration (UF), reverse osmosis, electrodialysis, diffusion, and Donnan dialysis and liquid membrane processes and they can be used either alone or in conjunction with any of the conventional processes. The actual process selected would depend on the physical, physico-chemical, and radiochemical nature of the effluents. The basic factors which help in the design of an appropriate system are permeate quality, decontamination, and VRFs, disposal methods available for secondary wastes generated, and the permeate.

**TABLE 29.4**  
**Membrane Applications for Different Contaminants**

Contaminant species	Membrane process
Particulate matter and suspensions	Microfiltration
Colloidal impurities	Microfiltration
High-molecular-weight organics	UF
Middle-molecular-weight organics	UF
Low-molecular-weight organics	NF, RO
Multivalent ionic solutes	NF, RO
Acids	Diffusion dialysis

For example, in fission product effluents where radio-contaminants having longer half-lives are present, the emphasis should be on very high volume reduction with permissible/acceptable decontamination factors so that the permeate could be directly discharged. For effluents contaminated with radionuclides of short half-lives, a good decontamination with reasonable volume reduction may be acceptable because the concentrate could be stored till the activities decay before discharge. The radioactive effluents requiring treatment may vary with respect to the type of radionuclide, its chemical nature, concentration, pH, concentration of inactive solutes, and presence of suspended matter.

### 29.3.5 REVERSE OSMOSIS

Reverse osmosis (RO) involves the passage of solvent through a semipermeable membrane, when a solution is pressurized in excess of its own osmotic pressure. This method uses high pressures (2–4 MPa) to force water through a semipermeable membrane that presents an effective barrier to permeation of ionic species or large molecules. It thus produces a concentrated solution (retentate)-limited to about 0.8 M by osmotic pressure considerations and a dilute (permeate) water stream with a decontamination factor of 10–100 in dissolved salts, for a single-stage process. The lower range is representative of monovalent species, the higher for divalent or trivalent species that are strongly rejected. Still higher values may be expected for alpha emitters owing to their larger atomic/molecular size. The possibility of radioactive effluent treatment by RO was recognized in the early 70s and several studies have been reported on the laboratory scale as well as on the pilot plant scale. Several systems are now in routine use in nuclear installations around the world. A typical flow sheet of a reverse osmosis plant for waste treatment is given in Figure 29.1.

Radioactive waste treatment applications have been reported [3–9] for the laundry wastes from nuclear power plants and mixed laboratory wastes. Another interesting application of reverse osmosis process is in decontamination of boric acid wastes from pressurized heavy water reactors (PHWRs), which allows for the recovery of boric acid, by using the fact that the latter is relatively undissociated and hence will pass with water through the membrane while most of the radioactivity is retained [10]. Reverse osmosis was evaluated for treating fuel storage pool water, and for low-level liquid effluents from reprocessing plants.

A variety of reverse osmosis membrane systems based on cellulose acetate, aromatic polyamides, and other polymers have been tested for their potential applications. Reverse osmosis membrane equipment is available for large-scale operation since the process is widely used for the production of potable water from sea or brackish waters and upstream of ion exchange in the preparation of ultrapure water for steam-generating boilers. In these applications, the feed concentrations may vary from 500 to 40,000 mg/L of dissolved solids. The RO technique can be used at pH values between 3 and 12 and up to 45°C.

In radioactive waste treatment, significant operational aspects include the following. Since the operation requires the use of high pressures, there is a need to ensure control of the activity release from possible leaks. As with evaporation, pretreatment of the feed may be necessary to prevent scaling, and where dirty waters are to be fed directly it would be advisable to consider the use of equipment with larger membrane flow channels, which would permit periodic foam ball cleaning of the membrane surface.

Reverse osmosis is a preconcentration technique and the concentrates, depending on the inactive load, can be sent to evaporation or chemical precipitation step. The permeate, depending on the radioactivity level, may be either discharged directly or released after passing the water through polishing columns. Normally, the decontamination factor achievable varies from a few tens to hundreds, depending on the nature of the input stream, and the membrane. The VRFs depend on the inactive salt load, operating pressure, and the selectivity of the membrane used.

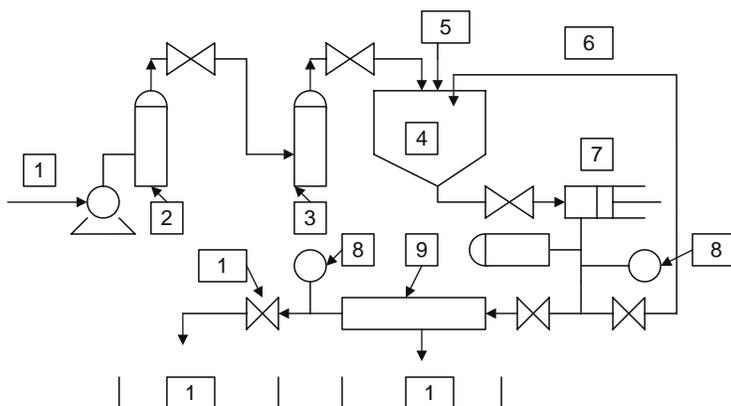

FIGURE 29.1 Flow sheet of RO plant.

Various performance indicators, such as VRF, percent solute rejection (SR), percent permeate recovery ( $R$ ) are computed as follows:

$$\text{VRF} = \frac{\text{initial volume of the feed}}{\text{final volume of the feed}}$$

$$\text{SR} = \left( \frac{\text{feed concentration} - \text{permeate concentration}}{\text{initial feed concentration}} \right) \times 100$$

$$R = \frac{\text{permeate flow rate}}{\text{feed flow rate}}$$

In BARC, a reverse osmosis pilot plant was successfully operated [11] for decontaminating low-level radioactive effluents having total dissolved solids in the range of few hundred parts per million contaminated with radioactive cesium and strontium. The pretreatment section consists of upflow particulate filter and cartridge filter. The upflow filter has been found to be effective in the removal of significant amounts of activity. This indicates that radioactivity is associated with large-sized suspended matter and the decontamination factor associated with upflow filter is directly proportional to the specific radioactivity of the feed introduced to the filter. In large-scale operations, the upflow filter generates significant quantities of secondary aqueous wastes due to the backwashing cycles which increase the waste volume. Also the filter media have to be disposed of periodically due to radioactivity build up that accumulates even with backwashing. On the other hand, only the cartridge filters used can remove the suspended loads, however, with frequent and costly replacement of the cartridges. There is a possibility to incinerate these cartridges, which would reduce the solid waste volume. From our experience, it can be said that there is no need to add any biocides or bio inhibitors as the accumulated radiation sources on the membrane surface themselves can prevent biofouling. Presently a 100 m<sup>3</sup>/day RO plant for decontamination and volume reduction of low-level radioactive effluents is operating at Trombay, India.

Uranium metal processing is one of the important constituents of a nuclear industry where nuclear grade metallic uranium is prepared for use as nuclear fuel. Like all other hydrometallurgical plants, uranium metal-processing plants also produce considerable quantities of metal-bearing liquid effluents, which are radioactive in nature. During the processing of uranium ore to get nuclear grade uranium metal, pure uranyl nitrate solution is obtained which is treated with ammonia-air mixture to precipitate ammonium diuranate.

This ammonium diuranate is filtered. Ammonium diuranate filtrate (ADUF) generated in uranium metal plant contains around 30,000 ppm ammonium nitrate and small amounts of dissolved and suspended uranium and its daughter products. The beta activity levels due to <sup>234</sup>Th and <sup>234</sup>Pa are significant and require processing before disposal of filtrate into the sea. Economic treatment and safe disposal of the filtrate demand a decontamination factor of at least 10 with a VRF of more than 10. This corresponds to a minimum solute rejection of more than 90% at more than 90% permeate recovery under reverse osmosis processing conditions. At first glance, reverse osmosis process with very high permeate recovery and high solute separation at such a high feed solute concentration does not seem reasonable. However, our laboratory studies [12] indicated that both ammonium and nitrate species are poorly rejected by cellulose acetate brackish water desalting reverse osmosis membranes, compared to sodium chloride. The solute rejection of ammonium nitrate decreases with increasing concentration.

### 29.3.5.1 Transport in Reverse Osmosis Process

The transport of solute and the solvent through semipermeable membrane under reverse osmosis conditions are depicted in Figure 29.2. The permeate flux ( $N_B$ ) in reverse osmosis is given by the following equation:

$$N_B = A[P - (\Pi_{X_{A2}} - \Pi_{X_{A3}})]$$

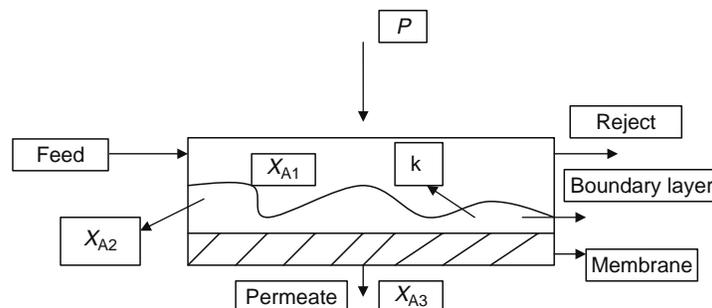

FIGURE 29.2 Membrane-solution interface.

where

$A$  is the membrane constant (m/s bar)

$P$  is the operating pressure (bar)

$\Pi_{X_{A2}}$ ,  $\Pi_{X_{A3}}$  are osmotic pressures of boundary layer and permeate streams with solute mole fractions  $X_{A2}$  and  $X_{A3}$ , respectively

For a solute with high rejection, permeate concentration would tend to zero. Thus,

$$X_{A3} \rightarrow 0 \text{ and } \Pi_{X_{A2}} - \Pi_{X_{A3}} \cong \Pi_{X_{A2}}$$

As recovery increases, the bulk solute concentration and hence  $X_{A2}$  increase. The recovery would then be limited by the value of  $\Pi_{X_{A2}}$  approaching the operating pressure  $P$ .

On the other hand, for poorly rejected solute like ammonium nitrate, the permeate concentration of solute would be significant, and hence

$$\Pi_{X_{A2}} - \Pi_{X_{A3}} < \Pi_{X_{A2}}$$

Since the permeate concentration is considerable, the rise in the bulk concentration of the feed ( $X_{A1}$ ) as well as the boundary layer concentration ( $X_{A2}$ ) with recovery would be less. Moreover, the solute rejection decreases with increasing concentration, thereby always keeping the term  $(\Pi_{X_{A2}} - \Pi_{X_{A3}})$  much less than  $P$ . Under these conditions, one can theoretically go up to a concentration where the osmotic pressure of the feed would approach the operating pressure, subject to the limitations of scaling and fouling. Accordingly, the VRF or recovery would not be a critical design step as long as the permeate quality is maintained within the desired limits. The high solubility of ammonium nitrate and the absence of scaling components make it theoretically feasible to attain high recoveries. However, iron fouling needs to be taken care off. If radioactive contaminants are selectively removed, then it is possible to use this process for decontamination of ADU effluents despite the high concentration of the total dissolved solids.

The treatment of ADUF by reverse osmosis [13] was found to be useful in concentrating activity in small volume while making a larger volume of the decontaminated effluent for direct disposal after required dilution. Porous cellulose acetate membranes were used in plate module configurations. The concentration of ammonium nitrate in the permeate stream is not very different from that of the contaminated retentate. With the addition of flocculating aids, the decontamination factors in the range of 1000 with VRFs in the range of 100 were achieved.

### 29.3.6 NANOFILTRATION

Nanofiltration (NF) membranes have average pore size of 10–30 Å, an intermediate range between reverse osmosis (10 Å) and ultrafiltration (>30 Å). Nanofiltration has the advantage of very low solute rejection for monovalent species, probably due to their very small hydrated radii and higher rejection for multivalent species which are large enough. The decontamination of ADUF was also investigated in a pilot plant study using nanofiltration membranes [12]. Because of the poor separation of ammonium nitrate, NF membranes have the potential to achieve high VRFs with high decontamination factors for radionuclides, which are multivalent. The studies carried out indicate that nanofiltration is better suited for the decontamination of ammonium diuranate filtrate effluents due to their near constant fluxes, high decontamination factors, and low ammonium nitrate solute rejections. Complexation has been used in conjunction with nanofiltration process for selective removal of trace toxic metal ions [14].

### 29.3.7 ULTRAFILTRATION

Ultrafiltration process is basically a physical filtration process on a very fine scale. It can retain large molecules, suspended, and colloidal particles, but can allow dissolved salts to pass through the bulk of the water. To keep the concentrate mostly in a uniform suspension requires high flows of liquid along the membrane surface. The technique uses similar configurations of equipment layouts as are used in reverse osmosis processes.

Ultrafiltration process is used in industries for the treatment of wastes and the associated recovery of useful products in the concentrate. Examples include the fractionation of milk whey and the treatment of cutting oil emulsions. Ultrafiltration process utilizes membranes having pore sizes in the range of 0.01–0.1 μm. The operating pressure is in the range of 3–5 bar. The mechanism of separation is essentially based on the size-based retention of the components. Cellulose esters, polyamide class of polymers, polyacrylonitrile, polyvinylidene difluoride, and polysulfones are largely used as membrane materials. It has application in the concentration of radioactivity, which is or can be converted to a colloidal or suspended state or possible included in large complex molecules. It has the potential advantage over reverse osmosis of being selective in its concentrating

action because soluble salts may pass through the membranes and be discharged with the bulk of the water, provided they are nonradioactive. It also operates at lower pressures (<0.5 MPa) than does reverse osmosis and at higher membrane fluxes. Although in most commercial units the membranes are polymeric materials, they are less sensitive to chemical and temperature conditions than reverse osmosis. Several inorganic membranes are available, permitting treatments which might incur high radiation dose.

Like microfiltration, ultrafiltration process can also be used in conjunction with chemical precipitation techniques to improve decontamination factors. Ultrafiltration processes could be useful for decontaminating alpha wastes from laundry and washing water streams of plutonium-processing plant on a large scale [15,16].

### 29.3.8 PRECIPITATION ULTRAFILTRATION

Removal of  $^{137}\text{Cs}$  by copper ferrocyanide precipitation followed by ultrafiltration is another promising option. This method could give higher DFs (100–1000) under optimum conditions compared to DFs of about 10 obtained in conventional methods of solid–liquid separation like settling or clariflocculation. It also requires lower dosage of chemical thus making it cost effective. Ultrafiltration combined with chemical precipitation or adsorption has been employed for treatment of radioactive effluents to improve the decontamination factors [17,18]. A typical flow sheet of the combined process is represented in Figure 29.3.

### 29.3.9 COMPLEXATION ULTRAFILTRATION

Ultrafiltration membranes work as a molecular size barrier; the pore size is too large to retain metal ions except in the colloidal form. Formation of high-molecular-weight species by complexation with water soluble-chelating agents leads to metal ion capture that permits the concentration of metallic solutions. A schematic of the process is represented in Figure 29.4. Selective metal ion extraction can be achieved if specific chelating groups are anchored on the polymeric chain. This combined process, called complexation ultrafiltration, could provide an alternative to ion-exchange resins.

A solution containing the metal ion to be extracted and a water-soluble polymer is delivered into an ultrafiltration unit (Figure 29.5). The feed stream, upstream of the UF system, is adequately stirred to enhance recovery of the radioactive ions. The metallic macromolecular complex is retained while low-molecular-weight solutes pass through the membrane. The efficiency of the process is mainly characterized by the passage of each species through the membrane. The transfer coefficient of a given solute,  $i$ , is defined by

$$T^i = \frac{C_f^i}{C_0^i}$$

where

$C_f^i$  and  $C_0^i$  are the concentration of species,  $i$ , in the filtrate and the feed solutions, respectively

$T^i$  is usually expressed as an equivalent parameter

$R^i$  is the retention coefficient, given by

$$R^i = 1 - T^i \text{ (when } R^i = 1, i \text{ retention has been completed).}$$

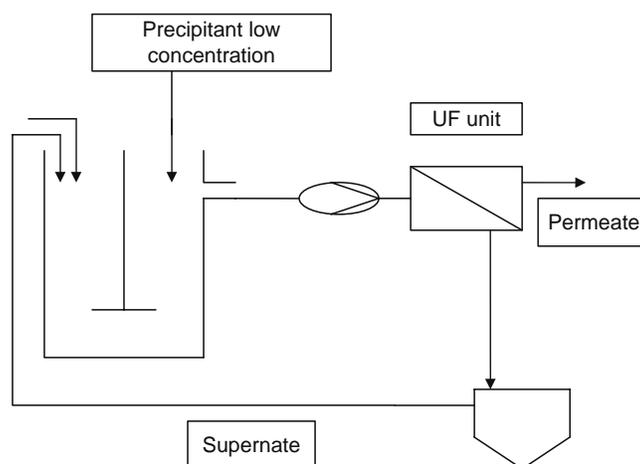

FIGURE 29.3 UF combined with chemical precipitation.

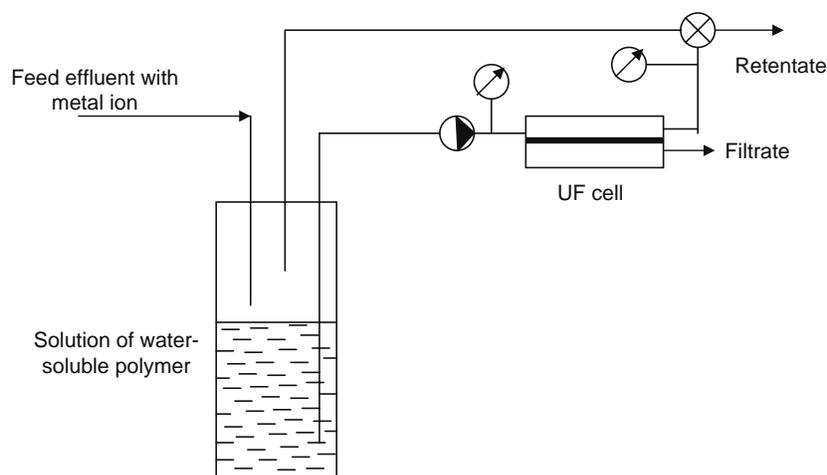

FIGURE 29.4 Schematic diagram of metal removal by means of the diafiltration process.

The filtration rate must be as high as possible so that the required membrane area is minimum. Flux rate ( $J$ ) through the ultrafiltration membrane is related to the applied pressure  $\Delta P$  by Darcy’s law:

$$J = \Delta P(\eta - r_m)$$

where

- $r_m$  represents the hydraulic resistance of the membrane toward the permeate
- $\eta$  is the dynamic viscosity of the solution

The filtration rate increases with increasing molecular weight cut-off (MWCO) by lowering  $r_m$ . MWCO is the molecular weight of the solute retained by the ultrafiltration membrane to the extent of 90% of the initial concentration. The accumulation of the retained solutes on the membrane or in the boundary layer next to the membrane surface, a phenomenon called concentration polarization, is the main cause of limitation of filtration rates. The concentration polarization is usually reduced by stirring the solution in the ultrafiltration unit or by tangential flow to the membrane surface or using higher flows to reduce the boundary layer.

The efficiency of the method is governed by some main requirements, such as complexation ability of the additive polymer and the ability of the membrane to retain the complexed metal ion. The retention of the macromolecular species should be complete to avoid loss of material. This condition entails that the molecular weight distribution of polymers does not overlap the pore size distribution of membranes. MWCO of the membranes should be chosen significantly lower than the average molecular weight of polymers. The treatment of large volumes demands high filtration rates. As can be seen in the above equation describing the flux rate,  $J$  decreases with increasing viscosity of the solution due to the high-molecular weight or to the high concentration of the polymers. Therefore, a compromise has to be found between MWCO and the molecular weight

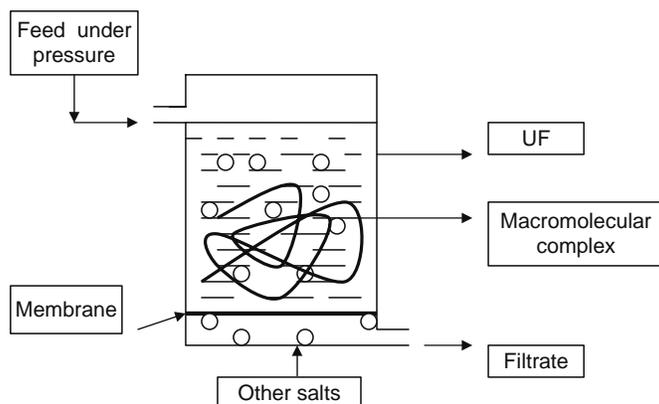

FIGURE 29.5 Principle of complexation UF.

of the polymer macromolecules. On the other hand, fouling of membranes may occur during ultrafiltration by polymer precipitation because of the low water solubility of the polymer. For this reason, polymers with good water solubility and are capable of forming complexes with metal ions should be chosen for use.

A variety of water-soluble macromolecules bearing ion-exchanger groups or chelating functions have been reported for use in complexation ultrafiltration processes [19–21]. Polyethyleneimine (PEI), a polymeric amine, has been used in many studies as a complexing agent as well as a versatile source of chelating derivatives. In addition to its chelating abilities, PEI exhibits good water solubility and chemical stability, yet has a high number of functional groups. However, the range of molecular weights available with PEI complexes does not exceed MW 50,000. This property requires the use of membranes with low MWCO to achieve desirable retention of the PEI.

Ultrafiltration membranes are made of various organic or inorganic polymers. Obviously, the best compatibility has to be found between membranes and solutes to avoid adsorption that will decrease the filtration rate. One of the most commonly used membranes is polyether sulfone—a nonionic hydrophobic polymer having high filtration rate. Unfortunately, this polymer is susceptible to strong interactions with hydrophobic solutes that will lead to irreversible fouling of the membrane surfaces. Hence, cellulosic materials are the preferred choice for these applications because of their low protein-binding properties. Radioactive cerium was separated [22] using polyethyleneimine complexation with indigenously made ultrafiltration membranes. Published results indicate that decontamination factors in the region of 1000 for alpha and 100 for beta–gamma radioactive species can be achieved with overall volume reduction of the order of  $10^4$ .

### 29.3.10 MICROFILTRATION

Microfiltration membranes have pore sizes ranging from 0.1  $\mu\text{m}$  and are suitable for the separation of colloidal impurities and suspended particles of submicron size, present in the raw effluents. The prime separation mechanism is mechanical retention. This process is generally used for the removal of turbidity and microorganisms from drinking water sources. The pressure applied is around 1–2  $\text{kg}/\text{cm}^2$ . In the primary cooling water of a light water reactor (LWR), corrosion products are produced which mainly consist of metal oxides containing radioactive nuclides, usually called cruds. This technique has been used [23] for separation of crud from wastes generated from operational practices in LWRs. While precoat or cartridge-type filters are generally used for removing such crud, these filters when spent produce secondary radioactive wastes. Further, the cartridge filters do not satisfactorily remove submicron-sized crud particles. Microfiltration membrane elements can be used for much longer periods before replacement, while filter-type cartridges may require frequent replacements.

Microfiltration can also be used in conjunction with chemical precipitation methods. Under optimum conditions, an integrated process of chemical precipitation and microfiltration will give a better decontamination and a lower quantity of sludge for disposal than conventional techniques using cartridge filtration and ion exchange [24]. Regenerated cellulose, cellulose acetate, polysulfone, polycarbonate, polypropylene, polytetrafluoroethylene, polyvinylidene difluoride, aromatic polyamide, and polyvinyl chloride are some of the polymeric materials used as microfiltration membrane systems. These membranes have limited radiation resistance and chemical tolerance. Ceramic microfiltration membranes have higher radiation stability and are capable of withstanding severe chemical cleaning to restore fouled membrane surfaces.

### 29.3.11 OSMOTIC CONCENTRATOR

The phenomenon of osmosis which led to the development of reverse osmosis technology has not been adequately exploited for industrial applications. This is primarily because the permeating solvent species is lost in the high concentration saline water stream, which provides the osmotic pressure differential necessary for the osmotic flow. The permeate stream is therefore not recoverable. Direct osmosis (DO) has sufficient potential for concentration of radioactive effluents as this process obviates the requirement of high-pressure support systems with their attendant problems. The driving force for dewatering can be easily realized from the salinity potential of seawater or its concentrates, which are abundant. An osmotic concentrator, fabricated and tested [25], indicated that it is possible to concentrate a radioactive feed solution, containing cesium and strontium isotopes with typically 300 ppm of mixture of inactive cesium and strontium chlorides. A concentration between 10 and 20 times was achieved by utilizing an optimum membrane and osmotic sink concentration. The circulation rates of the feed and sink can also be further controlled to achieve an optimum osmotic flux. The water permeation rate in DO is however less than in RO under comparable osmotic pressure and hydrostatic pressure gradients. A sketch of the osmotic concentration setup is shown in Figure 29.6.

### 29.3.12 ELECTRODIALYSIS

The basic principle of electrodialysis for desalination is to drive the cations and anions from saline water feeds under the influence of an electric potential gradient through cation- and anion-selective membranes. The electric potential prevents diffusion of oppositely charged ions in the other direction. A schematic of the process is shown in Figure 29.7. In a typical electrodialysis cell to deionize a salt solution, anion- and cation-exchange membranes are arranged alternatively in a

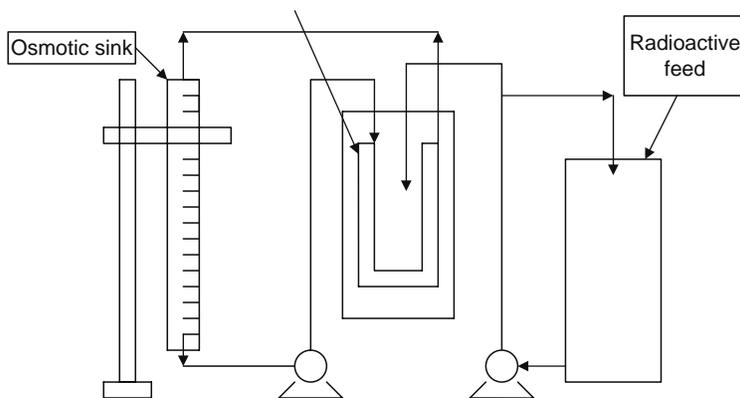

FIGURE 29.6 Bench scale osmotic concentrator.

stack, and a potential difference sufficient to force current through the stack is applied between the two electrodes placed at each end of the stack. For current to pass between the electrodes, ions must be transported through each of the membranes. By arranging the feeds to the various intermembrane compartments, it is possible to force ionic salts to pass from the dilute stream to the concentrated stream. In this way, a salt can also be split into its acid and base components. By combination of several cell pairs that comprise an anion- and a cation-selective membrane sheets in parallel, a stream concentrated in the original salts may be prepared. This configuration is the common method for industrial use, in which electrodialysis gives broadly the same result as reverse osmosis and has found very similar applications to general water treatment.

The energy consumption of an electrodialysis cell is determined effectively by the cell voltage and the current efficiency. The current efficiency is established by the membrane properties. In practice, the cathodic reaction almost always results in hydrogen evolution while the anodic reaction leads to the evolution of oxygen. The cathodic reaction increases the pH of the solution in this compartment, while the anodic reaction decreases the pH.

The cell voltage required depends on the product of current and voltage drop in the dilute streams, particularly toward the end of the process when the total ion concentration is very low. Hence, the cell must be designed to minimize this term, i.e., the gap between the membranes must be as small as possible.

The maximum useful current density through the membrane is normally limited by a phenomenon known as polarization. Concentration polarization is caused due to the depletion of the transported ion at the membrane surface, because of its faster electrolytic transport through membrane phase and its comparatively slower rate of transport through the solution phase. This causes excessive resistance at the stagnant layer near the membrane–solution interface. It is therefore necessary to avoid stagnant layers at the membrane–solution interfaces by operating at high Reynolds number or with turbulence promoters.

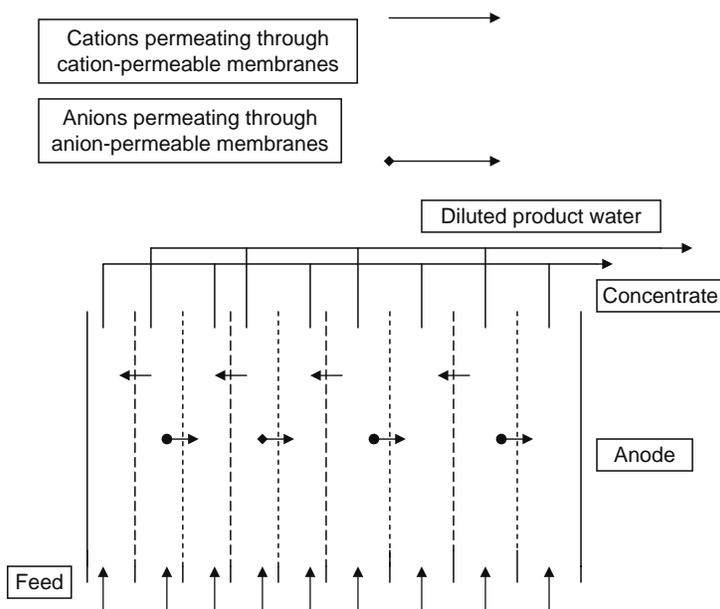

FIGURE 29.7 The principle of electrodialyser operation.

Application of electro dialysis is usually limited by the low electric conductivity of a diluted stream resulting from low concentrations of electrolyte. This limitation may be counteracted by filling the appropriate cells with ion-exchange resins at the expense of complications in construction. Although electro dialysis has the advantage of being a low-pressure process, this advantage is offset by the tendency of the ion-exchange membranes to be fouled by solids deposited on the concentration side of the cell. The construction of electro dialysis cells involves a number of seals around the individual membrane sheets. The assurance of leak-tight joint at all cells adds to the complication of replacement operations under radioactive conditions.

Electro dialysis has been examined [26] at the Japan Atomic Energy Research Institute (JAERI) for the removal of radioactive ions from low- and intermediate-level radioactive liquid waste using inactive coexisting salts as ionic carriers of very small amounts of radioactive ions. It has been found that the nature and the concentration of the existing salt species generally do not influence the decontamination factor obtained for radioactive ions. The efficiency for the decontamination of radioactive ions has been found to be higher for lower valence cations. It has also been observed that addition of inactive coexisting salt ions improves the decontamination factor but lowers the extent of volume reduction achievable.

Another example of electro dialysis applied to the nuclear industry [27] is the recovery of NaOH and H<sub>2</sub>SO<sub>4</sub> from the secondary liquid waste created by the regeneration of ion-exchange columns installed in LWRs. This application has been successfully demonstrated at a plant scale facility using simulated solutions. Long-term life tests on the ion-exchange membranes indicate a shorter life for anionic membranes than cationic membranes.

### 29.3.13 ELECTRODEIONIZATION

Large-scale operation on a radioactive feed stream has been reported [28] from Russia. Rauzen and others described a 100 m<sup>3</sup>/day facility, which was used to purify radioactive effluents. In this plant, two stages of electro dialysis were used in series. The diluate cells in the second stage contained ion-exchange resins and the water produced had a salt content equivalent to distilled water. This arrangement was found to be cheaper than a final ion-exchange cleanup. Another alternative tried was to use electro dialysis to recover acid and alkali from ion-exchange regenerant streams [28].

### 29.3.14 DIFFUSION DIALYSIS AND DONNAN DIALYSIS

Donnan dialysis is a membrane separation process that uses ion-selective membranes to prevent the flow of certain ions from one solution to another. A schematic of the process is presented in Figure 29.8. When a salt solution is separated from its corresponding acid by a cation-exchange membrane, the anions are excluded from the membrane, while the cations are redistributed across the membrane to attain Donnan equilibrium. By changing the salt solution periodically, it would be possible to shift the equilibrium favorably to effect simultaneous neutralization of acid on one side of the membrane (feed compartment) and acid recovery on the other side (receiver compartment). The driving force for ion migration is the chemical potential gradient for the cation across the membranes.

Diffusion dialysis is a special class of Donnan dialysis where anion-exchange membranes are generally used. The membranes do not allow cations to pass through, but anions are free to move across the membrane to equilibrate. However, H<sup>+</sup> ions which are much smaller will diffuse across the membrane to the receiver side. Hence, total acid diffusion is noticed in diffusion dialysis processes. Highly acidic radioactive streams could be deacidified by a diffusion dialysis process where specifically developed ion-exchange membranes are employed in a conventional electro dialysis stack design forming alternate diffusate and dialysate compartments. Free acid selectively diffuses through these anion-exchange membranes. The deacidified radioactive streams could again be treated by a secondary electro dialysis unit. An integrated membrane process consisting of diffusion dialysis followed by electro dialysis was evaluated [29] to deacidify and subsequently decontaminate a high-level radioactive stream by depleting the alpha activity. It was found that a diffusion dialysis process could be used to reduce the

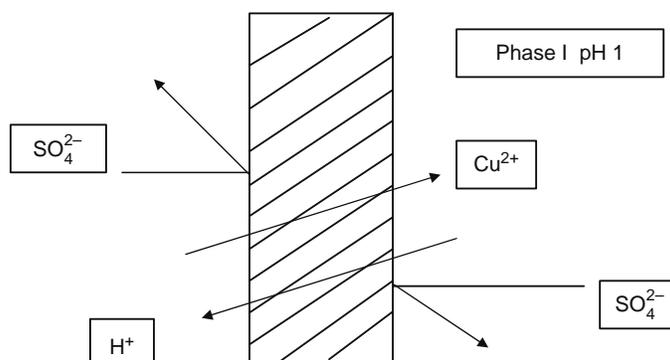

FIGURE 29.8 The principle of Donnan dialysis.

nitric acid concentration in the radioactive effluents from 3 to less than 0.3 M. The decontamination factor obtained with respect to cesium and strontium was in the range of 80–100.

Donnan dialysis and diffusion dialysis techniques are used [30] to deacidify and concentrate actinide bearing acidic solutions. Near complete deacidification could be achieved from 8 M nitric acid solutions with a high decontamination factor for the actinides. With cation-exchange membranes, the deacidification is accomplished by the build up of neutralized salt in the feed. With an anion-exchange membrane, the feed acidic solution is deacidified free of salt buildup. By superimposing direct osmosis with free deacidification, it was simultaneously possible to concentrate the deacidified actinide solution [30].

### 29.3.15 LIQUID MEMBRANES

Liquid membranes are made when a carrier mixed in a suitable solvent is converted to immiscible layer between two aqueous solutions. One of the components in the aqueous solution has preferential permeation into the immiscible membrane layer. The species in the feed can have a neutral, cationic, or anionic charge. Subsequently, these ions are removed by the permeate side solution by decoupling the carrier complex. The success of the liquid membrane process is primarily due to the diffusivity of ionic/nonionic species in liquids being an order of magnitude higher than in polymeric films. Further, the carrier molecules used in liquid membrane systems are very specific to different species and hence result in selective separation. This allows separation against an activity gradient. Various common forms of liquid membranes are bulk, emulsion, and supported liquid membrane (SLM) systems. Schematics of various liquid membrane systems are given in Figure 29.9. SLM systems are extensively investigated where the carrier is held in a porous polymeric membrane [31,32]. Development of liquid membrane process for removal of plutonium, uranium, and americium from dilute acidic solutions has been reported [33]. The removal of uranium and plutonium using SLMs with different carrier agents has been studied in BARC [34]. The recovery of uranium from phosphoric acid by this process has been considered to be an economical and efficient process as compared to solvent extraction.

The removal/recovery of actinides from aqueous reprocessing waste solutions is required to minimize radioactive discharges to the environment. Dihexyl-*N,N*-diethyl carbomoyl methyl phosphonate (DHDECMP) and tributyl phosphate (TBP) supported polypropylene hollow fibers showed promise in transferring americium and plutonium from high nitrate and low acid feeds to dilute oxalic acid-stripping solutions. Hollow fiber membrane supports exhibit the most efficient membrane area to feed volume ratio. Sorption of americium on inorganic exchangers from the strip solutions permits the recovery of americium. High-selective transport of U(VI) and Pu(IV) over several fission product contaminants was achieved employing TBP as the mobile carrier and dodecane as the membrane solvent [35].

For waste management purposes, various solvent extraction processes primarily for the removal of  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  from alkaline or weak acidic solutions have been developed on bench scale as well as on pilot scale [35,36]. Di-2-ethylhexyl phosphoric acid/kerosene system with Span 80 surfactant showed promise for the pertraction of  $^{90}\text{Sr}$  from aqueous solutions.

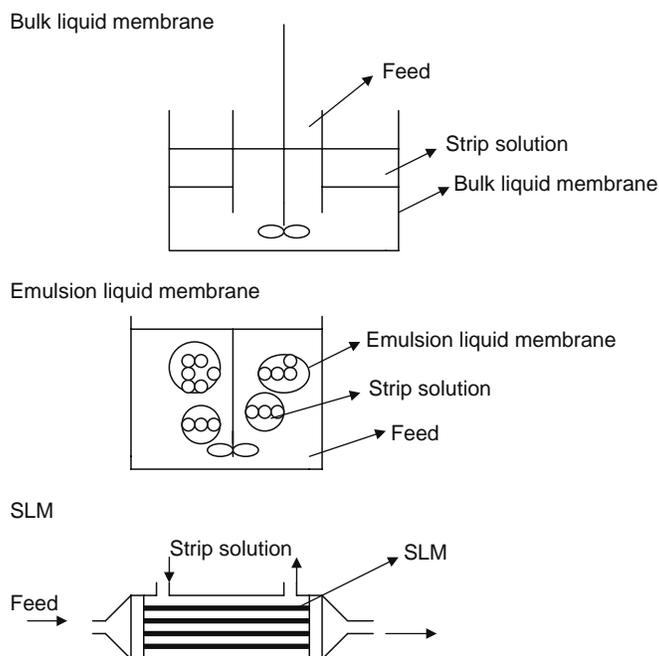

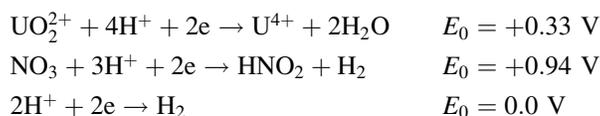

FIGURE 29.9 Schematic of various liquid membrane systems.

Recently, attempts were made to recover inert fission products like palladium from process effluents by SLM with carriers like bis(2-ethylhexyl)sulfoxide and thiocrowns [37].

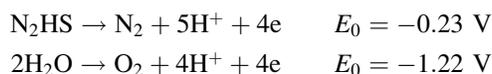

### 29.3.16 MEMBRANE ELECTROLYZERS FOR PRODUCTION OF URANYL NITRATE

The PUREX process is the oldest known and widely adopted for reprocessing of spent nuclear fuel. In this process, uranium and plutonium are co-extracted into an organic phase leaving behind the fission products in the aqueous phase. It is necessary to separate uranium and plutonium from each other for their end use in the manufacture of fuel. Redox reactions can be exploited to change the valency of uranium and plutonium to achieve the objective to separate and produce uranium and plutonium of high purity. Various reducing agents used for this purpose are ferrous sulfamate, hydroxylamine nitrate, hydrogen in presence of a catalyst, and uranyl nitrate. Uranyl nitrate can be produced electrolytically, which is simpler and amenable for large-scale production. Electrochemical reactions involved in this process are given below:

*At the cathode*

*At the anode*

Since oxygen is one of the products of electrolysis, if the electrolytic cell is undivided, reoxidation of  $\text{U}^{4+}$  ion takes place which hampers the production of uranyl with higher concentration. Cation-selective membrane spacers are effective in improving the production of uranyl nitrate solution.

### 29.3.17 RADIATION EFFECT ON POLYMERIC MEMBRANES

Studies on the effect of  $\gamma$  radiations on cellulose acetate reverse osmosis membranes [38] indicate that these membranes undergo degradation beyond a cumulative dose of 500 krad and continue to degrade at higher doses. Beyond a dose of 7 Mrad the membranes become brittle. The degradation is marked by increased water permeation rate and decreased solute separation. The solution viscosity and solubility of the membrane polymer and the tensile strength of the membranes decrease. The presence of dissolved oxygen was found to adversely affect the membranes during irradiation leading to a measurable degree of deacetylation. Ion-exchange membranes have a higher radiation resistance of up to 10 Mrad. At higher doses, loss of exchange capacity and membrane selectivity are noticeable. The electrical resistance of ion-exchange membranes primarily depends on its porosity and charge density as well as on the concentration of the electrolyte solution in which it was in contact. The electrical resistance of ion-exchange membranes decreases at higher radiation doses because of loss of functional groups causing more open channels for the electrolyte solution to freely pass through.

The fuel cycle, from mining of uranium and preparing the fuel elements for nuclear reactors, through the fuel use for generation of electricity, to management of burnt fuel and decommissioning of nuclear facilities, produces different types of radioactive waste. Radioactive waste is also generated during production and application of radioisotopes, as well as during processing of raw materials containing naturally occurring radioactive isotopes. All those wastes have to be processed and conditioned before safe storage or disposal to protect the human health and natural environment. The management of radioactive waste has to be reached with reasonable cost by implementing appropriate technologies. The treatment requirements depend on the radioactivity level, and chemical and physical properties of the waste streams. Number of methods can be used to treat aqueous

radioactive wastes, including chemical precipitation, evaporation, and ion exchange as well as less-developed solvent extraction, biotechnological processes, and membrane methods. Although membrane processes are still considered as novel technologies in this field, many applications in nuclear centers and laboratories around the world are reported. The chapter deals with some of these applications and research aiming in implementation of membrane techniques in nuclear industry.

### 30.1 RADIOACTIVE WASTE TREATMENT BY MEMBRANE METHODS

Conventional technologies that are used for liquid low- and medium-level radioactive waste processing as precipitation coupled with sedimentation, ion exchange, and evaporation are energy-consuming or introduce the third phase that results in production of secondary wastes (sludge from sedimentation tanks, spent sorbent from ion-exchange columns, or effluents from resin regeneration). These wastes need additional treatment and decontamination. All these disadvantages may be avoided by membrane methods that have already found application in the field of liquid radioactive wastes processing. The most advanced are technologies based on pressure-driven membrane processes: microfiltration (MF), ultrafiltration (UF), and reverse osmosis (RO). The choice of the process depends on waste composition or parameters that have to be reached during processing, e.g., decontamination factors (DFs) in relation to the limits defined in national or international regulations, volume reduction coefficients, or necessity of recycling some components of the solution. Different installations are used for treating the wastes from nuclear power plants or reprocessing plants, and for processing the wastes from production of radiopharmaceuticals and medical diagnostics. Radioactive wastes from production of radioisotopes and medicine are usually classified as low- and medium-level waste. They contained mainly  $\beta$  and  $\gamma$  emitters, while the wastes from the waste processing plants contain  $\alpha$ -bearing elements that can destroy polymeric membrane material. Very often the organic solvents and complexing agents or acids are present in these types of wastes. The wastes coming from nuclear reactor operation contain the fission (e.g.,  $^{89}\text{Sr}$ ,  $^{90}\text{Sr}$ ,  $^{124}\text{Sb}$ ,  $^{132}\text{Te}$ ,  $^{134}\text{Cs}$ ,  $^{136}\text{Cs}$ ,  $^{137}\text{Cs}$ ,  $^{140}\text{Ba}$ ,  $^{141}\text{Ce}$ ) as well as corrosion ( $^{60}\text{Co}$ ,  $^{58}\text{Co}$ ,  $^{51}\text{Cr}$ ,  $^{54}\text{Mn}$ ,  $^{59}\text{Fe}$ ,  $^{65}\text{Zn}$ ,  $^{95}\text{Zr}$ ) products.

Applying the membrane processes, it is possible to achieve the goals:

1. Purification of the effluents to the concentration levels enabling safe discharge to the environment
2. Concentration of the radioactive compounds with volume reduction that is sufficient for solidification
3. Separation and recycling of the valuable components, e.g., boric acid from cooling waters

Reverse osmosis enables complete retention of all dissolved compounds, even small monovalent ions. To avoid the membrane blocking and scaling before reverse osmosis, microfiltration, or ultrafiltration pretreatment can be applied. Apart from preliminary treatment, ultrafiltration can be used for separation of suspensions or colloids, which are often formed by actinides or ions such as  $^{54}\text{Mg}$ ,  $^{55}\text{Fe}$ ,  $^{60}\text{Co}$ , and  $^{125}\text{Sb}$ . Microfiltration found the application for waste dewatering after precipitation. Nanofiltration (NF) that uses lower pressures than reverse osmosis is applied for separation of bivalent from monovalent ions. The most common application of NF process in nuclear industry is boric acid separation from the reactor coolant.

#### 30.1.1 MEMBRANE SELECTION FOR NUCLEAR APPLICATIONS

The membrane is the most important part in separation processes: since its performance controls the efficiency and the selectivity of the process. Both flux and selectivity expressed in terms of separation or retention factors determine the process economics and usability, and finally the costs of the installation.

Radiation resistance of the material used as well as commercial availability of the membrane units and auxiliary equipment, process competitiveness in comparison with conventional methods, its economics and feasibility are important criteria for application of the membranes for radioactive waste processing.

Different membrane materials have found application in nuclear technology; for radioactive waste treatment both polymeric and inorganic membranes are used. The main advantages of polymers are wide spectrum of different types of material, easy formation of membranes, and easy modification for specific applications. The relatively low cost (less than \$1 per squaremeter) is also beneficial, as well as broad commercial availability. The advantages of inorganic membranes come from their extremely good resistance to the temperature, strong chemical environment, and ionizing radiation. Membranes manufactured in some primary processes can be modified for some purposes by regulation of pore size or change of membrane chemical properties. In the process of modification two kinds of material can be combined—organic and inorganic (hybrid membranes), giving tailor-made structure for special applications.

Polymeric membranes are manufactured as flat foils, hollow fibers, or tubular shape. Flat sheets can also be arranged as spiral-wound configuration, or pleated filter cartridges. The module design permits easy connection in any configuration and up-scaling of the installation. Such an arrangement allows gaining high-membrane area to volume ratio, which relatively lowers the cost of apparatus and leads to higher unit capacities. Appropriate selection of membrane configuration has to take into account energy expenditure (pressure drop) per product volume and appropriate hydrodynamic conditions in the apparatus

promoting turbulence and mass transfer, and reducing boundary-layer phenomena, as well as easiness of cleaning. In hollow fiber modules the feed flow in relatively narrow channels is laminar and thus the membrane is particularly susceptible to fouling. The channels in plate-and-frame modules are also small, and membranes are sensitive to fouling, however they are easy to clean. On the contrary, in tubular modules cross-flow velocities are usually larger, giving turbulent flow and large pressure drop. In spiral-wound modules the spacer may act as a turbulence promotor and thus reduces concentration polarization.

The problems with fouling are particularly important for nuclear applications, because frequent cleaning produces the secondary wastes, which are radioactive and need additional processing. The best practice for membrane installation operation is avoiding the fouling and scaling by all available means (antiscalant injection, feedwater pretreatment to remove oxidizing materials, iron, calcium and magnesium salts, particulates and oils, greases, etc.). Proper selection of the module, which can be easily cleaned by back-flushing or washing with cleaning solution, is very important. In tubular modules direct mechanical cleaning by foam balls is also practiced, however it is limited to the small units.

One of crucial parameters of the membranes employed for radioactive waste treatment is their radiation stability and durability. During long-time operation the membrane is exposed to the action of ionizing radiation. This may cause some structural changes in the membrane that affects its permeability and separation characteristics. The variety of the effects in the polymer structure results from ionizing radiation such as cross-linking and formation of a new structure, decrease of molecular weight as a result of breaking of the main chains of macromolecules, change of the character and the number of double bonds, oxidation of the polymer in the presence of oxygen, etc.

The effect of irradiation of polymer membranes was studied by several research groups [1–7]. All studies showed that polymeric membranes exhibit limited resistance to ionizing radiation, however the threshold values of doses are sufficiently high to use the membranes for low and medium radioactive solutions treatment for a period of time. Usually the practical lifetime for most membranes is of the order of 4–5 years that is sufficient to avoid deterioration of filtration and separation abilities. Ceramic membranes are expected to be more resistant to  $\gamma$ ,  $\beta$ , and  $\alpha$  emissions, but systematic studies have not been presented.

### 30.1.2 SYSTEM DESIGN

There are numerous ways in which the membrane modules can be arranged in filtration systems. The factors influencing the choice of the option include the type of the process, the expected concentration in the streams, the volume of the processed wastes, the acceptable dose to the membrane, and desired costs of the plant. The capital costs play an important role in low and medium capacity plants, while the components of operation costs, such as energy consumption, are of less importance. For design of large capacity installations the operation costs are key elements. High investment costs for additional equipments, such as control system, washing installation, or measurement apparatuses, are justified when they cause a decrease of operational costs of the plant. Nuclear installations need special control equipment and security systems and their capital costs are relatively high.

The plant can operate in batch or continuous mode. The simplest design is dead-end operation, frequently used in microfiltration where all the feed is forced through the membrane that results in continuous increase of feed concentration and worsening of permeate quality. This design is used when complete filtration of the feed is necessary. More often used arrangement is cross-flow, which decreases the membrane fouling, and can operate as co-current, countercurrent, cross-flow with perfect permeate mixing. The flow in the module is arranged as a single-pass or flow with recirculation. Batch systems are also employed in small-scale applications when the waste arises discontinuously. Single-pass configuration can be arranged in series arrays, parallel or tapered design. The loss of volume in a single-pass system is compensated by tapered arrangement. The tapered array is rather not considered for ultrafiltration and microfiltration, as the high cross-flow velocities. This result in high pressure drop cause low-permeate flux and small volume reduction, as well as negligible increase in concentration of the retentate. Very frequent arrangement is feed and bleed system that consists of the number of stages each fed with a circulation pump. The feed pump generates the applied pressure, while the circulation pump maintains the cross-flow velocity. All arrangements of the modules are described in various other books on membrane processes [8–10].

When the product from the single stage has no desired quality the cascade system can be employed. The cascade design is frequently used in nuclear industry, especially for isotope separation. The first uranium-235 enrichment as a uranium hexafluoride was conducted in a cascade composed of many stages with porous, metallic membranes. Since the molecular weight ratio of  $UF_6$  isotopomers is about 1.008, the gas diffusion enrichment factor was low ( $\sim 1.0043$ ) and the unit separation effect had to be multiplied in large number of stages to achieve high purity of the product. Stage is an element of separation cascade containing several separation units, connected in series or in parallel and arranged as a tapered or squared off design. A permeate from one stage feeds the next one, however not always permeate is a product of the cascade. The simplest scheme is cascade without reflux (Figure 30.1), which is reasonable when the retentate in enriching section is not a valuable material. The example of such an arrangement is a plant for production of deuterium by water electrolysis operated by Norsk Hydro [8].

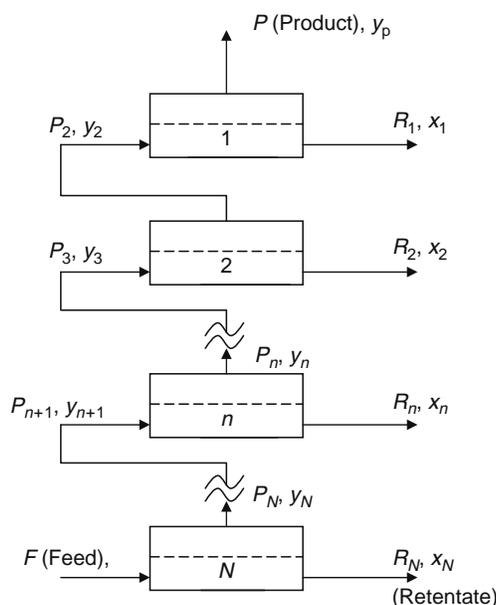

FIGURE 30.1 Cascade without reflux.

To avoid the product losses the recycling cascades are employed (Figure 30.2). The cascades with reflux are more complicated and the capital costs and costs of operation are higher; they are sensible only in the case of expensive raw material. Technical and economic considerations on such systems were performed in basic books for isotope separation [11,12], as well as by Hwang and Kammermeyer [13].

### 30.1.3 PROCESS OPERATION—CONSIDERATIONS FROM RADIOLOGICAL SAFETY POINT OF VIEW

#### 30.1.3.1 Process Control

All installations designed for nuclear industry have to fulfill very strict requirements of safety and reliability in the long run. Control and monitoring systems, automation, and washing installations are considered as essential part of the design.

##### 30.1.3.1.1 Automation

It is common that membrane plants are automated. The automation is used for starting up and shutting the installation, controlling the cleaning cycle, and the process parameters. However, some intervention of the operator in case of emergency has to be foreseen. All valves and remote-controlled devices ought to have the possibility of manual start-up and putting in motion. Membrane installation may be integrated into the central control system in the plant where it is used. However, in case of nuclear industry it is rather recommended to design self-contained units, fully automated by simple ladder logic controller or microprocessor control. All operating parameters such as pressure, temperature, flow, tank level, pH, conductivity, and specific activity are monitored and recorded. Continuous visualization of main parameters' trends is very important and helpful. The control system includes also automatic start-up and shutdown of pressure pumps, dosing pumps, as well as shutdown of the whole installation in the case of unexpected event or emergency. The exceeding of the allowable operating parameters' limits should result in the start-up of appropriate blocs and alarms.

In view of the radiological safety the personal contact with operating installation should be minimized. The location of data acquisition and control systems has to be planned in separate room, away from places of potential contamination. However, the necessity of eventual periodic sampling has to be taken into account, too. The sampling points have to be located in the places with easy operator access and arranged in a way eliminating leaks and contamination.

##### 30.1.3.1.2 Precautions against Uncontrolled Pressure Excess

Membrane installations operated in nuclear industry are pressure-driven systems; majority of them are reverse osmosis plants. Uncontrolled growth of operation pressure may result in module damage and valves' leaks resulted in contamination hazard. The selection of appropriate pumps and security devices can avoid the danger of pressure overgrowth and its detrimental implications. The security valves' outlets have to be connected with existing waste distribution systems to direct the eventual leaks to the waste collecting tanks.

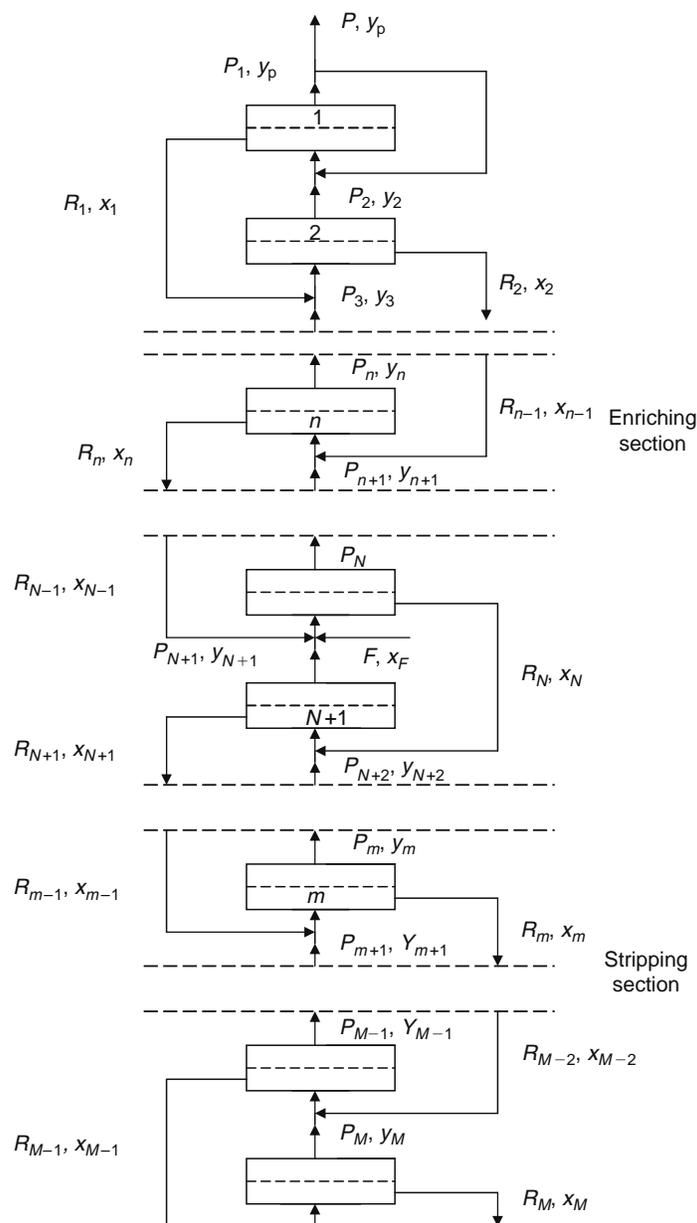

FIGURE 30.2 Recycling cascade with enriching and stripping sections.

#### 30.1.3.1.3 Precautions against Uncontrolled Temperature Excess

All polymeric membranes and modules have admissible temperature of operation. For most of them this temperature is  $40^{\circ}\text{C}$ , only for inorganic materials this temperature is much higher. In case of reverse osmosis there is a possibility of retentate and permeate temperature growth caused by the circulation under high pressure. The continuous temperature control of the streams with upper alarm has to be predicted. The systems collecting the excess heat (radiators, ribbed pipelines) allowing intensive cooling have to be designed.

#### 30.1.3.1.4 Precautions against Uncontrolled Overflow of the Tanks

All the tanks connected with membrane installation have to be equipped with tank level meters with devices and blockades of the pumps secured against overflow. Special collectors in the floor for contaminated solutions in case of unexpected overflow have to be designed.

### 30.1.3.2 Radiological Protection Requirements

Two systems for radiological control are required in case of membrane plant for radioactive waste processing: first, for process control and the second, for securing the staff and for avoiding the spread of contamination. The latter usually exists if the

installation is located in nuclear power plant or some other nuclear center. Some security devices have to be applied in the rooms where membrane plant will be placed. The lead shielding in places where increased radioactivity is expected, should be installed in accordance with precise preliminary measurements and dose estimations.

For process control purposes the radioactivity measurements of feed, permeate, and retentate solutions should be carried out. New batch of waste has to be controlled, and precise characteristics (radioactivity, conductivity, pH) of every new portion of the material should be done. The radioactivity of pure permeate before discharge has to be controlled, as well as periodic radioactivity of retentate before solidification or other stages of processing.

### 30.1.3.3 Membrane Control

#### 30.1.3.3.1 *Fouling in Radioactive Waste Treatment*

Fouling is one of the technical problems of membrane systems operation. The phenomenon occurs mainly in pressure driven membrane processes. There are four types of fouling: precipitation of dissolved solids, sediment of suspended solids, biological fouling and organic nonbiological fouling, caused by carbon-based molecules. The symptoms of fouling are decrease of permeate flow, increase of pressure drop across the module, and increase of total pressure in the unit. Therefore to keep the stable flux, pressure needs to be continuously increased. Usually 10%–15% reduction of the permeate flow should be a reason for immediate membrane cleaning. Otherwise, increase of pressure in the system and crystallization of salts or silica in the pores may result in the irreversible membrane structure change or damage.

Radioactive waste processing is usually a complex process combining often microfiltration and ultrafiltration with some other processes such as precipitation or binding with macromolecular ligands. During filtration of radioactive wastes, especially when suspensions or macromolecular species are separated, some deposit can be formed on membrane surface or inside the pores after several hours of operation. Particles deposited on the membrane surface can form the filter cake, which acts as a secondary membrane. The deposit causes the flux decline, however sometimes separation with secondary membrane can be better. This secondary membrane usually has smaller pores than original one and retains the molecules, which pass through the original membrane. As a result an accumulation of radioactive compounds takes place on the membrane surface. The membrane cleaning is usually done with a small volume of acidic, basic, and water solutions alternately. For polymeric membranes, temperature and chemical resistance of the polymers limit the choice of cleaning solutions. There is no such limitation in the case of inorganic membranes—ceramic or metallic. After washing, high concentration of radioisotopes is obtained in a small volume of cleaning solution. Sometimes the concentration of radioisotopes in secondary membrane can reach 90%. During the removal of radioactive strontium by ultrafiltration combined with precipitation with colloid  $\text{Ti}(\text{OH})_4$  after 2 h of operation 50% reduction of permeate stream was observed but 20-fold volume reduction and 140- to 150-fold decrease of  $^{90}\text{Sr}$  in the permeate were achieved [14]. The strontium balance showed that 94% of  $^{90}\text{Sr}$  was found in the secondary membrane. After washing, the UF membrane recovered its initial permeation properties and over 99.2% of strontium was transferred to the mixture of rinsing solution and retentate, volume of which was 18 times lower than feed solution. Similar effect, but not so intensive, was observed during ultrafiltration enhanced by complexation with polyethyleneimine—in the secondary membrane 7% of  $^{60}\text{Co}$  was retained, but it was hardly removable with rinsing [15]. Radiometric measurements of the membrane sample showed that some part of  $^{60}\text{Co}$  was persistently bound into the membrane. This was disadvantageous; especially for polymeric membranes, as the material of the membranes is permanently exposed to ionizing radiation emitting by bound radioisotopes that can result in the loss of the permeation abilities.

The most common methods of fouling prevention are wastewater pretreatment, the control of hydrodynamic conditions in the apparatus (low flux, high feed flowrates, turbulence promoting, dynamic filtration), or special construction of the module (cross-flow filtration).

#### 30.1.3.3.2 *Scaling Control*

During concentration of radioactive waste by pressure-driven membrane processes, such as reverse osmosis, the solubility limits of some dissolved salts can be exceeded. These salts precipitate on membrane surface or in other parts of the plant causing the damage of the membrane or severe corrosion of the elements of the installation. The most common compounds that precipitate easily causing scaling are calcium salts ( $\text{CaCO}_3$ ,  $\text{CaSO}_4$ ,  $\text{CaF}_2$ ,  $\text{CaHPO}_4$ ), barium and strontium sulfates, and silica and magnesium carbonates. The methods of scale minimization include: proper pretreatment, acid injection to reduce carbonates, water softening by lime or lime soda, ion exchange, removal of bivalent ions with nanofiltration and antiscalant addition. The scale inhibiting compounds are injected into the parts of the installation with the high risk of scale formation. These places have to be specified in the project design of the plant. Antiscalants delay precipitation by formation of microcrystals with low agglomeration abilities that interfere with crystallization of the other salts. The most common scale inhibiting chemicals are polyphosphates, polycarboxilites, polymalonates, and polyacrylates. In Chalk River Laboratories the antiscalant agent effectively preventing scaling in RO plant was Pretreat Plus (King Lee Technologies, San Diego, California) [16–20]. At the Institute of Atomic Energy in Poland in three-stage RO plant the sodium hexametaphosphate (Calgon) was

chosen. To prevent scaling in RO pilot plant designed and operated by ANSTO antiscalants AS-1000 (phosphinocarboxylic acid) and AS-1300 (polycarboxylic acid) were used [21].

One novel method for scale control is magnetic and electrostatic technology suggested by US Department of Energy [22]. This nonchemical technology is recommended for scale and hardness control as a reliable energy saver in certain applications that can be used as a replacement for most water-softening equipment.

#### 30.1.3.3.3 Membrane Cleaning

The periodic cleaning of the membranes exposed to the action of foulants and scalants present in the wastes is necessary. The frequency of the cleaning depends on the composition of the wastes. Its necessity is recognized basing on the pressure drop or rapid flux decrease. If the flux drops by several percent, the membrane has to be restored. The volume of the cleaning solutions should be as small as possible, to minimize the amount of secondary wastes.

The selection of the cleaning agents and their concentration depends on the membrane and on the kind of foulants present in the waste. Manufacturers of the membranes usually recommend some cleaning solutions, acidic or basic and detergents, which have to be tested during pilot plant experiments. The most popular agents are citric acid, sulphuric acid, sodium hydroxide, sodium tripolyphosphate, sodium ethylenediaminetetraacetate, and ethylenediaminetetraacetic acid (EDTA). These compounds are relatively inexpensive and widely applied, however sometimes specially prepared membrane manufacturers' formulations are superior and worthy of consideration. Such reagents, however, are very good centers of nucleation and initialization of fouling and scaling. Therefore, the subsequent fouling can be even more severe after restoration of the membrane. Various cleaning agents are available in the market. They can minimize the production of secondary wastes because they can clean the membranes very effectively. For polymeric RO membranes applied in Chalk River Laboratories, for example, good results were obtained using MEMCLEAN, alkaline detergent containing EDTA [16–20,23]. For cleaning ceramic membranes used at the Institute of Nuclear Chemistry and Technology (INCT), Warsaw, the P3-ultrasil, Henkel EKOLAB, was effective. On the other hand, laboratory preparations (e.g., alkali and acid based solutions) also proved very useful [24].

Apart from chemical cleaning, mechanical or compressed air restoration of the membranes can be possible. Mechanical cleaning is restricted only for some configurations, namely tubular modules, with easy access to the membranes. The foam balls introduced into the tubular membrane lumen can scrape the substances deposited on the surface, however they cannot remove the foulants from the membrane pores. The pores can be cleaned by backflushing with pressurized air or water shock in opposite direction. The method is limited to those membranes which are strong enough to withstand this force, or to the membranes on sufficient support. Some configurations (e.g., spiral wound) are not recommended for this method of cleaning.

A recent approach [25] is a method of direct membrane cleaning (DMC) applied for conductive membranes, such as stainless steel, graphite, and conductive ceramics. By short current pulses (1–5 s at 50–200 mA/cm<sup>2</sup>) electrolytic generation of microscopic gas bubbles takes place, which removes the solid deposit from the membrane surface without interrupting the filtration process. Such a cleaning enables the cross-flow velocities and transmembrane pressures to be reduced that implicates reduced plant wear and low-energy consumption with minimizing the size of the pressure pumps. The process was demonstrated on microfiltration and ultrafiltration membranes of different geometries. DMC was used during the treatment of low-level radioactive waste by microfiltration combined with inorganic sorbents: 44 ppm of nickel hexacyanoferrate for Cs removal, 33 ppm of zirconium phosphate for Sr removal, and 45 ppm hydrous titania for Ru, Ce, and actinides removal. Additionally Fe(OH)<sub>3</sub> was introduced to enhance actinides and Cs retention, and to trap fine particles on precipitated floc. When the mixed sorbents were concentrated to 5% by microfiltration, rinsing with 0.1 mM NaOH, which made the slurry conductive and ready for subsequent electrolytic dewatering up to 30% of solids, reduced the salt content. Finally the concentrate was immobilized with cement powder.

#### 30.1.3.3.4 Secondary Wastes

Membrane installations generate secondary wastes that have to be taken into consideration before plant design. Reverse osmosis produces permeate, which can be discharged after radioactivity control, and retentate that can undergo further processing. Usually the retentate is not suitable for solidification and further volume reduction is necessary.

Secondary wastes are also generated during regular cleaning procedures, because fouled membranes have to be washed or cleaned by cleaning solutions. The concentration of radioisotopes in these solutions is sometimes high and they need treatment by recycling to the feed at the inlet of membrane installation. The additional volume of the waste has to be taken into account in plant design, as well as the influence of extra load on the membrane performance.

The plant itself is a source of secondary solid waste; membranes, and spent filter cartridges and related small parts have to be processed by common methods such as compaction or incineration to reduce their volume or have to be left for decay, if adsorbed radioisotopes have short half-life time.

#### 30.1.3.3.5 Membrane Exchange

For the treatment of conventional, nonradioactive liquid waste the predicted lifetime of membranes is 4–5 years. The effective lifetime depends on the conditions in which the membrane is used; the characteristics of solutions treated, pressure, and temperature. While selecting the membrane for radioactive waste processing, one has to remember about its resistance and

stability under ionizing radiation exposure. The membranes, which are used in the installation, have to be tested before final decision about their application. In spite of that, expected lifetime for polymeric membranes will not be longer than 5 years. After this period membranes have to be exchanged. Depending on membrane type and configuration the whole membrane modules or the cartridges where the membranes are assembled can be exchanged. The necessity of membranes' exchange has to be taken into account on the design stage. Security considerations, easiness of operations, and easiness of decontamination are very important. Sufficient space has to be reserved for work with membrane modules, which have to be exchanged and means of minimization of contamination have to be foreseen.

Spent membranes and membrane cartridges do not undergo regeneration; they are treated as a solid radioactive waste. They can be stored for decay or processed as other solid waste material.

#### 30.1.3.4 Decontamination of the Space and Equipment

All potential points of leaks and other hot spots have to be identified in the stage of design. The decontamination procedures in case of accident have to be elaborated. The specification of the equipment for eventual decontamination and the means of decontamination are defined in laboratory instructions and manuals. All necessary safeguards and security systems are the elements of the project design. In case of emergency all means limiting the decontamination spreading out have to be used.

## 30.2 MEMBRANE PROCESSES EMPLOYED FOR LIQUID RADIOACTIVE WASTE TREATMENT

### 30.2.1 REVERSE OSMOSIS

Reverse osmosis has been employed in full scale in many nuclear centers around the world. Permeate after reverse osmosis can be directly discharged to the environment or recycled as service water within nuclear power plant. There are a number of industrial RO applications and facilities in the stage of pilot plants operating for radioactive waste processing. Some examples of installations are presented in Table 30.1.

#### 30.2.1.1 Three-Stage Reverse Osmosis Installation for Low- and Intermediate-Level Radioactive Wastes Processing

Laboratory and pilot plant experiments carried out at INCT showed that reverse osmosis is very useful for the treatment of liquid low-level radioactive wastes from Polish nuclear laboratories. However, to reach high decontamination the process should be arranged as a multistage operation with microfiltration or ultrafiltration pretreatment [32,33].

The RO process was implemented at the Institute of Atomic Energy, Świerk. The wastes collected there, from all users of nuclear materials in Poland, have to be processed before safe disposal. Until 1990 the wastes were treated by chemical methods that sometimes did not ensure sufficient decontamination. To reach the discharge standards the system of radioactive waste treatment was modernized. A new evaporator integrated with membrane installation replaced old technology based on chemical precipitation with sorption on inorganic sorbents. Two installations, EV and 3RO, can operate simultaneously or separately. The membrane plant is applied for initial concentration of the waste before the evaporator. It may be also used for final cleaning of the distillate, depending on actual needs. The need for additional distillate purification is necessitated due to entrainment of radionuclides with droplets or with the volatile radioactive compounds, which are carried over.

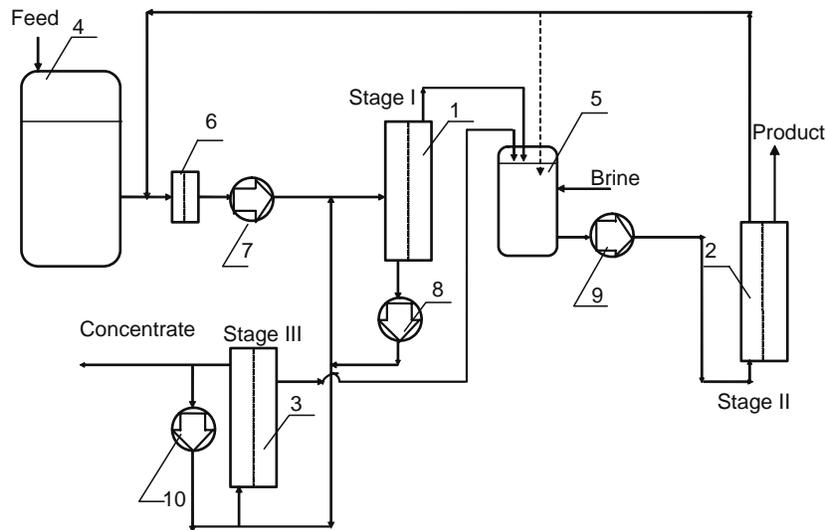

Evaporation is, however, a very efficient cleaning process, although it is highly energy consuming. The application of the membranes at the beginning of cleaning cycle reduced significantly the energy consumption.

Membrane installation, capacity of  $\sim 1 \text{ m}^3/\text{h}$  pure permeate, was composed of three stages of reverse osmosis (Figure 30.3) preceded by pretreatment with polypropylene depth filters. The first two stages were used for purification, and the third one for final concentration. Two types of spiral-wound RO modules were used in the installation: SU-720R and SU-810 (TORAY). Both types of modules worked under a pressure of 20 bar and with high salt rejection, higher than 99%. The membrane was manufactured from cross-linked fully aromatic polyamide composite. Two Model SU-720R modules connected in series placed in a single housing formed the first stage of reverse osmosis. The second stage was the same as the first one: two modules placed in a single housing. The third stage was composed of two housings in parallel, two Model SU-810 (TORAY) modules in each vessel. The view of the plant is shown in Figure 30.4.

Liquid radioactive waste was directed from the waste storage tank to the  $8 \text{ m}^2$  feed reservoir. After pretreatment with PP depth filters and injection of antiscalant, the wastes were directed to the first stage of RO. The retentate from this stage was concentrated in the third RO unit. The concentrated solution could be directly solidified if the concentration of the total solute was appropriate ( $< 250 \text{ g}/\text{dm}^3$ ). The salt concentration is limited by the conditions of concrete solidification. If the concentration was not sufficient, the further concentration took place in the evaporator. Permeate from the first and third stages was directed to the permeate reservoir before the second RO unit. The product from the membrane installation (permeate from the second stage) was of required radiochemical purity and after the control of specific activity and salinity was discharged to the communal sewage.

**TABLE 30.1**  
**Examples of Nuclear Facilities Applying RO for Liquid Radioactive Wastes Processing**

Facility	Type of the Waste	Process and Type of the Membranes Used	Capacity	Results	References
Chalk River Laboratories (Canada)	Mixed aqueous waste	Tubular (TRO) and spiral-wound (SWRO) RO (Filmtec SW30HR) with MF pretreatment	3 m <sup>3</sup> /h	2200 m <sup>3</sup> per year processed wastes VRC = 200–400 Retention: 99.9% ( $\alpha$ ); 99% ( $\beta$ and $\gamma$ ); 99.5%–99.8% solids	[16–19,26]
ANSTO (Australia)	Low-level radioactive wastes from laboratories and radioisotope production	Two passes for permeate purification and two stages of concentration by RO spiral-wound modules (4" Filmtec XLE-4040 and 2.5" Filmtec BW30–2540) with UF pre-treatment (PCI FPA10 modules)	1.2 m <sup>3</sup> /h	High purity effluent was obtained. Flux decline in UF tubular unit was observed, resulting from irreversible fouling of membranes by surfactants coming from radiopharmaceutical production. The additional pretreatment step was recommended	[21,27]
Nine Mile Point nuclear power plant (United States)	BWR floor drains and other wastes from NPP	RO systems based on Thermex	36,300 m <sup>3</sup> /year	11 m <sup>3</sup> /year of solid waste generated; total organic carbon in the effluent <50 ppb, conductivity of 0.058 mS/cm. The plant operates without secondary wastes	[28]
Pilgrim nuclear power plant (United States)	BWR floor drains and various other wastes	RO systems based on Thermex		The waste volume decreased in time of the system operation, personnel exposure associated with radioactive waste operation was reduced	[28]
Wolf Creek nuclear power plant (United States)	Floor drains and other wastes	Spiral-wound RO with tubular UF modules for pretreatment	Processing rate of drum dryer (DD): 4620 L/d	The installation equipped with DD unit and demineralizer system; high-salinity solutions are filtered; VRC = 10–20	[28,29]
Bruce nuclear power plant (Canada)	Wastes from chemical cleaning of steam generator	UF (Zenon ZPF-12 tubular membrane modules) and two-stage RO (Filmtec SW30HR) coupled with wet oxidation technology (WAO)		Permeate meets the criteria for sewer usage; the RO concentrate is returned for further processing (WAO, solidification)	[30]
Comanche Peak nuclear power plant (United States)	Floor drains, resin sluice water, and boron recycling water	UF with RO and NF (RWE NUKEM)	2.28 m <sup>3</sup> /h	The suspended matter is rejected by UF unit, dissolved compounds by RO. NF membranes were used for passage of boron. Membrane technology followed by IEX performed better than existing demineralizer	[28]
Dresden nuclear power plant (United States)	Wastes contaminated by transuranic elements	UF with RO	Two tanks of total volume 1440 m <sup>3</sup> for processing	Permeate from the installation passed deep bed demineralizers; after radioactivity control was discharged from the plant. Volume reduction of tank wastes by factor of 10	[28]
Savannah River site	Reprocessing wastes with high concentration of sodium nitrate	MF (cross-flow filters, 0.2 $\mu$ m) and RO (high salt rejection spirally wound elements)		Plant met the discharge criteria; one of the major problems was biofouling of the MF membranes	[28,31]
IEA, Warsaw, Poland	Wastes from nuclear laboratories and application of radioisotopes	Two passes for permeate purification, two stages of concentration by RO spiral-wound modules (SU-720R, SU-810 [TORAY])	1 m <sup>3</sup> /h	Complete purification of effluent ( $\beta$ and $\gamma$ emitters is lower than 10 kBq/m <sup>3</sup> , $\alpha$ emitters lower than 1 kBq/m <sup>3</sup> , TDS < 0.1 g/dm <sup>3</sup> ), concentrated retentate for solidification	[33]

**FIGURE 30.3** A scheme of three-stage RO plant. 1–first stage RO, 2–second stage RO, 3–third stage RO, 4–feed tank, 5–intermediate tank, 6–depth filters, 7,8,9,10–pumps.

The laboratory experiments showed the influence of the total concentration of ballast non-active salts on decontamination factors. As the concentrations of total solute in permeate from the first and third stages were very low a decrease of retention of radionuclides was observed. To improve the efficiency of radioisotopes removal additional salt injection took place before the second stage.

The characteristics of permeate and retentate streams in terms of upper limits at the exit of RO plant were presented in Table 30.2. The concentration of salt in permeate is lower than  $0.1 \text{ g/dm}^3$ . The concentration of some specific elements as heavy metals has to be in conformity with the limits of impurities for wastes discharged to the inland waters. Total specific activity for  $\beta$  and  $\gamma$  emitters is lower than  $10 \text{ kBq/m}^3$ , while for  $\alpha$  emitters it is lower than  $1 \text{ kBq/m}^3$  (the limits for liquid waste). The total salt concentration in retentate is limited by ability of binding the solution with the concrete, the specific radioactivity by nuclear

**FIGURE 30.4** (See color insert following page 588.) Three-stage RO plant for radioactive waste processing at Institute of Atomic Energy in Swierk.

**TABLE 30.2**  
**Characteristics of the Streams After RO Installation**

<i>Retentate</i>	
Total concentration (g/dm <sup>3</sup> )	250
Specific activity	10 <sup>7</sup> kBq/m <sup>3</sup> (0.3 Ci/m <sup>3</sup> )
<i>Permeate</i>	
Total concentration (g/dm <sup>3</sup> )	0.1
Specific activity	0.01 ALI <sub>p</sub> /m <sup>3</sup> or <10 kBq/m <sup>3</sup> (β and γ) and <1 kBq/m <sup>3</sup> (α)

safety regulations. On the basis of parameters defined below the filtration abilities of the membranes to clean radioactive waste and the performance of the installation were assessed. The values calculated from the experimental results are presented in Table 30.3.

$$R = \frac{c_f - c_p}{c_f} \times 100\% \quad (30.1)$$

$$DF = \frac{A_f}{A_p} \quad (30.2)$$

$$K_{TDS} = \frac{c_f}{c_p} \quad (30.3)$$

$$CF = \frac{A_R}{A_f} \quad (30.4)$$

The retention of the dissolved salts by 3RO unit was higher than 99% in each case; decontamination factors were also high. Predominant purification took place in the first stage of reverse osmosis; the second stage played the role of final purification. Permeate in majority of cases was sufficiently pure for discharge. However, when the initial activity of the waste was high (the A feed solution), the radioactivity of the product was too high for discharge and hence permeate was returned to the installation

inlet tank. Injection of the salt solution (NaCl) before the second stage increased decontamination factor in that stage from 3.09 to 91 and for entire plant to 13,700 (the numbers obtained for A waste sample).

The results of radioactive waste sample C treatment with 3RO are shown in Figure 30.5. The feed radioactivity is 2,200 Bq/dm<sup>3</sup>. After processing permeate has radioactivity below discharge limits (3.9 Bq/dm<sup>3</sup>) and can be discharged; the concentrate of radioactivity 16,000 Bq/dm<sup>3</sup> can undergo further processing. The average decontamination factor for entire plant is 564.

### 30.2.1.2 Other Applications

Reverse osmosis preceded by microfiltration or ultrafiltration is considered as an option for the treatment of radioactive wastes from Romanian nuclear centers. Effective studies are carried on at Research Center for Macromolecular Materials and Membranes, Bucharest and at Institute of Nuclear Research, Pitesti aiming in employing these pressure-driven techniques for cleaning the wastes from decontamination of nuclear installations and reactor primary circuit [34,35].

There are assessments predicting the use of reverse osmosis for the processing of the wastes from medical application [36,37] and for the removal of caesium-137 from decontamination wastes after accident in the steel production factory [38]. RO is considered as a method for removal of radioactive pollutants from contaminated water (removal of <sup>137</sup>Cs and <sup>90</sup>Sr) in the vicinity of atomic power plants [39], as well as for removal of small quantities of radionuclides (<sup>222</sup>Rn, <sup>234</sup>U, <sup>238</sup>U, <sup>226</sup>Ra) from drinking water [40,41].

## 30.2.2 NANOFILTRATION

Membranes having effective pore sizes between 0.001 and 0.01 μm are used in nanofiltration. NF is placed between reverse osmosis and ultrafiltration, and because of that it is sometimes considered as loose reverse osmosis. Typical operating pressures for NF are 0.3–1.4 MPa. The process allows to separate monovalent ions from multivalent ions, which are retained by NF membrane. The process can be used for separation of organic compounds of moderate molecular weight from the solution of monovalent salts. The very well-known application in nuclear industry is boric acid recovery from contaminated cooling water in nuclear reactor. There are some examples of nanofiltration applications and studies done with the aim of implementation in nuclear centers described in literature. Some of them are listed in the Table 30.4.

## 30.2.3 ULTRAFILTRATION

Ultrafiltration operates at lower pressures (0.2–1 MPa) than reverse osmosis and with higher permeate fluxes. It uses more porous membranes, pore size of 0.001–0.1 μm. In such a case, low-molecular weight dissolved compounds pass through the membrane, while colloid and suspended matters are rejected by UF membrane.

In nuclear industry ultrafiltration was applied in the pretreatment stage before reverse osmosis that needs removal of potential foulants from feed streams. Very often ultrafiltration is combined with precipitation or complexation. Small ions bound by macromolecular chelating agent form complexes, which are retained by UF membrane. Such an enhanced ultrafiltration becomes an efficient separation process with high decontamination factors, sometimes compared with those

**TABLE 30.4**  
**Examples of Application of NF for Liquid Radioactive Wastes Processing and Isotopes Separation**

Facility	Type of the Waste/ Process Stream	Process and Type of the Membranes Used	Results	References
Chalk River Laboratories (AECL, Canada)	Reactor coolant (cleaning and boric acid recovery)	Three-stage installation, NF membranes	The products of the plant are concentrated boric acid, which after purification can be recycled and the concentrate of radioisotopes for immobilization.	[42]
Bugey nuclear power plant (France)	Reactor waters (separation of ionized silica and boric acid)	NF	NF allows the separation with 92% recovery for silica and 16.5% for boron. The corrosion, activated cations ( $\text{Sn}^{2+}$ , $\text{Ag}^+$ , $\text{Co}^{2+}$ ) are retained by the NF membranes.	[43]
ANSTO (Australia)	Uranium mill effluents	NF membranes in cross-flow membrane cell	The rejection for uranium was greater than 75%. Some of the tested membranes showed potential for separation of radium, sulfate and manganese.	[44]
ESWE—Institute for Water Research and Water Technology, Wiesbaden (Germany)	Water with dissolved uranium	NF membranes from Osmonic Desal (Desal 5 DK, Desal 5DL and Desal 51 HL) and Dow (NF 90 and NF 45)	Divalent anion complex $\text{UO}_2(\text{CO}_3)_2^{2-}$ and four- valent anion complex $\text{UO}_2(\text{CO}_3)_3^{4-}$ were rejected between 95% and 98% by four membranes and between 90% and 93% by NF90 membrane.	[40]
Kyungpook National University (Korea)	Simulated nuclear waste containing strontium	NF with complexation with polyacrylic acid, Nitto Denko NTR7410, NTR7250 and NTR729HF membranes	Greater Sr removal at elevated pH was attributed to the formation of $\text{SrCO}_3(\text{s})$ due to dissolution of atmospheric $\text{CO}_2$ . Improvement of Sr removal was achieved with the addition of PAA, an increase of membrane fouling was observed at lower pH.	[45]
CEN de Cadarache	Simulated nuclear waste containing strontium	NF with complexation with polyacrylic acid, Filmtec NF 70 membranes	The effect of complexation was diminished in high concentration of non-active sodium nitrate. 98.2% concentration of strontium was achieved and 70% of sodium nitrate from the waste was eliminated in two-stage process.	[46]
Laboratoire de Catalyse et Synthèse Organique, Université Claude Bernard, Lyon	Separation of lanthanides and actinides, separation of lanthanide isotopes	NF/complexation with EDTA, DTPA and new ligands on the basis of DTPA. Sepa MG-17 NF membrane (Osmonics)	Separation factors $\alpha(^{150}\text{Nd}/^{142}\text{Nd}) =$ $1.0021 \pm 0.0016$ and $\alpha(^{160}\text{Gd}/^{155}\text{Gd}) =$ $1.0028 \pm 0.0014$ were obtained.	[47–50]
Laboratoire de Catalyse et Synthèse Organique, Université Claude Bernard, Lyon	High-salinity wastes containing caesium	NF/complexation with resorcinarens and calixarens	The $\text{Cs}^+/\text{Na}^+$ selectivity from 3 mol/L aqueous $\text{NaNO}_3$ solution was about 90%. With the two- stage process 99% removal of trace quantities of caesium was achieved and sodium retention not higher than 10%.	[51]

obtained by reverse osmosis. Radioactive cations can be removed in precipitation process forming less-soluble particles (carbonates, phosphates, oxalates, or hydroxides) which are later filtered with UF membrane. These hybrid methods are effectively used in many plants processing  $\alpha$ -bearing radioactive waste streams. Number of installations is under operation in nuclear centers and many efforts are done to implement ultrafiltration for radioactive wastes processing. Ultrafiltration installations were tested at nuclear power plants around the United States. These experiments proved usability of UF systems for the treatment of aqueous wastes from floor drains, water from reactor cooling system, as well as for some type of waste from reprocessing plants. In some cases, the pilot plant experiments were followed by construction of full-scale installations. The examples of the full-scale plants operated in some nuclear centers, as well as testing facilities, applying UF for radioactive wastes processing are performed in Table 30.5.

There was a suggestion to treat the wastes from laundries cleaning the contaminated cloths by ultrafiltration [54–56]. These wastes contain surfactants, high alkalinity and high-salt concentration. It is difficult to process them by evaporation where considerable foaming takes place with contaminated droplets carryover. The concept of UF use for this kind of waste is advantageous because of the possibility of detergents recycling and reuse. The detergents are recovered in permeate, while all suspended particles, fibers, and radionuclides are rejected in the retentate.

One of the current researches devoted to membrane treatment of radioactive waste is directed toward seeded ultrafiltration and all methods, which combined with ultrafiltration, give considerable enhancement of separation (Table 30.6).

**TABLE 30.5**  
**Examples of Nuclear Testing Facilities Applying UF for Liquid Radioactive Wastes Processing**

Facility	Type of the Waste	Process and Type of the Membranes Used	Results	References
Enhanced Actinide Removal Plant at Sellafield	Wastes containing actinides after precipitation stage	Two-stage UF	First stage produces a concentrate of a few wt% solid content that is dewatered in a second stage	[25]
Paks nuclear power plant	Contaminated boric acid solutions	Plate and frame UF modules with polysulphone membranes	The volume reduction of about 45 and decontamination factors in the range 10–100 were obtained	[52]
Nukem, Hanau	Low-level wastes from a fuel fabrication plant	UF with co-precipitation pretreatment	DFs of about 100–200; VRC achieved by UF 10–15 times greater than that obtained with precipitation	[53]
River Bend nuclear power plant (United States)	Floor drains from BWR	UF with IEX	Permeate from UF is additionally polished in ion-exchange beds and after that water is recycled in the plant. Feedwater turbidity decreases from 20–150 NTU to <0.1 NTU	[28]
Salem nuclear power plant	Low-level radioactive wastes, which originate from floor drains from PWR, laboratories, sampling points and auxiliary equipment drains	Tubular UF modules and demineralization unit	UF membranes remove particles smaller than 0.05 $\mu\text{m}$ , oil, grease, colloids, and metal complexes protecting IEX beds. The quantity of $^{58/60}\text{Co}$ , $^{54}\text{Mg}$ , and $^{100}\text{Ag}$ , is reduced	[28]
Seabrook nuclear power plant (United States)	Floor drains from PWR and spent resins tank drain-down	UF with cation resin demineralization	Colloidal $^{58}\text{Co}$ removed below discharge limits and more than 90% of TSS was removed by UF system	[28]
Callaway nuclear power plant (United States)	Floor drains and equipment drains tanks, reactor coolant water	UF with IEX	70% of radioactivity and suspended solids were removed from coolant water with UF; 89% of radioactivity and suspended matter from floor drains. The full-scale plant configured in 2001 consisted of UF and ion-exchange units, processed the waste for direct disposal	[28]
Diablo Canyon nuclear power plant (United States)	Spent media transfer liquid containing high concentration of radioactive submicron particles	Two mobile, skid-mounted tubular UF plants	Systems produced the liquid free from particulate activity that can be introduced into the IEX columns without the danger of serious fouling and deterioration of their performance	[28]
Mound Laboratory (United States)	Wastes from a fuel reprocessing plant	4.5 m <sup>3</sup> /h installation composed of 32.3 m long tubular UF elements, of total surface area 6.5 m <sup>2</sup>	80%–99% of $\alpha$ emitters were removed in the test operation and high retention of transuranic elements in full-scale installation was observed ( $^{241}\text{Am}$ —98.9%, $^{238}\text{Pu}$ —98.6%, $^{237}\text{Np}$ —69.1%, $^{233}\text{U}$ —93.7%)	[28]

Extensive studies were done within the International Atomic Energy Agency (IAEA) coordinated research programme on the use of inorganic adsorbents for the treatment of aqueous wastes and backfill of underground repositories [61]. In 1992–1996, IAEA coordinated research programme on waste treatment and immobilization technologies involving inorganic sorbents that resulted in elaboration of new technologies of production of sorbents, which can be applied in nuclear industry. The sorbents can be used in minced form that can be directly introduced into the feed streams treated by ultrafiltration or in more coarse form for ion-exchange columns followed the membrane process [62,63].

The processes of UF and enhanced UF for low and intermediate-level radioactive waste treatment were studied at INCT, Poland. Liquid radioactive wastes originating mainly from application of radioisotopes are collected from all of Poland at Institute of Atomic Energy, in Świerk. They contain various radioactive substances (total specific activity <10<sup>7</sup> kBq/m<sup>3</sup>) and ballast non-active salts (concentration <5 g/dcm<sup>3</sup>), as well. In the solution, small radioactive ions such as  $^{51}\text{Cr}^{3+}$ ,  $\text{H}^{51}\text{CrO}_4^-$ ,  $^{60}\text{Co}^{2+}$ , and  $^{137}\text{Cs}^+$  are present; most of them can easily pass through the membrane for which cutoff value is ~2000 MW. The decontamination factors obtained by using ultrafiltration membranes are low (1.07–1.12). The possibility to improve the removal efficiency and to increase decontamination factors is the application of reverse osmosis or ultrafiltration enhanced by complexation. Ultrafiltration membranes that are permeable to the small ions retain the macromolecules or particles formed in the process of complexation or sorption.

**TABLE 30.6**  
**Examples of Test Facilities Using Enhanced UF for Liquid Radioactive Wastes Processing**

Facility	Type of the Waste/Process Stream	Process and Type of the Membranes	Type of Sorbent/Binding Agent	Results	References
Cadarache Nuclear Research Centre	Synthetic solutions and actual liquid radioactive wastes	UF with sorption	Activated charcoal and nickel hexacyanoferrate, soluble polymers	Good removal of plutonium, strontium, cesium isotopes, moderate of ruthenium and cobalt	[54]
Harwell Laboratory, UK	PWR wastes (wastes containing actinides—colloidal forms of plutonium and americium—in alkaline solutions, laundry wastes)	UF with sorption (seeded UF)	Manganese dioxide, sodium nickel hexacyanoferrate, hydrous titanium oxide, zirconium phosphate, ferric hydroxide, different commercial sorbents	The process is capable of reducing the amount of radioactivity in aqueous effluents to very low levels	[57–60]
University of Colorado, Department of Chemical Engineering	Environmental waters	Polymer-assisted UF	Hyperbranched chelating polymers (glucoheptanamide, polyamidoamine and polyethylenimine derivatives)	Removal of boric acid from water solutions, remediation of water	[64]

The selection of appropriate complexing agent is very important to remove the radioisotopes with high efficiency. Each ion needs specific ligand, which has to fulfil special requirements:

1. High molecular weight, selected for each UF membrane cutoff
2. Good solubility in water
3. Ability of selective binding the ions and molecules
4. Stability of complexes under the process condition
5. Nontoxic, not causing potential hazard
6. Low price and market availability

Many different complexing agents and adsorbents were examined. As ligands attaching ions of Cr, Co, and Cs, polyethylenimine (PEI), microcrystalline chitosan (MCH), polyacrylic acid (PAA) and its derivatives, polyvinylpyrrolidone (PVD) and suspension of hexacyanoferrates of transient metals were applied [62,71].

The experiments were carried out with laboratory-scale units and with pilot plants. The polymeric (capillary-type UF module Amicon H26P30–43, cutoff =  $3 \times 10^4$  MW, membrane surface area  $2.5 \text{ m}^2$ ) and ceramic UF membranes (Membralox and CeRam Inside) were employed. The solution of selected radionuclides, simulated sewage, and original liquid low-level radioactive wastes was used in filtration tests. Chelating complexing agents were added to the feed solution to bind the radioactive ions. After mixing and seasoning the sample was filtered with UF membrane at fixed pH and ambient temperature.

### 30.2.3.1 Removal of Radionuclides from Water Solutions by Ultrafiltration/Complexation

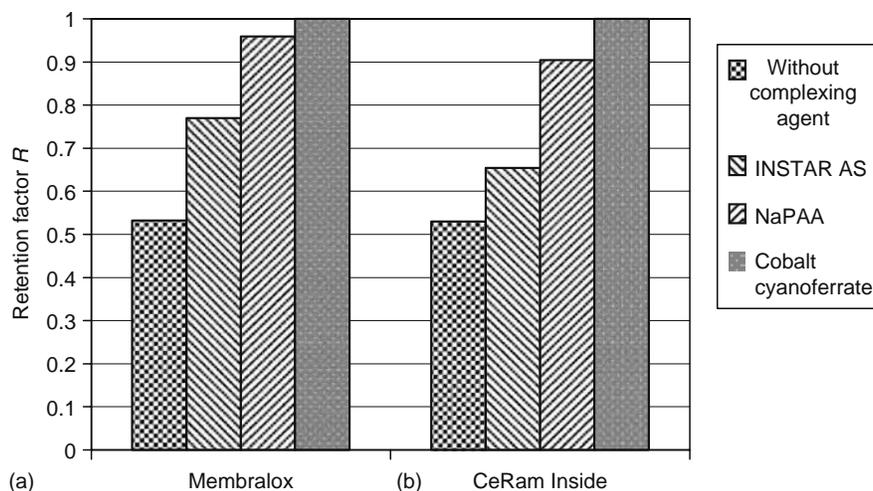

Membralox tubes, 250 mm long and 7/10 mm diameter with the membrane placed inside the tube and CeRam Inside three-channel tubes, were tested at INCT [24,71,72]. The pore size of ceramic membranes was in 1 kDa to 100 nm range. The tests were performed with non-active and radioactive model solutions. The experiments proved that membranes in UF range were not sufficient to achieve high decontamination factors and the process has to be combined with chemical complexation or sorption. The experiments showed significant increase of retention factors and decontamination factors when macromolecular compounds were added. Example of the results for two membranes: Membralox tube with 50 nm filtering layer and CeRam 15 nm is shown in Figure 30.6. The retention of caesium ions was similar for both membranes. When ultrafiltration was combined with complexation with macromolecular ligands the retention was improved. Retention factors for Membralox 50 nm were higher than for CeRam. An exception was the case when sodium cyanoferrate was added. For both membranes the retention factors were close to 1. For two membranes the application of macromolecules resulted in the increase of retention.

The retention and decontamination factors for cobalt ions were low when UF membranes were applied (Figure 30.7). To intensify effect of separation the complexing agents, polyacrylic acid of different cross-linking, polyacrylic acid salts, polyethylenimine, and Instar AS (complexing agent containing macromolecular acrylamide and sodium acrylate copolymer) were added to the feed solution. The results of ultrafiltration of cobalt ions complexed before filtration by the soluble polymers are presented in Figure 30.7. The experiments showed high influence of the polymer, its chemical form and average molecular weight on retention factors. The best results were obtained when sodium polyacrylate of high-molecular weight or polyethylenimine were employed.

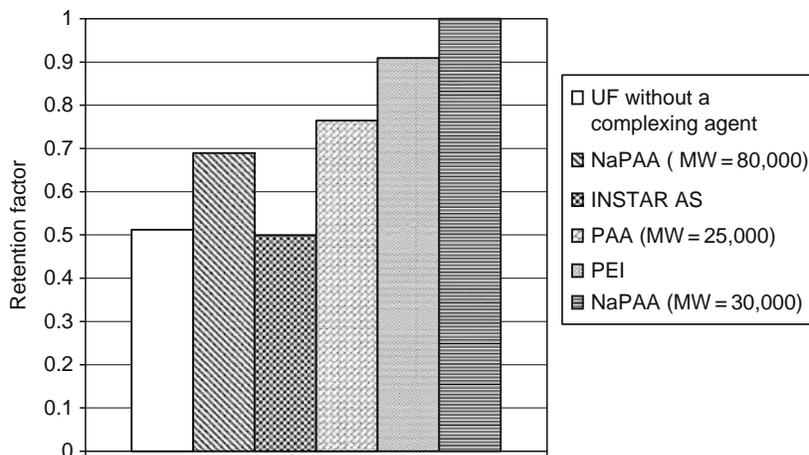

Application of macromolecular chelating polymers allows catching small radioactive ions with good efficiency. Soluble polymers efficiently bound radioactive cobalt and chromium, however the complexation of  $\text{HCrO}_4^-$  ions was difficult. Chromate ions were removed with MCH, which is a good sorbent for all metals, however decontamination factors for radioactive chromium in the form of  $\text{H}^{51}\text{CrO}_4^-$  were moderate. Caesium isotopes were effectively removed with cyanoferrates of transient metals; copper cyanoferrate more effectively binds caesium than cobalt cyanoferrate. The meaningful dependence of retention and decontamination factors on pH was observed (Figure 30.8). Favorable conditions of binding the caesium with cyanoferrates are in alkali environment, under  $\text{pH} > 8$ , while the best complexation abilities of soluble polymers are in neutral conditions. It was found that the best conditions of binding  $^{51}\text{Cr}^{3+}$  and  $^{60}\text{Co}^{2+}$  ions with PEI macromolecules occur at  $\text{pH} = 4-6$ . The most effective adsorption of ions  $^{137}\text{Cs}^+$  by CuFC was found at  $\text{pH} = 9.5-10.5$ .

Binding abilities of the soluble polymers fall down slowly with the concentration of alkali metals. In Figure 30.9, the results of UF/complexation with polyethylenimine (PEI), polyacrylic acid of different cross-linking (PAA1 and PAA2) and polyacrylic acid amide were presented. In each case the decontamination factors for  $^{60}\text{Co}$  decrease when concentration of alkali metals increase from 0.1 to 2.5  $\text{g}/\text{dm}^3$ . The increase of alkali metals causes decline of decontamination factor for radioactive caesium, while cyanoferrates are applied as a sorbents (Figure 30.10).

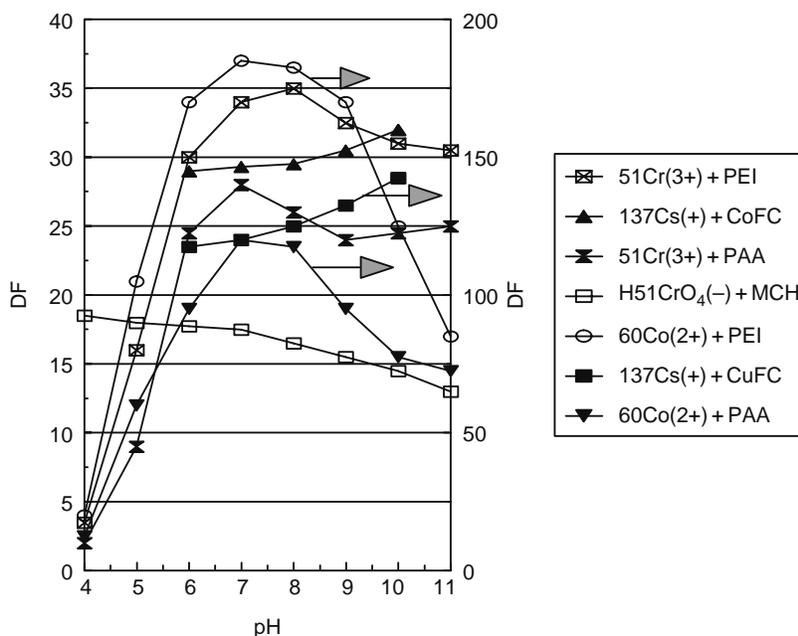

The concentration of the complexing agent should be selected for each radioisotope–complexing agent pair. Usually the concentration ratio, the ligand to the ion bound by this ligand, is in the range 1–20. Figure 30.11 shows DFs for europium-152 as a function of concentration of NaPAA of MW = 8000, which was selected to remove this radioisotope. The best binding conditions were found at concentration of 8  $\text{g}/\text{dm}^3$ , which corresponds to the concentration ratio of polymer to europium,

such as 18.5:1. For this concentration ratio DF was the highest. Further increase of ligand concentration did not result in increase of decontamination factor.

### 30.2.3.2 Treatment of Original Radioactive Waste

When actual radioactive waste is treated by UF/complexation method the decontamination factors for each radioactive component of the sample differ from those obtained for single ion-solutions. The ions interfere and compete in complexation process and the salinity of the wastes influences removal that results in lower decontamination factors. The characteristics of radioactive waste used in ultrafiltration experiments are shown in Table 30.7. The sample had relatively low salinity (<1 g/dm<sup>3</sup>); its specific radioactivity was in medium-level liquid waste range (~150 kBq/dm<sup>3</sup>). The main portion of radioactivity came from cobalt-60 and caesium-137, but some quantities of lanthanides and small amount of actinides (<sup>241</sup>Am) were also present. Decontamination factors obtained for actual waste differed from DFs obtained for solutions of single radioisotopes. As was proved before [71], the concentration of alkaline metals influenced DF markedly. The competition between different ions bound by chelating ligands or adsorbents resulted in increase of retention and decontamination factors for original liquid waste. The results of UF/complexation tests are shown in Table 30.8 and decontamination factors calculated for selected radioisotopes in Figure 30.12.

The hybrid UF/complexation process appeared very effective for removal of americium and europium isotopes; in the majority of permeate samples the concentration of these radioisotopes was below detection limits or very small. Good removal of <sup>60</sup>Co was observed with sodium polyacrylate of MW > 15,000 Da and with polyethyleneimine. The complexation of caesium ions with chelating polymers was rather moderate; good results were obtained with cobalt cyanoferrate and decontamination factors were higher than 100. Average decontamination factors for total waste radioactivity were low, except for the case when two complexing agents were dosed to the effluent simultaneously: PEI and CoCF (Table 30.8). The results obtained in the experiment when cobalt hexacyanoferrate together with soluble polymer (PEI) were applied showed significant

<sup>a</sup> Concentration of metals performed as a total concentration of the element in different chemical forms.

increase of <sup>137</sup>Cs removal, however the decontamination factors for other radioisotopes decreased in comparison of the tests when only single chelating polymer was applied as a complexing agent.

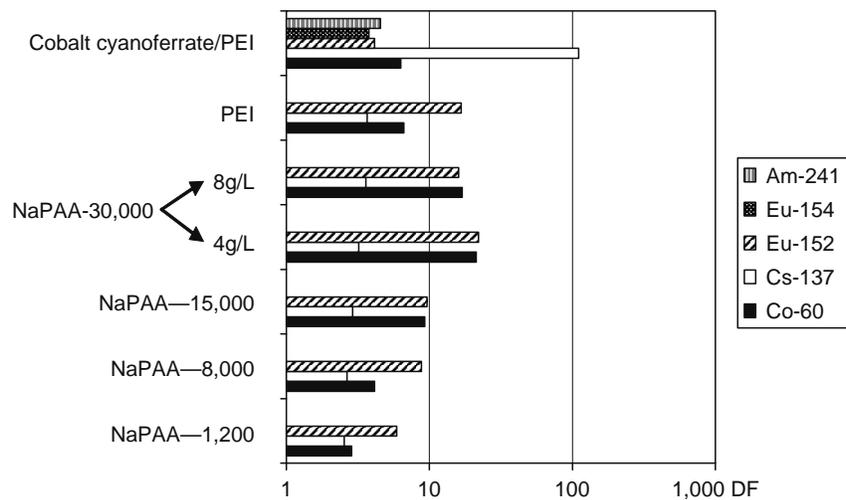

One of the major limitations of UF/complexation is that removal of isotopes by this method is efficient when the mixture of the ligands binds the ions effectively under the same conditions (the same pH, concentration of alkali-metals salts, etc.). To overcome this problem the process may be run in multistage system and the complexing agents are dosed in the successive stages to remove some specific ions separately. The above process was divided into two steps to enable high-removal efficiency. At first, CoCF slurry was introduced into the feed solution to bind the caesium ions. After some hours the feed was filtered with UF ceramic membranes up to threefold volume reduction. Sodium polyacrylate, MW 30,000, was added to permeate and after seasoning and pH adjustment the solution was filtered. The DFs for such a process arrangement were performed in Figure 30.13. In the first stage of filtration high removal of Cs-137 was achieved, while other radioisotopes were rejected in moderate rate. In the second stage, where sodium polyacrylate was employed decontamination factors were much higher for most of the radioisotopes present in the waste. Only <sup>137</sup>Cs ultrafiltration gave DFs smaller than 1 that corresponds with higher specific activity in permeate. Low DF < 1 shows that Cs-137 is not bound by NaPAA and passes through the membrane. Additionally, low concentration of this radioisotope and generally low total salinity of the effluent may cause low decontamination for caesium after the treatment in the first stage. This was earlier observed during operation of three-stage RO plant, where decrease of total salinity before the final purification stage caused significant decrease of decontamination factors [33].

For all radioisotopes present in the waste sample DFs, in the case where cyanoferrate and chelating polymer were applied subsequently in two-stage process, were higher than those obtained when the complexing agents were added to the feed solution simultaneously. All decontamination factors were higher than DFs obtained for a single soluble polymer (NaPAA or PEI) (Table 30.9).

Apart from radioactive compounds the radioactive wastes may contain non-active but chemically toxic substances. The national standards and regulations describe the discharge limits for these substances, too. Heavy metals are toxic compounds, most often present in liquid radioactive wastes. The experiments showed that most of these metals are removed by UF/complexation method. The method is inefficient for removal of monovalent ions, bivalent cations and anions are retained in 25%–50%, but high retention of the metals like Mn, Fe, Co, Cu, Pb, Cr was observed. The retention factors for those metals in two-stage experiment described above, were as follows:

Mn 94%  
 Fe 99%  
 Cu 99%  
 Pb 87%  
 Cr 75%  
 Co 94%

Advantages of ceramic membranes employed in nuclear industry were found in their extremely high chemical and physical stability (full pH range), resistance to oxidants, solvents, and ionizing radiation. Ceramic materials are advantageous when the solutions composed of organic compounds or high radioactive wastes containing the  $\alpha$  emitters are treated. High

temperature resistance allows washing with warm streams and sterilization by steam. This is very important when macro-molecular complexing ligands causing membrane fouling are applied.

### 30.2.3.3 Pilot Plant Experiments

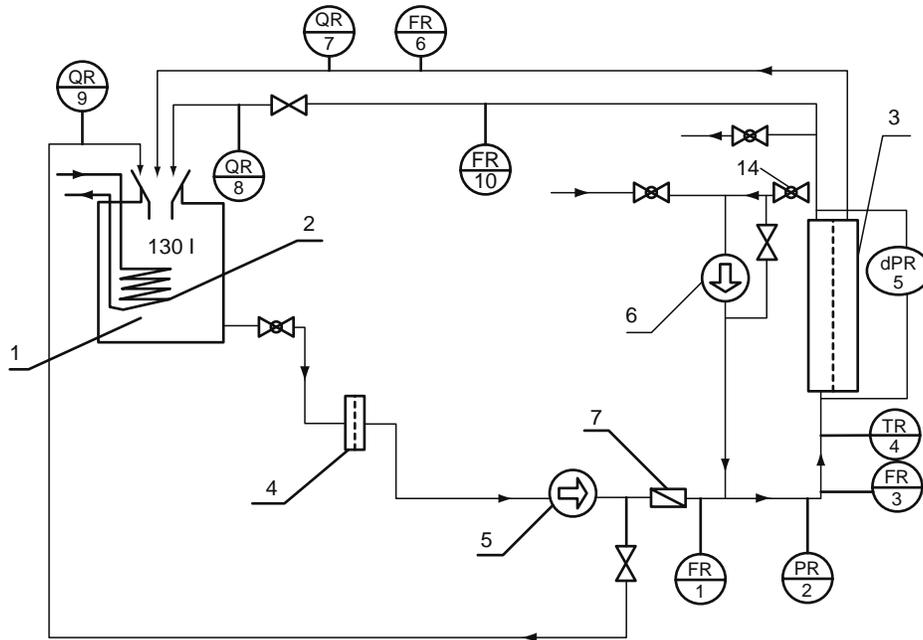

The apparatus equipped with Sunflower CeRam Inside (23–8–1178), characterized in Table 30.10, was used in pilot plant tests. The plant consisted of feed tank (1) equipped with cooler; (2) membrane module housing; (3) pretreatment filters; (4) pressure pump TONKAFLO; (5) circulating pump Grundfos; (6) non-return valve; (7) two needle valves and four ball valves (Figure 30.14).

The filtration experiments were conducted in cross-flow mode at pressure 0.25–0.5 MPa in the system. In that pressure range for filtration of water, permeate flux was 26–85 L/m<sup>2</sup>h. All process parameters were recorded with data acquisition system; periodically the samples of permeate and retentate were collected for chemical analysis.

Original radioactive liquid waste from the storage tank in nuclear center was treated in the process UF/complexation. The main radioactive components of the waste sample were <sup>60</sup>Co, <sup>65</sup>Zn, <sup>133</sup>Ba, <sup>134</sup>Cs, <sup>137</sup>Cs, <sup>152</sup>Eu, and <sup>241</sup>Am. When ultrafiltration was applied solely the rejection of radioactive compounds was very low and the decontamination factors were between 1.02 and 1.05. Therefore ultrafiltration was combined with complexation by soluble polymers. The application of sodium polyacrylate (NaPAA) 15,000 and 30,000 of molecular weight, in concentration range 0.4–3 g/L gave slight increase of decontamination factors to 1.3–2.8. In addition, dosing of INSTAR AS up to concentration 3 g/L resulted in an increase of decontamination factor to 3.1. Since the major portion of total activity came from radioactive isotopes of caesium, the use of cobalt hexacyanoferrate as a binding agent was advisable. The cobalt hexacyanoferrate was introduced as a suspension prepared from 0.02 N solutions of Co(NO<sub>3</sub>)<sub>2</sub> · 6H<sub>2</sub>O and K<sub>4</sub>[Fe(CN)<sub>6</sub>] 3H<sub>2</sub>O. As is shown in Figure 30.15, first portion of the suspension caused an increase of DF to 30 and further increase of complexing agent concentration did not change decontamination factor radically. The results of the radiochemical analysis are shown in Table 30.11, where isotopic composition of the forth samples is performed. The notation of the samples was as follows: S, feed solution composition; P<sub>1</sub>, permeate treated with 1 g/L of NaPAA; P<sub>2</sub>, permeate after complexation with 3 g/L NaPAA; and P<sub>3</sub>, after the treatment with CoCF and INSTAR AS. The calculated decontamination factors for each radioisotope as well as DFs for total activity in processed waste were presented in

Figure 30.16. The radiochemical analyses of the last sample of permeate showed complete retention of  $^{134}\text{Cs}$ ,  $^{152}\text{Eu}$ , and  $^{241}\text{Am}$  when complexation/UF process was employed. About 1770-fold decrease of concentration of  $^{137}\text{Cs}$  was observed; the decontamination factors for other radioisotopes were high, as well. However, due to high initial  $^{65}\text{Zn}$  content, the concentrations of this radioisotope in permeate ( $P_4$ ) was also high; the radioactive zinc was not removed sufficiently. Therefore, additional cleaning procedure should be applied to reduce  $^{65}\text{Zn}$  concentration and to meet discharge standards. It is likely that the dosage of the polymer was too small to complex all radioisotopes sufficiently (the increase of DF with subsequent dosages of polymer was observed, see Figure 30.16). Further portions of cobalt hexacyanoferrate did not cause the increase of decontamination.

The membrane performance was good, during almost 60-h operation and the permeate flux was stable after initial decline. The biggest flux decrease was observed when macromolecular sodium polyacrylate was introduced: first after dosing 0.4 g/L of NaPAA, then after injection of the next portion (1 g/L NaPAA). In that time, permeate flux declined from 52 L/m<sup>2</sup>h in the beginning (without the complexing agent), to 11 L/m<sup>2</sup>h after injection of 1 g/L of the polymer. Further increase of polymer concentration did not result in the flux decline, as well as addition of CoCF suspension.

The complexation/ultrafiltration process is efficient for retention of non-active hazardous components of the wastes, e.g., heavy metals, which concentration has to be reduced according to national regulations. In the process described above, the retention of heavy metals was high, and reached 98% for manganese, 98.6% for iron, 92.4% for copper, 91.5% for nickel, and 94.7% for zinc. Some part of bivalent ions was also retained, for instance, Mg in 67%, Ca in 58%,  $\text{SO}_4^{2-}$  in 22.6%.

The enhanced ultrafiltration is effective but hardly controlled process, because of its sensitivity to the process conditions, such as pH, temperature, or concentration of alkaline ions. However, it can be easily applied for the wastes containing the radionuclides that are effectively attached to the macromolecules of the various ligands at the same or similar pH value.

Current development of the hybrid treatment processes is being directed toward searching the new, cheap sorbents, and complexing agents, among them natural polymers such as chitin, lignin, huminates, and lignosulphonate are considered [73]. Using huminates in the ratio 1:25–1:50 with combination of ceramic membranes selectivity higher than 99% for ions such as  $\text{Sr}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Co}^{3+}$ , and  $\text{Ca}^{2+}$  was obtained. Chitosan and cellulose, mostly abundant biopolymers, are increasingly being used as a coagulant and flocculent in the processes of water and wastewater purification [74,75]. Due to the amine groups present in the polymer chain chitosan is a good sorbent for transient metals [76,77]. It can be formed in granules for fixed beds, as well as a water solution of the acetate [78]. With conjunction of the membrane, chitosan may cause six- to tenfold increase of removal of Cu(II), Co(II), Ni(II), and Zn(II) from water solutions [79]. Apart from other natural sorbents such as biomass, powdered wood bark, nutshell, modified wool or cotton, the use of cheap, inorganic sorbents such as natural zeolites, clays, or fly ash is considered [80].

**FIGURE 30.16** Decontamination factors for selected components of radioactive wastes treated in UF/complexation process. (Reprinted from Zakrzewska-Trznadel, G. and Harasimowicz, M., *Desalination*, 162, 191, 2004. Copyright [2004] with permission from Elsevier.)

New potential applications of sorbents in conjunction with a membrane are expected from the development of molecular-imprinted or ionic-imprinted polymers that are capable of metal-ion recognition. This concept based on preparation of matrix in the presence of the molecular or ionic template. After removal of the target molecule/ion the prepared solid can react with the solution of the molecules/ions from which the imprinted molecule/ion should thus be preferentially extracted from the mixture [81–83].

### 30.2.4 MICROFILTRATION

In nuclear technology, microfiltration is used either for pretreatment purposes or for concentration of coarse particles after precipitation process. For high-level radioactive wastes the ceramic filters are used, giving for some types of effluents high decontamination and concentration factors. The MF facilities used in nuclear industry to treat liquid radioactive wastes are summarized in Table 30.12.

### 30.2.5 MEMBRANE DISTILLATION

Membrane distillation (MD) is a separation method that employs porous liophobic membrane, non-wettable by the liquid. Because of liophobicity of the polymer, only vapor is transported through membrane pores. The condensation takes place on the other side of the membrane in air gap, cooling liquid or inert carrier gas. Usually MD is employed to treat water solutions, therefore hydrophobic membranes manufactured from polymers such as polypropylene (PP), polytetrafluoroethylene (PTFE),

**TABLE 30.12**  
**Examples of Nuclear Testing Facilities Applying MF for Liquid Radioactive Wastes Processing**

Facility	Type of the Waste	Process and Type of the Membranes Used	Results	References
AECL Chalk River Laboratory (Canada)	Mixed low-level radioactive wastes	MF was used as a pretreatment step in RO installation	MF hollow fiber membranes remove the suspended solids larger than 0.2 $\mu\text{m}$ . The filtrate from MF forms the feed for the SWRO system, the backwash solution undergo further volume reduction in thin film evaporator	[17,18]
AECL Chalk River Laboratory (Canada)	Groundwater and soils decontamination	Hollow fiber MF system consisted of 40 cross-flow filtration modules, $\sim 6$ cm in diameter, 50 cm long, and 1 $\text{m}^2$ surface area	The system demonstrated the usability of MF for the treatment of soil leachate and removal of radionuclides from ground water. The radioactivity of $^{90}\text{Sr}$ was reduced from 1700–3900 to 2 Bq/L	[28,84–86]
Rocky Flats (United States)	Groundwater containing uranium isotopes, organic toxic compounds, and heavy metals	Tubular MF modules, pore size 0.1 $\mu\text{m}$	The removal efficiency of uranium isotopes by the system was 99.9%	[28]

or poly(vinylidene fluoride) (PVDF) are used in the process. The driving force in the MD process is a gradient of partial pressures of the components of the solution in gaseous phase. The main advantages of membrane distillation applied for radioactive wastes processing are

1. Moderate process conditions, ambient pressure, and moderate temperature
2. High retention and decontamination, higher than that for conventional evaporators
3. Low operational costs for medium-sized installations, the possibility of utilization of waste heat, e.g., from cooling system of nuclear reactor
4. The possibility to achieve high concentrations, close to saturation
5. The possibility of use of plastics as construction materials for apparatus, because of moderate process conditions—minimization of corrosion and capital costs
6. Compact installations (one stage units)

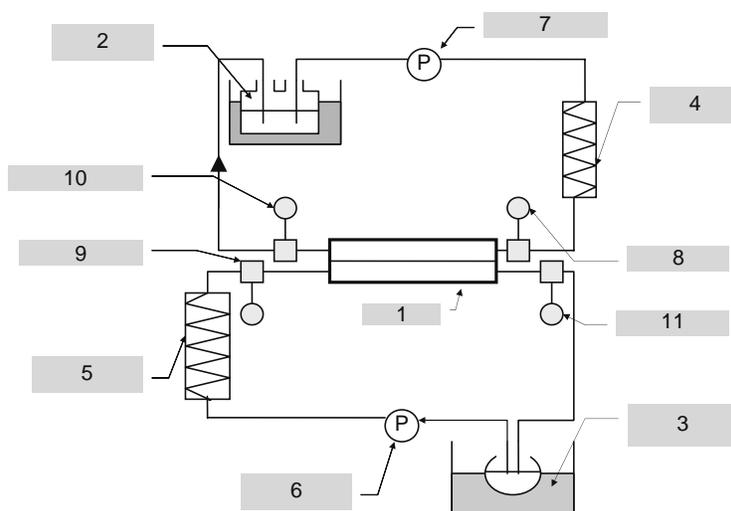

In contrary to other methods, also to reverse osmosis, MD allows complete purification in single stage, not involving additional processes for polishing permeate. It is a simple, economic, and environment friendly method when it is used for radwaste processing.

Membrane distillation was developed at INCT for liquid radioactive waste processing [91]. For many years the process was studied as a method for stable isotopes enrichment. Using porous PTFE membranes, stable isotopes of oxygen and hydrogen were enriched in natural water with relatively high separation factors [92–95]. It was proved that MD distillation is a competitive method for enrichment of oxygen-18, the isotope that finds now a big demand on the market because of high consumption by positron emission tomography [96]. Membrane method in some cases seems useful for heavy water enrichment, as well.

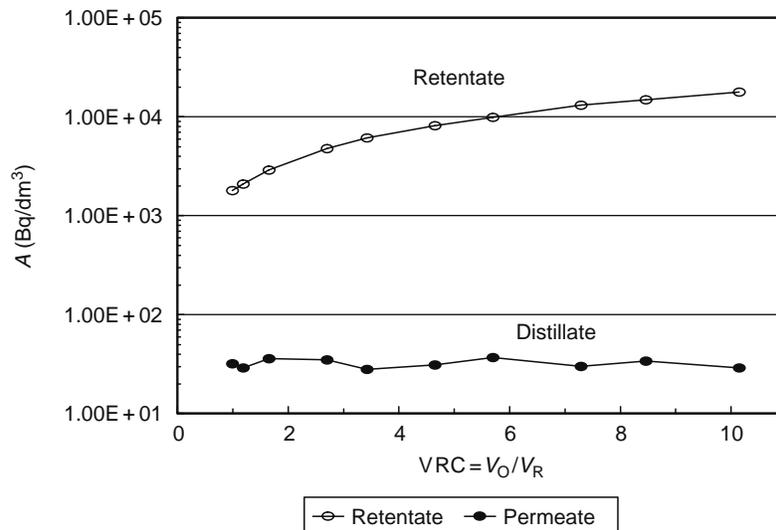

Since membrane distillation exhibits high ability of concentration of aqueous solutions with high retention of acids, salts, and other low-volatile compounds, it can be used for concentration of different radioactive waste streams with high volume reduction and high retention factors [97–99].

The process conducted in batch-type counter-flow apparatus (Figure 30.17) equipped with capillary PP Accurel membranes showed good effectiveness of membrane distillation for purification of radioactive waste. Permeate obtained was pure water. All solutes together with radioactive compounds were rejected by the hydrophobic membrane. At tenfold volume reduction of the initial portion of waste, approximately tenfold concentration of radioactivity in the retentate stream was reached, while radioactivity of permeate retained on the level of natural background (Figure 30.18). As was observed in experiments small sorption in the system took place. However, permeate was free of radioactive substances and other dissolved compounds, the concentration and radioactivity factors sometimes slightly differed from volume reduction factors.

Membrane distillation for concentration of radioactive waste was also tested in pilot plant experiments. The facility used in the tests consisted of spiral-wound module, equipped with PTFE membrane, effective surface area of 4 m<sup>2</sup>. The installation enabled the recovery of the part of heat by two installed heat exchangers (Figure 30.19).

**FIGURE 30.17** Laboratory setup for testing MD process. (1) membrane module, (2) feed reservoir, (3) distillate reservoir, (4,5) heat exchangers, (6,7) peristaltic pumps, (8–11) thermometers.

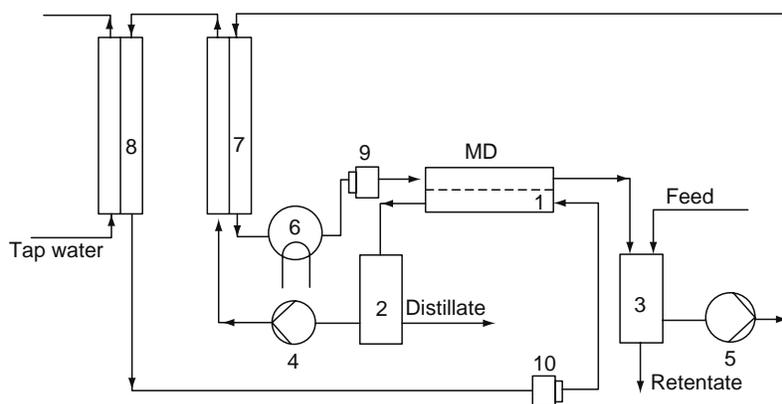

**FIGURE 30.18** Concentration of radioactive waste in batch-type MD apparatus. (From Chmielewski, et al. *Sep. Sci. Technol.*, 32, 709, 1997. Copyright [1997] Reproduced with permission of Taylor & Francis.)

The experiments were conducted in the temperature range 35°C–80°C at feed inlet, and 5°C–30°C at distillate inlet, and with feed and distillate flow rates up to 1500 dm<sup>3</sup>/h. Under these conditions permeate stream was 10–50 dm<sup>3</sup>/h (60–300 dm<sup>3</sup>/m<sup>2</sup> day). During the experiment run the activity of the distillate was stable on the level of natural background radioactivity and the concentrating of radioactive compounds took place in retentate. Retention of radioactive ions in retentate was almost complete (decontamination factors  $\rightarrow \infty$ , Table 30.13). Most of radionuclides were not detected in distillate; only trace amounts of Co-60 and Cs-137 were present. Also retention coefficients of non-active ions were high (Table 30.14).

The experiments have proved that membrane distillation can be applied for radioactive wastewater treatment. In one-stage installation the membrane retained all radionuclides and decontamination factors were higher than those obtained by other membrane methods. The distillate obtained in the process was pure water, which could be recycled or safely discharged into the environment. It seems the process can overcome various problems of evaporation such as corrosion, scaling, or foaming. There is no entrainment of droplets, which cause the contamination of condensate from thin-film evaporator. Operation at low evaporation temperature can decrease the volatility of some volatile nuclides present in the waste, such as tritium or some forms of iodine and ruthenium. The process is especially economic for the plants, which can utilize waste heat, e.g., plants operating in power and nuclear industry.

In membrane distillation, there is a possibility of loss of membrane hydrophobicity during long-time operation. However, during 80-h tests with DM pilot plant the changes in membrane wettability were not observed. The liquid entry pressure for PTFE membrane used in experiments was about 0.23 MPa, which is sufficiently high in comparison with the pressure in the MD installation. According to the manufacturer suggestion the pressure applied in the MD module cannot exceed 0.07 MPa. To reduce the risk of liquid entry into membrane pores the pressure on the distillate side was kept a little higher than pressure on the retentate side.

However, the presence of compounds lowering the surface tension, may result in wetting the hydrophobic membrane. These compounds have to be removed before entering the membrane system by appropriate pretreatment. At small concentration these substances can be removed by sorption, oxidation, or phase separation, whereas at high concentration they can be removed by ultrafiltration. The main nonactive components of the wastes treated in the above experiments, were the inorganic salts such as sulfates, nitrates, or chlorides that increased the surface tension. It was proved that the presence of salts crystallizing in-membrane pores may also result in wetting the membrane during long-time operation of MD installations, especially at low distillate temperatures [100]. Such a situation may take place in the module entrance, when distillate temperature is relatively low. Precipitate deposition, scaling, and pore blocking are the problems of all membrane installations. The appropriate pretreatment or dosing antiscaling additives are the methods of minimization of these phenomena. The problem of scaling is more serious in evaporation installations that are widely used in nuclear industry and operating in higher temperatures than membrane distillation.

The experiments with concentration of inorganic salts showed that 25% concentration of the solute could be achieved by using MD. It is the upper limit for concrete solidification. Usually such a big concentration is not reached, because limit of radiation dose is exceeded for solidified waste, originating from concentrated radionuclides. Distillate is pure water and can be discharged to the sewage or surface waters or can be recycled.

In Table 30.15, decontamination factors for different processes for low- and medium-level radioactive waste treatment are shown. Membrane distillation with its high decontamination factors is a competitive method in this field. However, it has to be mentioned that these high-decontamination factors are achieved from low-volatile solute after adequate pretreatment.

**TABLE 30.15**  
**DFs for Most Common Methods of Low- and Medium-Level**  
**Radioactive Wastes Processing**

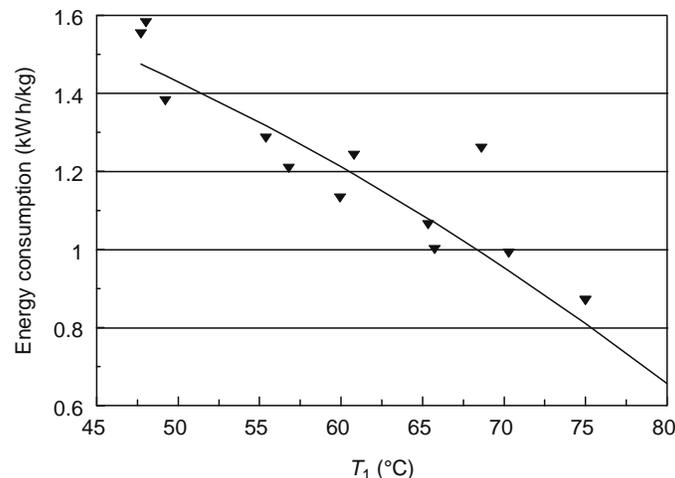

Process	DF
Chemical precipitation	$10 < DF < 10^2$ ( $\beta, \gamma$ ), $10^3$ ( $\alpha$ )
Organic ion-exchange	$10 < DF < 10^3$
Inorganic ion-exchange	$10 < DF < 10^4$
Evaporation	$10^4 < DF < 10^6$
Bioaccumulation	$DF > 10^3$
Biosorption	$DF < 10^3$
RO	$10 < DF < 10^3$
MD	$DF \rightarrow \infty$

A majority of the methods require multistage systems; even when evaporation does not always yield the product of radiochemical purity. In addition, it is an energy-consuming method and have process barriers described above. The other treatment methods also have some constraints. Ion exchange consumes large volumes of expensive resins that need regeneration and in consequence large quantities of secondary waste are created. Biological processes produce big quantities of sludge with high concentration of radionuclides and intermediate products.

Many years of operation of membrane processing facility in Chalk River Laboratory proved reliability of reverse osmosis. However, reverse osmosis requires involvement of high pressures, cannot avoid membrane fouling and the necessities of frequent cleaning operations resulting in production of secondary wastes. It requires multistage system to achieve sufficient purity of the product and high volume reduction. Thin film composites are less resistant to the radiation and strong chemical environment than PTFE or PP membranes. New possibilities may create the commercialization of inorganic RO membranes.

The opinions on the advantages of membrane distillation are diverse. Low investment costs for small and medium-capacity installations are pointed out on the one hand. For bigger facilities both capital and operation costs can be lower than in conventional processes [101,102]. While on the other hand, more moderate opinions on benefits of membrane distillation are published, as well [103].

One of the main barriers for commercial implementation of membrane distillation is relatively high-permeate fluxes from unit membrane area, along with high-energy consumption in the process. The latter can be overcome when MD installation is used in nuclear power plant, and when waste heat from cooling circuit can be utilized. Another possible way to minimize energy consumption is efficient recovery of heat by appropriate design of the installation or using membrane modules with integrated heat recuperation based on the spiral-wound GORE-TEX principle [101,104]. According to the evaluation of the company these modules consume 150–280 kW h<sub>th</sub>/1 m<sup>3</sup> of distillate, while for modules without integrated heat recovery the energy consumed equals ~600 kW h<sub>th</sub>/m<sup>3</sup>. However, as demonstrated pilot plant experiments performed at INCT, the latter was hardly achieved with the installation described above. In Figure 30.20, energy consumption per unit of the product for various

**FIGURE 30.20** Energy consumption per unit of the product in MD process. (Reprinted from Zakrzewska-Trznadel, G., Harasimowicz, M., and Chmielewski, A.G., *J. Membr. Sci.*, 163, 257, 1999. Copyright [1999] with permission from Elsevier.)

**TABLE 30.16**  
**Influence of Process Parameters on Energy Consumption**  
**Per Unit of Permeate**

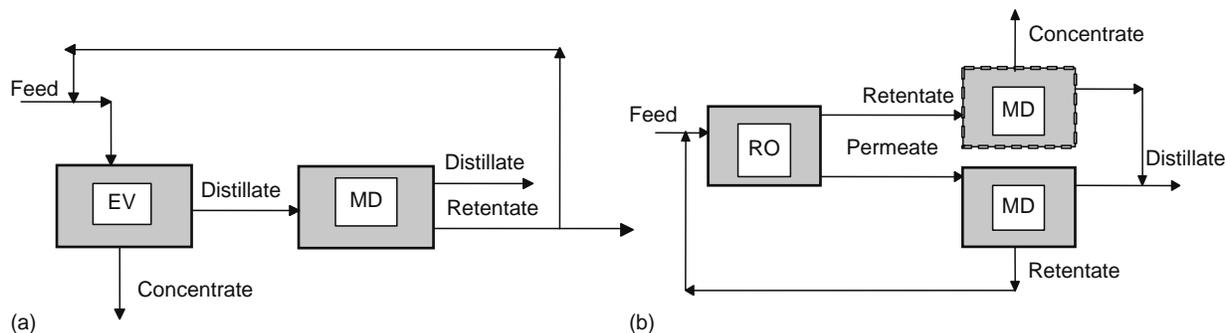

$T_1$ (°C)	$T_2$ (°C)	$V_R$ (L/h)	$V_D$ (L/h)	$V_{cool}$ (L/h)	$V_P$ (L/h)	$E/V_P$ (kWh/L)
69.6	22.8	720	720	1200	23.60	0.96
65.4	21.7	870	870	1200	18.52	1.06
65.5	16.5	870	870	2700	19.36	1.17
49.3	22.1	1380	1380	840	17.28	1.30
49.3	18.6	1380	1380	1260	18.60	1.38
49.2	22.4	1620	1500	840	24.70	1.31
49.2	20.0	1620	1500	1260	24.95	1.35

feed inlet temperatures ( $T_1$ ), estimated from experimental results, was shown. The favorable are the high process temperatures; at  $T_1$  temperature over 80°C the energy specified by manufacturer of the membrane module can be achieved. The thermal energy consumption in the process depends not only on temperatures, but also on intensity of distillate cooling (to keep the proper temperature gradient across the membrane) and volume flow rates in the apparatus:  $V_R$  and  $V_D$  (Table 30.16), however the influence of these parameters is moderate. The lower cooling water flow implicates decrease of energy consumption. Between flow rate of retentate, distillate, and process temperatures are interactions, therefore optimization of process parameters is necessary to get sufficient permeate fluxes and low-energy consumption per unit of the product.

Membrane distillation modules are at present expensive in comparison with RO elements and their costs influence significantly the capital costs of the MD installations. The market of MD systems is limited; in spite of the many advantages MD method is not widely accepted by the industry. Moderate interest of users influences the production capacities and in consequence reduces the wide implementation of the MD method in different branches of industry. It was proved that advantages of MD decreases with increase of the installation capacity; big installations, of productivity comparable with RO, need large number of modules. Anyway, the comparison of two processes: RO and MD proved technical and economic reasonability of the latter in some cases, such as radioactive waste concentration. The advantages of MD come from

1. Possibility of running the process to high-solute concentrations, sufficient for direct solidification
2. Achieving the high concentration in one stage
3. Elimination of high pressures
4. Reduction of sorption of such radioactive ions, e.g.,  $^{60}\text{Co}^{2+}$ ,  $^{137}\text{Cs}^-$ , and  $^{134}\text{Cs}^-$  inside the pores (the pores are filled with water vapor)
5. Infrequent washing cycles through minimization of fouling and inner sorption, reduction of quantities of secondary wastes

Membrane processes are versatile and flexible; they can be combined with other methods in hybrid processes. Adapted to actual needs they can treat various process streams of different compositions and concentrations. Membrane distillation coupled with evaporation or reverse osmosis may improve the purification efficiency and increase decontamination factors. The flow chart of such hybrid processes is presented in Figure 30.21. In Figure 30.21a, the combination of MD unit with evaporator is shown.

**FIGURE 30.21** (a) Combination of evaporator with MD module. (b) Combination of RO unit with two modules of MD. (Reprinted from Zakrzewska-Trznadel, G., Harasimowicz, M., and Chmielewski, A.G., *Sep. Purif. Technol.*, 22–23, 617, 2001. Copyright [2001] with permission from Elsevier.)

Evaporation is a widely used method for radioactive waste processing. One of disadvantages of the process is radionuclides carry over with small droplets. The contaminated condensate needs additional polishing with ion-exchange resins. The installation of MD module for final cleaning of the condensate can avoid the use of ion exchange. The unit that plays the role of demister can be driven with waste heat from nuclear power plant.

Another possibility of MD use is combination with reverse osmosis that in fact can be the loose RO not involving enormously high pressures. The permeate from RO with reduced amount of multivalent ions is directed to MD module where final polishing takes place (Figure 30.21b). The preliminary volume reduction undergoes in RO module; the retentate is concentrated and volume-reduced in MD module. This solution eliminates the evaporator and ion exchange together replacing these conventional processes with membrane techniques.

The use of hybrid methods gives multiple benefits when it combines the processes which supplement one another or eliminate the drawbacks of the single process. Multistage reverse osmosis results in high-effluent decontamination, however it cannot be run up to high-retentate concentration. High concentration is not the limitation for thin-film evaporators, but the condensate needs final polishing by other method. Membrane distillation combines itself the advantages of both processes, simultaneously avoiding all constraints of RO and EV. In the case of availability of cheap sources of thermal energy, e.g., waste heat, the supplementation of reverse osmosis, or evaporation with membrane distillation seems to be justifiable.

### 30.3 FUTURE OF MEMBRANE PROCESSES IN NUCLEAR TECHNOLOGY

#### 30.3.1 LIQUID RADIOACTIVE WASTE PROCESSING BY MEMBRANE PROCESSES: ADVANTAGES AND LIMITATIONS

Continuous development of membrane processes applied in nuclear technologies is of considerable interest. Implementation of new membrane materials with high chemical and radiation resistance, and new module designs allow spreading applications of membrane processes into different fields of nuclear industry. The main barriers in the use of membrane methods are the following:

1. Necessity of periodical interruption of the process resulting from membrane fouling or blocking and successive cleaning of the installation. It is evaluated that about 1% of secondary wastes come from cleaning the apparatus and membranes [25].
2. Need of pretreatment of the streams before membrane installations.
3. Installations operating under high pressure require sophisticated apparatus and pressure pumps.

The elaboration of proper pretreatment methods, application of antiscalants, and minimization of secondary wastes created during cleaning cycles are of great importance. At present the research work on use of pressure-driven processes for radioactive waste treatment is focused on following issues:

1. Application of ultrafiltration coupled with other processes such as precipitation, sorption, or complexation
2. Combining membrane processes with other methods into integrated processes, such as ultrafiltration–evaporation, reverse osmosis–ion exchange
3. Elaboration of effective methods of fouling control and membrane cleaning, avoiding the membrane blockage and flux decline
4. Use of nanofiltration with pores at the boundary of reverse osmosis and ultrafiltration that allows to separate multivalent ions such  $\text{Ca}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{SO}_4^{2-}$  from monovalent. It is possible with nanofiltration to separate multivalent radioactive ions from non-active salts, as sodium nitrate
5. Replacing polymeric membranes by inorganic, more resistant to ionizing radiation and aggressive chemical environment
6. Testing the influence of process conditions on stability and lifetime of particular membrane installation elements—the influence of salts that cause scaling ( $\text{Na}_2\text{SO}_4$ ,  $\text{Na}_2\text{CO}_3$ ,  $\text{NaHCO}_3$ ,  $\text{Ca}_3(\text{PO}_4)_2$ ), the influence of radiation on membrane material

Despite of some technical and process limitations, membrane techniques are very useful methods for the treatment of different types of effluents. They can be applied in nuclear centers processing low- and intermediate-level liquid radioactive wastes or in fuel reprocessing plants. All the methods reported in the chapter have many advantages and can be easily adapted for actual, specific needs. Some of them are good pretreatment methods; the other can be used separately as final cleaning steps, or can be integrated with other processes. Membrane methods can supplement or replace techniques of distillation, extraction, adsorption, ion exchange, etc. Evaluation of membrane processes employed for liquid radioactive waste treatment is presented in Table 30.17.

### 30.3.2 NEW FIELDS OF APPLICATION OF MEMBRANE PROCESSES IN NUCLEAR INDUSTRY

#### 30.3.2.1 Removal of Tritium from Nuclear Waste (Liquid and Gaseous Effluents)

Nuclear Energy Agency of the Organisation for Economic Co-operation and Development (OECD/NEA) considers tritium as one of the four volatile, hazardous radionuclides ( $^3\text{H}$ ,  $^{14}\text{C}$ ,  $^{85}\text{Kr}$ , and  $^{129}\text{I}$ ) that are created in nuclear cycle with long-term risk [105]. Tritium, a radioactive isotope of hydrogen, emitting mild  $\beta$  radiation is created in nuclear reactors and in reprocessing plants by neutron activation of isotopes of  $^2\text{H}$ ,  $^3\text{He}$ ,  $^6\text{Li}$ , and  $^{10}\text{B}$ . The largest quantities of tritium are produced in heavy water reactors ( $\sim 5.42 \times 10^7$  GBq/GW<sub>el</sub> per annum) [106]. Less amounts are emitted by fast breeder reactors and high-temperature graphite reactors; the smallest quantities are created in light water reactors ( $\sim 5.55 \times 10^5$  GBq/GW<sub>el</sub> per annum). It was

evaluated that reprocessing plants with a capacity of 1400 t/a, processing fuel from LWR can emit  $(1.85\text{--}3.70) \times 10^7$  GBq per year of radioactive tritium [106], that is commensurate with emission from natural sources.

One of technical problems of removal of tritium is its low concentration in technological and waste streams. In heavy water reactors moderator (PHWR) the ratio DTO:D<sub>2</sub>O is  $10^{-5}$ , and in water streams from fuel reprocessing plants, HTO:H<sub>2</sub>O,  $10^{-7}$  [107]. In this way, great volumes were contaminated with tritium: hundreds and thousands of cubic meters per year need processing. Majority of the treatment methods is based on technologies used for deuterium enrichment such as water distillation, distillation of hydrogen, electrolysis, ion exchange, and some combined methods such as electrolysis–catalytic exchange, the so-called CECE process [108,109].

Among alternative technologies for separation of tritium, membrane methods are considered. *Nafion*, Du Pont membranes, were applied for separation of hydrogen isotopes in installations for tritium removal from heavy reactor water and from nuclear reactor atmosphere. The monitor for HTO and HT control was constructed in Chalk River Laboratories in Canada [110]. At High-Energy Accelerators Research Organization (KEK), Japan, the work on apparatus for measurement of tritium emitted from high-energy accelerators, equipped with hollow-filament membranes for gas separation, is carried on [111].

The studies on separation of water isotopomers (HTO, HDO, H<sub>2</sub>O) with membranes from poly[bis(phenoxy)phosphazene] and carboxylated derivatives were carried on in Pacific Northwest Laboratory [112,113]. Using these membranes tritiated water was extracted from fuel storing pool water of 3  $\mu\text{Ci/L}$  concentration of tritium, and from facilities under supervision of US DOE in Hanford and Savannah River. Separation with 10,800 pCi/L tritiated water obtained by membrane method was not higher than 33% (depletion in the permeate fraction). Water containing 3  $\mu\text{Ci/L}$  of HTO was depleted by 22% in a similar system [113].

The membrane permeation was tested for separation of HTO from water at INCT [114]. Membranes made from regenerated cellulose, polysulphone, and polytetrafluoroethylene were used. Separation factors  $\alpha_{\text{H}_2\text{O}/\text{HTO}}$  obtained in membrane process were not higher than 1.04 for cellulose and 1.02 for polysulphone, while for PTFE membranes were as high as 1.06–1.22.

Number of works published recently concerns application of polymeric gas separation (GS) membranes for separation of hydrogen isotopes, with particular consideration of tritium compounds (HT, HTO) [115–125]. For this purpose, membranes manufactured from glassy and amorphous polymers are applied, mainly polyimide and polycarbonate membranes, as well as polyphenylene oxide membranes assembled in modules of different configuration (e.g., Mc Generon Inc., type B210, Ube Industries, Ltd. Type NM-B05A, Parker, type 2112-NX-1–300 [116]. Super high permeation (SHP) modules—produced by UBE Ltd., which have 10 times higher gas permeability than used at present high-permeable HP modules—seem to be very promising. This allows reducing the space occupied by membrane installation, eliminating the costs of expensive compressors that can be replaced by blower [121]. Conventional methods of tritium removal from atmosphere are limited to catalytic oxidation, followed by adsorption of water on molecular sieves. The method is effective, however has disadvantages resulted from size of apparatus and management of produced water. The method can be used for small glove boxes; in case of large compartment the volumes of installations increase; adsorption system requires large desiccators and high-volume tanks for tritium storage. The advantage of membrane method is the possibility of reduction of processed gas volume to the one tenth of the volume related to conventional method, as well as simultaneous water removal.

### 30.3.2.2 Isotope Separation

The history of separation of isotopes by membrane permeation may be derived from early work of Graham in the middle of nineteenth century on molecular effusion. The most spectacular application of molecular effusion was uranium-235 enrichment for military purpose during the Second World War. In spite of the competitiveness of centrifugal method, up to now gaseous diffusion is an important method of production of fuel based on natural uranium in countries such as United States and France, including EURODIF [126,127], supervised by France, Spain, Italy, and Belgium, which have in their disposal the installations in Tricastin and Pierrelatte, as well as in Russia, China, Great Britain, and Argentina [127]. There is no broad information available on membranes used in gaseous diffusion, however it was known that French technology used sintered and anodic alumina, gold–silver alloys, nickel, Teflon, zirconia, and porcelain [128].

Ceramic and metallic porous membranes are still used for separation of isotopes other than uranium, such as argon and neon [129,130], or hydrogen [131–137]. Polymeric membranes for separation of isotopes of hydrogen were applied at National Institute of Research and Development for Isotopic and Molecular Technologies in Cluj, Romania [138,139]. Polymers such as polyethylene terephthalate (PET), polyethylene (PE), polytetrafluoroethylene (PTFE), cellulose acetate (CA), and polyvinyl chloride (PCV) were used. The selectivity of these membranes was lower than palladium membranes and microporous *Vycor* glass, however number of advantages are expected in low costs of polymeric membranes, the possibility of formation of capillaries with big surface area and avoiding high pressure and temperatures.

Polymeric membranes for separation of hydrogen and oxygen isotopes were studied at INCT, Warsaw [92–95,140–141]. Both hydrophilic barriers, such as regenerated cellulose and hydrophobic PTFE membranes, were tested. The regenerated cellulose appeared to be a very good system to get high separation factors and to consider membrane permeation as possible and competitive method for enrichment deuterium and <sup>18</sup>O in natural water.

Research on separation of hydrogen isotopes is focused on the aspects related to safe operation of nuclear reactors and separation of tritium. Apart from separators based on palladium alloys [142–145], one can find catalytic units with different metallic membranes and various types of integrated systems with catalytic ceramic reactors [146–154].

Using different membranes and various membrane techniques, isotopes of chlorine [155], carbon [156], lithium in aqueous solutions [157,158], and uranium in  $\text{CH}_4$  [158,159] were separated. Isotopes of gadolinium and neodymium were separated in hybrid system of nanofiltration/complexation [50].

### 30.3.2.3 Gaseous Radioactive Wastes—Noble Gases Separation

Apart from radioactive tritium separation from reactor atmosphere or off-gas, polymeric membranes can be applied for separation of noble gases produced by nuclear power plants and fuel reprocessing plants as an alternative to commonly used adsorption or low-temperature distillation methods.

Research on removal of noble gases by permeation method with dimethyl silicon membranes was carried out in Oak Ridge National Laboratory [160]. On the basis of experimental work, the calculations for different industrial cascades separating krypton and xenon from the space of molten salt and sodium cooled breeder reactor or from the off gas from a plant processing spent reactor fuel were performed.

In the process of separation of noble gases, silicon rubber membranes [161,162] and high-resistant siloxane rubbers (polyvinyltrimethylsilane—PVTMS and block-copolymer, composed of polyarylate and polydimethylsiloxane of different weigh ratio, the so-called sylar) [163,164] were employed.

For this purpose the polymer membranes were formed in tubes [165] placed in modules, operating in cascade configuration [166,167]. Preliminary storage of treated gases for decay to prolong the lifetime of membranes were practiced. After 20 day storage of radioactive gases containing  $^{85}\text{Kr}$ —0.004 mol and  $^{133+135}\text{Xe}$ —0.2 mol, at flow rate of  $1\text{ cm}^3/\text{s}$  silicon membranes at the end of the cascade were found to be stable after a number of months. The lifetime could be prolonged to several years by 30 day storing [168]. During separation of mixtures of noble gases the decrease of effective separation factors for particular components was observed. However, the presence of each of them caused plasticizing effect of the polymer enhancing the transport through the membrane [169].

During the last years increasing interest on noble gas separation by membranes is being noticed [170–172]. Hollow fiber membranes from polyimide [171], flat sheet membranes from PET or oriented polypropylene [172] were applied in the tests.

## NOMENCLATURE

$A_f$	specific activity of feed
$A_p$	specific activity of permeate
$A_R$	specific activity of retentate
CF	concentration factor
$c_p$	concentration in permeate
$c_f$	concentration in feed
DF	decontamination factor
$K_{\text{TDS}}$	TDS reduction coefficient
$R$	retention coefficient
$T_1$	feed (warm stream) inlet temperature
$T_2$	cold stream (distillate) inlet temperature
$V_R$	warm stream (retentate) flow rate
$V_D$	cold stream (distillate) flow rate
$V_C$	cooling water flow rate
$E$	energy consumption in MD process
$V_P$	permeate flow rate
VRC	volume reduction coefficient
$x_A, x_B$	A and B components concentration in retentate
$y_A, y_B$	A and B components concentration in permeate
$\alpha_{A/B}$	separation factor for A and B components mixture

## ABBREVIATIONS

AECL	Atomic Energy of Canada Limited
ANSTO	Australian Nuclear Science and Technology Organisation
BWR	boiling water reactor

CA	cellulose acetate
CECE	combined electrolysis-catalytic exchange
DD	drum dryer
DMC	direct membrane cleaning
DSC	differential scanning calorimetry
DTPA	diethylenetriaminepentaacetic acid
EDTA	ethylenediaminetetraacetic acid
EERC	Energy and Environmental Research Center
EV	evaporation
HF	hyperfiltration
IAEA	International Atomic Energy Agency
IEA	Institute of Atomic Energy
IEX	ion exchange
INCT	Institute of Nuclear Chemistry and Technology
INEEL	Idaho National Engineering and Environmental Laboratory
LANL	Los Alamos Nuclear Laboratory
MCH	microcrystalline chitosan
MD	membrane distillation
MF	microfiltration
MWCO	molecular weight cutoff
NF	nanofiltration
OECD/NEA	Organisation for Economic Co-operation and Development/Nuclear Energy Agency
PA	polyamide
PAA	polyacrylic acid
PEI	polyethylenimine
PET	polyethylene terephthalate
PHWR	pressurized heavy water reactor
PLC	programmable logic controller
PP	polypropylene
PS	polysulphone
PSA	polysulphonic acid
PTFE	polytetrafluoroethylene
PU	polyurethane
PVA	polyvinyl amide
PVC	polyvinylchloride
PVD	polyvinylpyrrolidone
PVDF	poly(vinylidene fluoride)
PVTMS	polyvinyltrimethylsilane
PWR	pressurized water reactor
RO	reverse osmosis
SWRO	spiral-wound reverse osmosis
TDS	total dissolved solids
TRO	tubular reverse osmosis
TRU	transuranic elements
TSS	total suspended solids
TUF	tubular ultrafiltration
UF	ultrafiltration
WAO	wet air oxidation

## 31.1 INTRODUCTION

Separations of long-lived actinides play a pivotal role at different stages of nuclear fuel cycle, namely, (a) recovery and purification of fissile/fertile nuclides from their respective ores, (b) fuel reprocessing using processes such as PUREX/THOREX, (c) minor actinide partitioning, and (d) lanthanide–actinide separations. Their analytical separation is also an important step in chemical quality control of nuclear fuel materials and the estimation of the actinide elements in various waste streams. PUREX process employing tri-*n*-butyl phosphate (TBP) as extractant has been successfully employed for the industrial scale production of Pu from the spent fuels emanating from a variety of thermal and fast reactors. There is, however, only a limited experience in the recovery of  $^{233}\text{U}$  from irradiated Th using the THOREX process. However, separation scientists in nuclear industry are gearing up for the new challenges of reprocessing spent fuels discharged from Pu-based fast reactor fuels as well as Th-based advanced heavy water reactor fuels. Existing processes may have to be further modified to meet the demands of larger Pu content, larger radiation damage to the solvent, larger inventory of fission products, and above all the complex situation of dealing with a Th–Pu–U based ternary system. There is also a growing interest in the areas of partitioning of actinides from high-level waste. In view of its excellent track record, TBP continues to be the prime choice of separation scientists and technologists. However, its poor extractability of trivalent actinides, large secondary waste volumes, and interference of the degradation products in overall Pu recovery and decontamination from fission products are a cause of concern. The actinides, in particular, have a fascinating chemistry in solution (e.g., disproportionation, variable oxidation state, polymerization, etc.), which presents a stimuli as well as a challenge to the separation chemists. Hence, there is a need to develop alternative extractants, which are efficient, versatile, and

environmental friendly. Novel extractants are continuously being designed to carry out selective separation of actinides or fission products from reprocessing/waste streams. Figure 31.1 shows some of the extractants employed for the recovery/purification of actinides in the nuclear fuel cycle or for analytical applications. In view of the high cost of some of these emerging extractants, it is imperative to develop simultaneously novel separation techniques, which employ relatively small inventory of extractants. Liquid membrane (LM)-based separations hold a particular promise toward this end [1–3].

Membrane-based separation methods are popular in chemical industry for effluent treatment, desalination, and gas purification. However, their application for separation of actinides relevant to nuclear industry is still at infancy stage. The past few decades saw the use of exotic reagents such as crown ethers, calixarenes for the selective complexation and removal of actinides

*Note:* BLM—Bulk liquid membrane; ELM—Emulsion liquid membrane; SLM—Supported liquid membrane; and HFSLM—Hollow fiber supported liquid membrane.

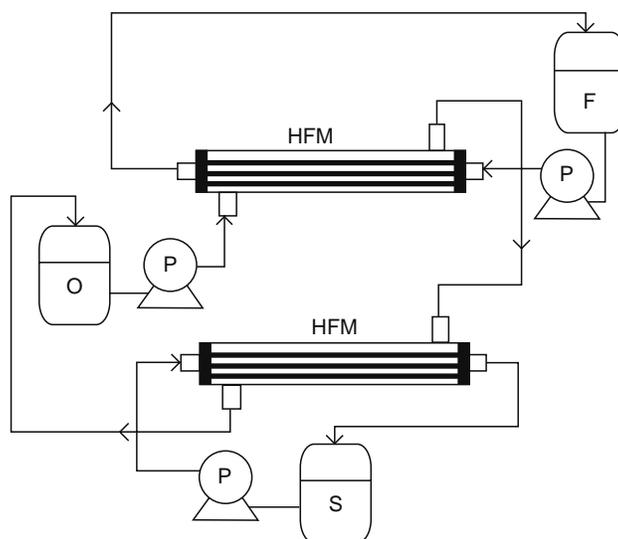

from solutions containing complex mixture of metal ions [4–7]. Specially designed uranophiles have been synthesized for the recovery of ppb level of uranium from seawater [8,9]. Di-cyclohexano 18 crown 6, a crown ether, was utilized by a French group for the separation of Pu from a synthetic spent fuel solution [10]. The two major drawbacks of the solvent extraction methods, namely, third phase formation and phase disengagement time, can be overcome with the LM-based separation methods as they involve nondispersive mass transfer. Hollow fiber supported liquid membrane (HFSLM) separations are particularly attractive due to large surface to volume ratio, fast mass transfer rates, and continuous flow [11–14].

This chapter deals with the transport of actinide ions across liquid membranes resulting in their recovery/separation from complex matrices. The transport behavior of lanthanides is also discussed in many places, which has chemical similarity with the trivalent actinides and are often used as their homologs. The transport behavior of actinides/lanthanides across other membranes such as ceramic/metallic and grafted membranes is also included. Table 31.1 gives a summary of the extractants discussed in this chapter.

### 31.1.1 LIQUID MEMBRANES AND THEIR CLASSIFICATIONS

Membranes are barriers, which separate two solution phases and allow the selective permeation of solutes from one side of the barrier to the other. Depending on the driving force and dominant mechanism of separation, they are classified into different types. The nonequilibrium membrane processes, such as liquid membranes and diffusion dialysis, are useful in the separation of specific components present in very low concentrations. These techniques have shown good promise in the removal of metal ions, such as uranium and copper, and acids from the effluent streams. Liquid membranes basically comprise of organic carriers with high specificity for a particular species. They usually consist of a water immiscible organic membrane (abbreviated as M) layer separating an aqueous source phase, or feed (abbreviated as s.p. or F), consisting of a mixture of metal ions and receiving aqueous phase where the metal ion of interest gets concentrated (abbreviated as R or r.p.) preferentially. Liquid membranes are also known as liquid pertraction or simply as pertraction and closely resemble solvent extraction, which is pivotal in the metal transport process [15]. In fact, pertraction is a combination of extraction, permeation, and stripping of the desired species and can be treated as a continuous multistage extraction/stripping process. A large number of reviews, appeared during the last few years, underline the importance of this upcoming area [16–20].

Broadly speaking, there are three different types of liquid membranes. Bulk liquid membrane (BLM) is a stirred organic phase of lower density than the aqueous phase positioned under it or vice versa. In emulsion liquid membrane (ELM), the receiver aqueous phase containing oil droplets is dispersed into the feed aqueous phase. The total volume of the receiving phase inside the oil droplets is at least ten times smaller than that of the source phase. The thickness of the membrane (organic film) is very small, while the surface area is enormous resulting in very fast separations. Though the efficiency of mass transfer in the liquid membranes is inversely proportional to the thickness of the membrane phase, too thin a film has poor stability due to low but finite solubility in F and R. It can also be disturbed by pressure differences created by the two aqueous phases.

**FIGURE 31.2** Pictorial depiction of a double module hollow fiber liquid membrane set up. HFM—Hollow fiber module; F—Feed; O—Organic extractant; S—Strip or receiver phase; and P—Pump. (Reproduced from Mohapatra, P.K. and Manchanda, V.K., *Indian J. Chem.*, 42A, 2925, 2003. With permission.)

However, ELMs are quite difficult to prepare and after transport, the oil droplets have to be separated and broken up to recover the receiving phase. Compared to the ELM, the BLMs are easier to operate. The supported liquid membranes (SLM) are categorized into two types of supports, namely, a flat-sheet supported liquid membrane (FSSLM) or a hollow fiber supported liquid membrane (HFSLM). Here a polymeric filter with its pores filled with the organic phase acts as membrane. The three different types of liquid membranes have already been schematically represented in Chapter 29. A schematic representation of a hollow fiber setup is shown in Figure 31.2.

### 31.1.2 MECHANISM OF METAL ION TRANSPORT

Due to the favorable thermodynamic conditions created at the F/M interface some components are selectively extracted from the F and transported into the membrane liquid. Simultaneously, at the M/R interface, conditions are such that the back extraction is favored. Various factors that could affect the transport of a metal ion through the LM are (a) the (transport) resistance encountered by the metal ion in the F and R phases, (b) the physicochemical properties of the carrier and diluent, and (c) the nature of membrane support such as its pore size, porosity, tortuosity, hydrophilicity, surface tension, and surface area to volume ratio encountered in the transport process.

In the absence of any external driving force, the simple transport can be expressed by Fick's law of diffusion, where the flux ( $J$ ) is influenced by concentration gradient as follows:

$$J = D_m \{C_{mf} - C_{mr}\} / d_m \quad (31.1)$$

where

$D_m$  is the diffusion coefficient of the complex in the membrane

$d_m$  is membrane thickness

$C_{mf}$  and  $C_{mr}$  are the concentration of metal ion at the membrane–feed interface and membrane–receiver interface, respectively

However, such transport can be limited by concentration gradient and the transport is bound to cease after equalization of the activities of the solute in the source and the receiver phases. In order to effect uphill transport (from nearly half to quantitative transport to the receiver phase), a specific complexing agent for the solute is required. In that case, a finite concentration gradient can always be maintained between the source and the receiver phases, which can effect the uphill transport.

Under efficient stripping condition ( $C_{mf} \gg C_{mr}$ ) and neglecting the aqueous diffusion layer ( $C_{mf} \sim C_f$ ), Equation 31.1 gets simplified to

$$P = J / C_f \quad (31.2)$$

where

$C_f$  is the bulk concentration of metal ion in the feed  
 $P$  is the permeability coefficient [8]

The permeability coefficient,  $P$ , can be obtained using the following equation:

$$\ln(C_{f,t}/C_{f,o}) = -(Q/V)Pt \quad (31.3)$$

where

$C_{f,t}$  and  $C_{f,o}$  are the concentration of metal ion in aqueous feed at time  $t$  and initial metal ion concentration (at  $t=0$ ), respectively  
 $Q$  is  $A\varepsilon$  where  $A$  is the geometrical surface area and  $\varepsilon$  is the porosity  
 $V$  is the aqueous feed volume (mL)

Equation 31.3 is however valid only when carrier is not saturated by the metal ion.

### 31.1.2.1 Classification of Liquid Membrane Transports

In carrier-mediated transport studies, two terms are used, namely, facilitated transport and coupled transport. Facilitated transport is generally referred to as the case where the transport mechanism is independent of any other ion, while in case of coupled transport the transport rate of a particular ion is dependent on the concentration of another ion. The mechanism of facilitated transport is shown in Figure 31.3a, while those of the two different types of coupled transport (cotransport and counter-transport) are schematically explained in Figure 31.3b and 31.3c. In case of cotransport, the metal ion is transferred along with a counter-anion, while simultaneous transport of another ion from receiver phase to source phase occurs in case of counter-transport.

In all the cases described earlier, the LM is interspersed between two aqueous solutions. The distribution ratio ( $D_M$ ) between the organic phase absorbed in the membrane pores and aqueous feed solution (source phase) of metal species permeating the LM is high enough to favor metal extraction into the membrane phase. The distribution ratio of metal ion between the membrane phase and aqueous strip solution (receiving phase) at this stage is made as low as possible to favor complete back extraction of the metal species from the liquid membrane. If the metal carrier is an acidic extractant, HL, the difference in  $D_M$  between the feed and strip sides of the SLM is generally achieved by a pH gradient. In this case, we deal with a counter-transport phenomenon (Figure 31.3c) and the chemical reaction, which is responsible for the coupled transport that can be schematized as

If the metal carrier is a neutral extractant L, the difference in the  $D_M$  between feed and strip is generally obtained by a concentration gradient of the counterion,  $X^-$ , which is accompanying the metal cation into the membrane (Figure 31.3b) and the chemical reaction, which is responsible for the cotransport, can be schematized as

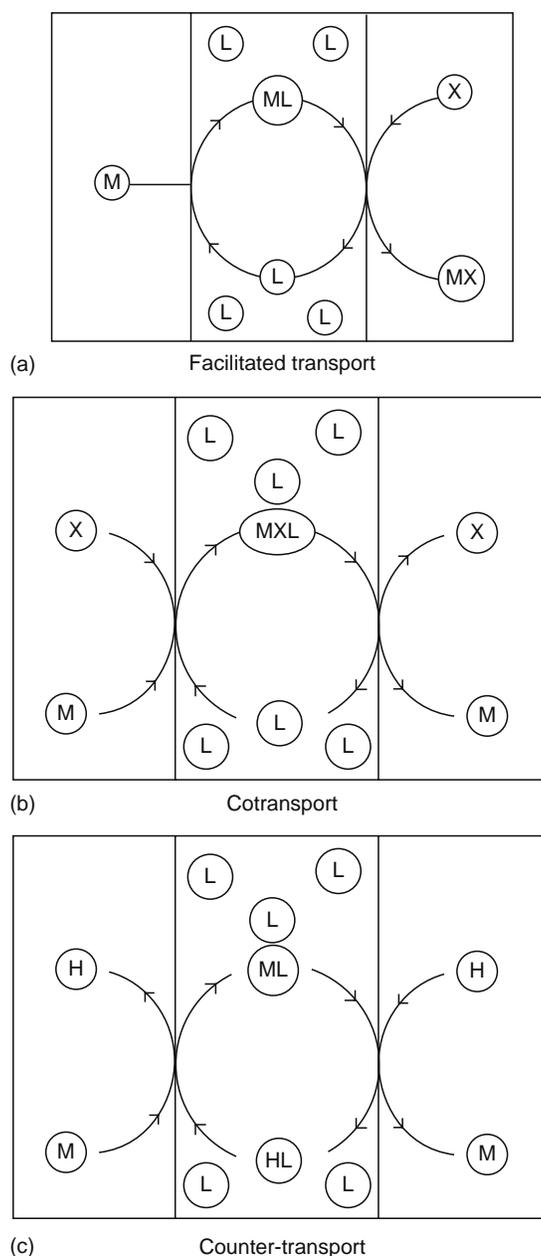

Finally, if the metal carrier is a basic extractant (i.e., a long-chain amine), L, the difference in  $D_M$  between feed and strip is generally obtained by a concentration gradient of the counterion,  $X^-$  as well as  $H^+$  which is accompanying the metal cation into the membrane and the chemical reaction that is responsible for the coupled transport can be schematized as

The aqueous phase pH and counterion concentration gradients are often used as driving forces. However, any other expedient that assures a large chemical potential gradient between the two opposite sides of the membrane can be used as long as coupled transport of metal ions and some other chemical species occur through the SLM.

From this schematic description of coupled transport, it follows that metal species can be transported across the membrane against their concentration gradient. This type of uphill transport will continue until all the metal species, which can permeate the SLM, have been transferred from the feed to the strip side, provided the driving force of the process is maintained. This situation often occurs in practice when very dilute solutions of metal species are involved or when the concentration of the chemicals responsible for the driving force is continuously adjusted to keep it constant. It follows that in an SLM permeation process very high concentration factors can be obtained by using a volume of the strip solution that is much lower than that of

**FIGURE 31.3** Pictorial depiction of metal ion transport in the presence of an organic carrier.

the feed solutions. Moreover, by using a carrier molecule, HL or L, which is very selective for a given metal species, very clean separation processes can be performed. Since, during permeation, the carrier acts as a shuttle moving metal species from the feed to the strip solution and then diffusing back (being continuously regenerated during the process), very small amounts of carrier are used in SLM separation. Other potential advantages of SLM separations over separations performed by traditional solvent extraction technique are the lack of solvent entrainment phenomena, the simplicity of the equipment involved, and the low-energy consumption of the process [21]. Moreover, in comparison to the separation processes performed with solid membranes, SLMs offer the additional advantage of higher fluxes since diffusion in liquids is much faster than that in solids.

The various steps that characterize the transport of metal species through SLMs can be described with the help of Figure 31.4. Step 1: The metal species, after diffusing to the source–membrane interface, react with the metal carrier,  $H^+$  ions are simultaneously released into the feed solution (counter-transport, acidic carrier) or  $X^-$  ions accompany the metal ions into the membrane (cotransport, neutral, or basic carriers), Step 2: The metal–carrier complex diffuses across the membrane because its concentration gradient is negative, Step 3: At the membrane–receiver interface the metal–carrier complex releases metal ions into the aqueous phase,  $H^+$  ions replace  $M^+$  ions into the membrane (counter-transport) or  $X^-$  ions are simultaneously released together with  $M^+$  ions into the strip solution (cotransport), Step 4: The uncomplexed carrier diffuses back across the membrane.

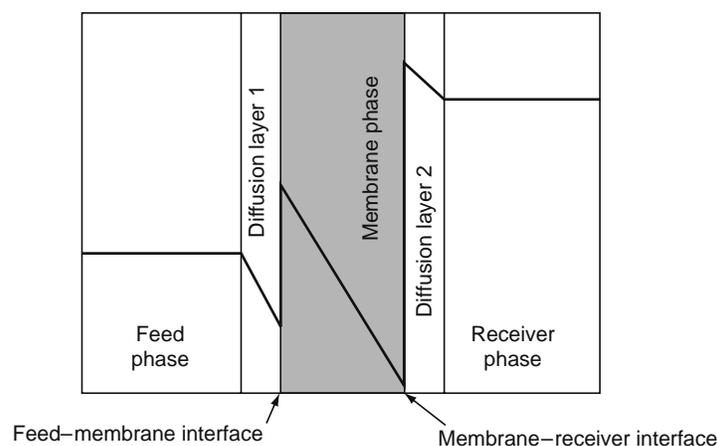

FIGURE 31.4 Mechanism of metal ion transport in the case of an FSSLM. Metal ion concentration is indicated by the thick lines.

## 31.2 TRANSPORT OF ACTINIDES BY LIQUID MEMBRANES

### 31.2.1 SEPARATION OF ACTINIDES BY BULK LIQUID MEMBRANES

Bulk liquid membrane is a stirred organic phase of lower density than the aqueous phase positioned under it, or vice versa. The two aqueous phases, namely, the feed and the receiver, are separated by an immiscible organic carrier phase. As the driving force in the transport is through the bulk organic phase, it often provides the resistance to the transport of the metal ion of interest. If not stirred properly, the transport rates can be much lower than expected. As the transport rates are diffusion controlled, the membrane thickness or the distance between the feed and receiver phase as well as stirring speed governs the transport behavior of the solutes. Though the Shulman bridge BLM cell is used more often in literature, cells of other designs are also being used. The type of BLM cell is decided by the diluent density. Different types of BLM cell configurations have been used in literature [22–25].

One of the important factors influencing BLM studies is the amount of the organic phase that often decides the transport rates. Effective stirring as well as minimization of the membrane thickness could result in good transport rate. Bhattacharyya et al. have studied the transport of  $\text{Am}^{3+}$  through a toluene solution of Cyanex-301 (bis(2,4,4-trimethylpentyl)di-thio phosphinic acid) as a function of the stirring speed and observed an increase in mass transfer with an increase in the stirring speed [26]. Although >95% Am transport occurred in 5 h, the transport of  $\text{Eu}^{3+}$  was <5% under identical conditions suggesting that their effective separation is feasible on suitable adjustment of feed and strip parameters.

Tri-*n*-butyl phosphate and di-2-ethylhexyl phosphoric acid (HDEHP) have been mainly used as extractants in several hydrometallurgical operations in the nuclear fuel cycle. Shukla and Mishra [27] have studied the extraction as well as transport behavior of uranium through BLM using 40% TBP in dodecane. The transport of  $\text{UO}_2^{2+}$  by TBP at the feed-membrane interphase is represented by the following extraction equilibrium:

Based on Equation 31.1, pertraction rates of uranium were expected to increase with increasing  $\text{HNO}_3$  concentration. A maximum flux ( $J$ ) at 2 M  $\text{HNO}_3$  indicated the formation of  $\text{TBP} \cdot \text{HNO}_3$  complexes at higher nitric acid concentration. Formation of such species is well known in the solvent extraction studies reported earlier [28]. Similarly, the increase in transport rates with increasing TBP concentration was valid up to only 30% TBP beyond which the strong viscosity effects decreased the flux.

Shukla and Mishra have also carried out BLM studies on the transport rates of Pu(IV) from nitric acid medium using 30% TBP in dodecane as the carrier and 0.5 M ascorbic acid as the strippant [29]. The flux is given by the following empirical equation:

$$J_{\text{Pu}} = A(T/\eta)[\text{NO}_3^-]_{\text{a}}^4[\text{TBP}]_{\text{o}}^2 \cdot C_{\text{Pu,feed}} \quad (31.8)$$

where

$A$  is the membrane surface area ( $\text{cm}^2$ )

$T$  is the temperature (K)

$\eta$  is the viscosity (cP)

$C_{\text{Pu,feed}}$  is the concentration of Pu in the feed ( $\text{Mdm}^{-3}$ )

**TABLE 31.2**

<sup>a</sup> Rate constant for Eu(III) transport into the strip phase.

<sup>b</sup> Rate constant for Eu(III) transport in the membrane phase.

The species extracted into the BLM phase is  $\text{Pu}(\text{NO}_3)_4 \cdot 2\text{TBP}_{(o)}$  which is similar to that reported in the solvent extraction studies [30]. With increase in carrier concentration in the organic membrane, the increase in the amount of plutonium that could be extracted into the membrane is countered by the increase in the viscosity of the carrier solution. These opposing effects resulted in maximum plutonium permeation with about 30% TBP in dodecane [29]. More than 85% transport was observed in about 5 h when 5 mg/L solution of Pu in 2 M  $\text{HNO}_3$  was used as the feed. Selective transport of Pu(IV) over fission product contaminants, such as Ce-144, Ru-106, and Cs-137, was also observed.

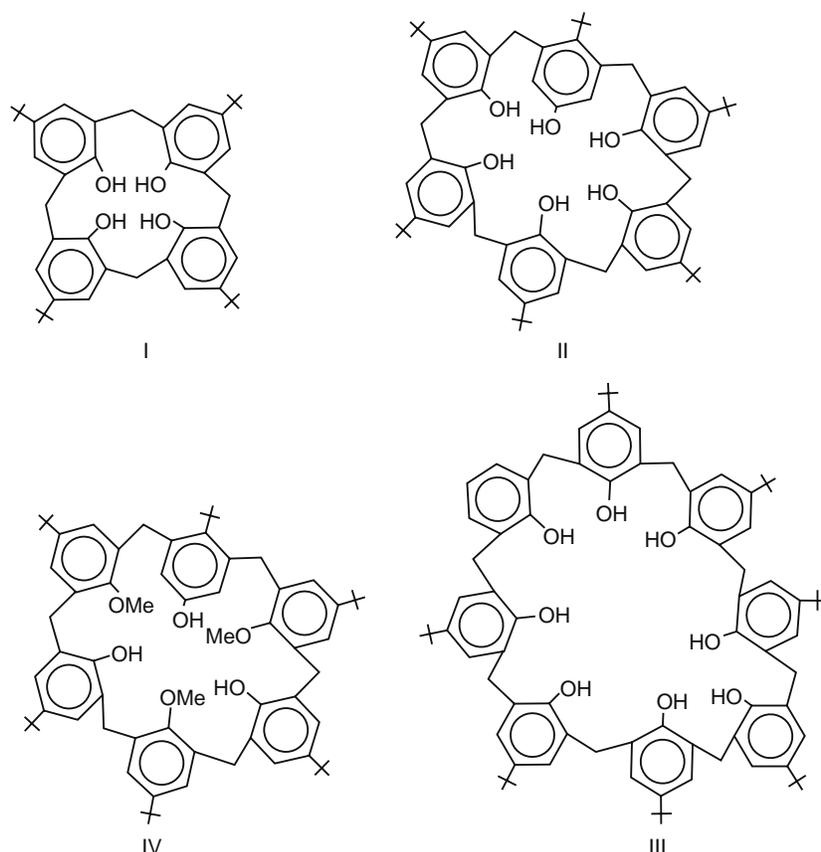

Bulk liquid membrane comprising di-(2-ethylhexyl) phosphoric acid (HDEHP) in chloroform was successfully used as a carrier for the selective and efficient transport of Th. It was observed that 99% of Th selectively permeated across the membrane in <3 h, while the transport of other cations present along with thorium was <3% during the same time [31]. In a study involving Eu(III), coupled transport through a BLM containing mono-2-ethylhexyl 2-ethylhexylphosphonate [HEH(EHP)] in kerosene revealed that there was a counter-transport of protons [32]. Expectedly, increase in the transport rates was observed with increases in the feed pH value and carrier concentration initially. According to the counter-transport mechanism, an increase in the acid concentration in the receiver phase increased the transport rate. There was notable effect of temperature on the transport rates of Eu(III) as indicated in Table 31.2. The activation energy values were calculated to be  $14 \pm 1.0$  and  $54 \pm 3.4$  kJ mol<sup>-1</sup> for the extraction and stripping at the feed–membrane and membrane–strip junctions, respectively [32].

Ramakumar et al. [33] investigated the transport behavior of uranium across the BLM made from several substituted calixarenes (Figure 31.5) in chloroform and 0.1 M nitric acid as the receiver phase. The presence of TOPO and crown ether (18 crown 6) enhanced the transport rate, which was ascribed to synergistic extraction effect.

### 31.2.2 EMULSION LIQUID MEMBRANES

Emulsion liquid membrane is a technique very similar to the solvent extraction process where the separation is achieved by mixing the primary emulsion (strip/organic phase in the emulsion form) with the feed instead of the mixing of aqueous and organic phases as in the solvent extraction processes. Therefore, unlike the solvent extraction processes, ELM studies involve simultaneous extraction and stripping in a single step [34–36]. The emulsification is first done by rapid mixing of the strippant solution and the organic extractant containing the surfactants. The prerequisite is that the primary emulsion must be stable enough so that the mixing of the feed and strip phases is avoided. Precaution must be taken such that the volume reduction of the feed and dilution (due to volume increase) of the strip phases are prevented. Two or more stages are required for a complete separation of the metal ion as the ELM technique is a rate as well as equilibrium-controlled process. The main advantage in the case of ELM is that the use of phase modifier (used in the case of solvent extraction to prevent third-phase formation) is not required. Moreover, the presence of surfactant reduces the loss of the extractant to the aqueous phase significantly. The role of the extractant is extremely important as it helps in getting the metal ion concentrated by active transport against its concentration gradient across the liquid membrane.

Table 31.3 gives a few typical examples on recovery of actinides by ELM. Myriad literature reports exist on the use of HDEHP for metal extraction involve ELMs. Comparative studies between column and batch liquid emulsion membrane techniques based on HDEHP/HCl system were carried out to develop a system for the isolation of <sup>234</sup>Th from natural uranium, which showed that, kinetically, the equilibrium for thorium separation using batch technique is faster than the continuous column system [37]. The effective separation of <sup>234</sup>Th from natural uranium was found to be independent of time. El-Sherif studied

the separation of Th from U and extraction of Am by ELM using HDEHP in cyclohexane as the carrier, polyethylene glycol di-oleate as surfactant, and HCl as a stripping solution [38]. A liquid membrane-based process is used for pilot scale extraction of uranium from wet process phosphoric acid (WPPA) where uranium concentration is up to 100 ppm which in principle makes it

ideal for treatment with a membrane process [39]. The membrane system studied was based on extraction using HDEHP–TOPO reagents that were contained within the organic phase of water in oil emulsion. El-Reefy et al. have also used HDEHP-based ELM containing aqueous HCl to study the permeation of Eu(III) and Am(III) from aqueous solutions containing lactic acid and diethylenetriamine-*N,N,N',N'',N'''*-pentaacetic acid (DTPA) with a view to separate them [40]. The kinetics of Am permeation was fast under these conditions, <55% permeated within 2 min; while the kinetics of Eu permeation was relatively slower (equilibrium occurred after 8 min). This difference in permeation rates can be used to separate Am(III) from Eu(III).

Uranium extraction by liquid surfactant membranes containing HDEHP as a mobile carrier has been studied by Akiba et al. in connection with the stability of water-in-oil (W/O) emulsion [41]. The apparent rate constant ( $k_{\text{obs}}$ ) increased with increase in carrier concentration and with external pH value, while it varied slightly with internal acid concentrations. The emulsion globules were demulsified by a high-voltage electrostatic method to recover the extracted uranium. The extracted uranium was efficiently recovered leaving little remnants in the liquid membrane phase. The extraction of uranium as uranyl nitrate complex in the nitrate acid solution was also carried out by Suropto et al. [42] using an emulsion that consisted of kerosene as the solvent, sorbitan mono oleate (SPAN 80) as the surfactant, HDEHP as the carrier agent, and phosphoric acids as the internal phase, while 2 M nitric acid was used as the external phase. Within 5 min an extraction efficiency of >94% was obtained though the amount of extracted uranium by the ELM was limited. In a mechanistic study by Zhou et al., the kinetics of extraction of uranium (VI) from sulfuric acid solutions with HDEHP in cyclohexane and liquid surfactant membranes containing HDEHP as a mobile carrier was investigated using Lewis cell technique [43].

Macasek et al. [44] carried out extensive studies on the extraction of U(VI), Ce(III), Tc(VII), Co(III), Sr(II), and Cs(I) using ELM made by various extractants such as TOPO, HDEHP, TOA, dicarbolides, di-picryl amine, etc. in SPAN 80 as the surfactant. When TOPO was used as the extractant, significant extraction of acid was observed. Use of  $\text{Na}_2\text{CO}_3$  as the strippant led to the breaking of the emulsion due to the release of carbon dioxide. On the other hand, the emulsions of diluted sulfuric acid in D2EHFA/cyclohexane solution were very good extractants of uranium as >99% recovery was achieved within 20 min using an emulsion comprising <0.1 M D2EHFA, <1 M SPAN 80, and 1–2 M  $\text{H}_2\text{SO}_4$ . When Kelex 100 (8-hydroxy quinoline) was used as the extractant, the recovery percentage decreased to <50% in about 25 min of agitation. On the other hand, Kulkarni et al. [45] used an ELM comprising TOPO, SPAN 80, and paraffin for the recovery of U from dilute nitric acid medium using 0.05 M  $\text{Na}_2\text{CO}_3$  as the internal phase. Optimization of the mixing time (10 min) was done to achieve maximum pertraction, minimum swelling, and minimum breaking of the emulsion.

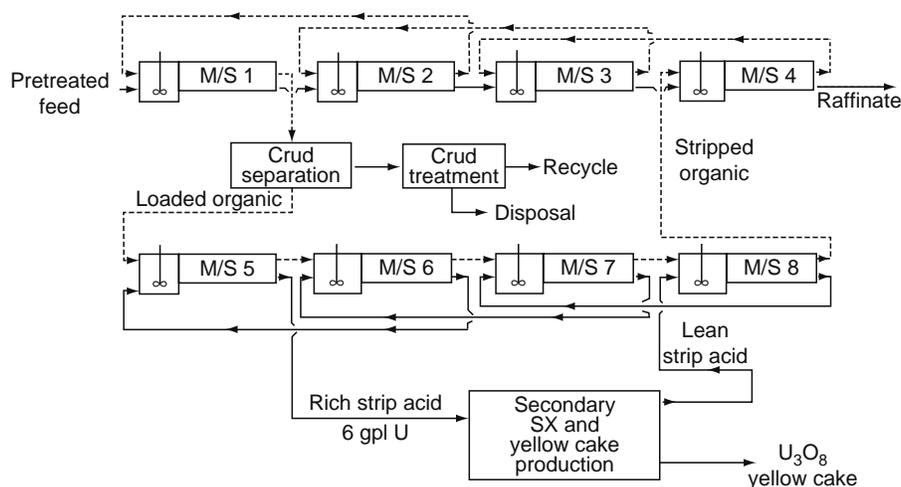

The transfer kinetics of uranium (VI) through an ELM with di-1(1-methylheptyl) phosphoric acid (DMHPA) as a mobile carrier was investigated by Han et al. [46]. The experimental results showed that more than 96% of the initial U(VI) is recovered. Extraction of uranium (VI) by a liquid surfactant membrane containing 5,8-diethyl-7-hydroxy-6-dodecanone oxime (LIX 63) was investigated by Akiba et al. [47] and the apparent rate constants were calculated. The feed comprised of tracers ( $10^{-5}$  M) of U in pH 3–4.5, while the strippant used for the water-in-oil emulsion was sulfuric acid (pH 1.5). The apparent rate constants of extraction increased with an increase in carrier concentrations and external pH values, while they were slightly dependent on the stripping phase acidity. Increase in surfactant concentration led to decreased extraction of U and an optimum value was obtained using 2% of SPAN 80. It was important to note that the stripping rate was not the rate-determining step in the mass transfer process.

Han et al. [48] studied the transfer behavior of uranium (VI) through an ELM using *N,N*-di-*n*-butyloctanamide (DBOA) as a mobile carrier and suggested that the liquid membrane process can effectively and rapidly concentrate uranium (VI) from nitric acid medium. Hirato et al. [49] have used tri-*n*-octyl amine (TOA) and SPAN 80 in kerosene as the organic phase and the emulsion was made using 1 M  $\text{Na}_2\text{CO}_3$  solution as the internal phase. The feed comprised of uranium in sulfuric acid medium. More than 99% extraction was achieved using 0.05 M TOA at 3% surfactant concentration. The higher efficiency of the ELM system as compared to the solvent extraction system is clear from the data presented in Table 31.4. Out of the various internal

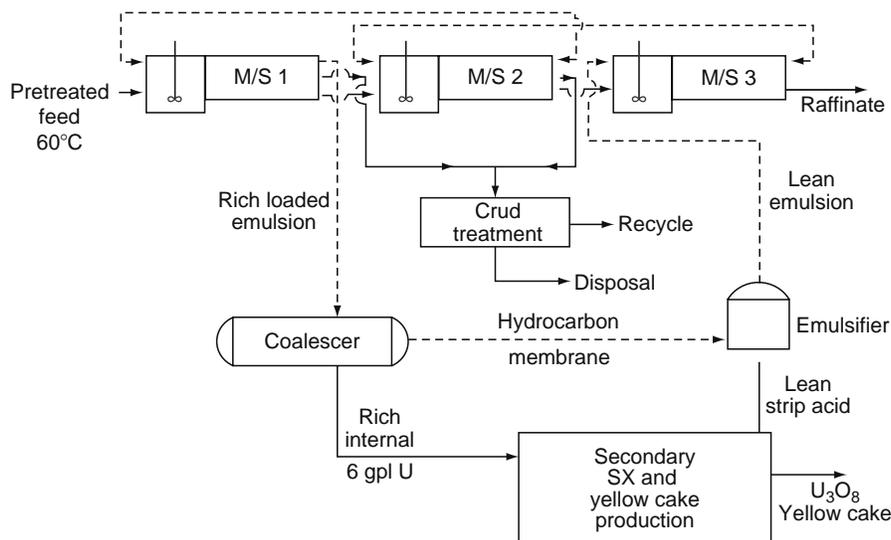

**FIGURE 31.6** Process flow diagram for U recovery by SX method. (Reproduced From Hayworth, H.C., Ho, W.S., Burnes, W.A. Jr., and Li, N.N., *Sep. Sci. Tech.*, 18, 493, 1983. With permission.)

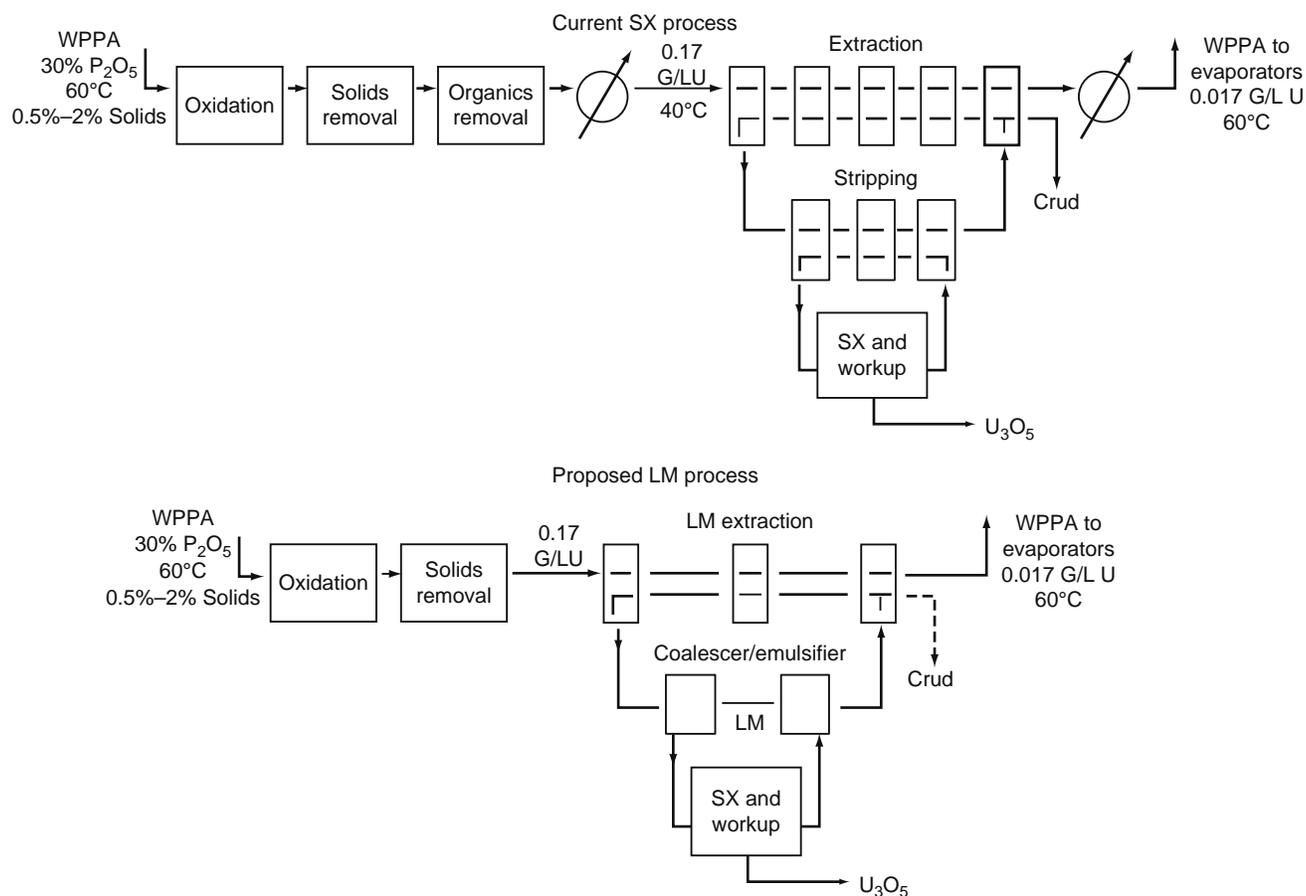

solution used in their study,  $\text{Na}_2\text{CO}_3$  was found to be the most effective. By a two-stage extraction, the U concentration in the outer phase (at a phase ratio of carrier:internal phase:external phase = 1:1:10) could be brought down by a factor of 1000.

Hayworth et al. [50] have investigated the extraction of uranium from WPPA by liquid membranes of the emulsion type containing HDEHP/TOPO as the extractant. They reported that the ELM is economically superior to a system based on solvent extraction. The schematics of U recovery by the solvent extraction and the ELM method are shown in Figures 31.6 and 31.7, respectively. In the ELM process (Figure 31.7), the pretreated feed (or external phase) was contacted with a lean emulsion in a mixer-settler train. The comparison of the current solvent extraction process and proposed ELM process for the recovery of U from wet process phosphoric acid (WPPA) is shown in Figure 31.8. The proposed ELM process is suggested to be more efficient than the solvent extraction process. Bock et al. [51] have also investigated the liquid membrane separation of U from WPPA.

The coupled transport of europium(III) ion and hydrogen ion, via ELM containing PC-88A ((2-ethylhexyl) phosphonic acid mono-2-ethylhexyl ester) as mobile carrier and SPAN 80 as surfactant in diluent *n*-dodecane, was studied by Lee et al. [52]. The extraction behavior of U(VI) by PC-88A was investigated by Nakamura et al. [53] where the extracted species was found to be  $\text{UO}_2(\text{HA})_2$  (where  $\text{HA} = \text{PC-88A}$ ). Uranium was transported from the feed solution to a receiving solution of dilute sulfuric acid and was facilitated by a large concentration gradient of hydrogen ions across two sides of the LM. The addition of 1-decanol to the membrane solution improved the U stripping and contributed further to stabilize the PC-88A membranes

**FIGURE 31.7** Process flow diagram for U recovery by the liquid membrane method. (Reproduced from Hayworth, H.C., Ho, W.S., Burnes, W.A. Jr., and Li, N.N., *Sep. Sci. Tech.*, 18, 493, 1983. With permission.)

**FIGURE 31.8** Comparison of ELM and SX processes for the recovery of U from WPPA. (Reproduced from Hayworth, H.C., Ho, W.S., Burnes, W.A. Jr., and Li, N.N., *Sep. Sci. Tech.*, 18, 493, 1983. With permission.)

without any leaching into the aqueous phase. ELM recovery of Pu from aqueous nitrate solutions using PC-88A (existing as a dimer) in *n*-dodecane and SPAN 80 as carrier and surfactant, respectively, suggested about 90% recovery/removal of Pu from the waste in perchloric acid medium with the concentration factor of the order of 16 in 20 min of contact time [54]. Larger concentration of Pu (about 20 mg/L in the outer phase) could be extracted from perchloric acid medium using PC-88A in dodecane emulsion in SPAN 80 in about 60 min. Studies from nitric acid medium have shown that a feed comprising 4 M  $\text{HNO}_3$  can be effectively used for Pu separation.

EI-Reefy et al. observed that U(VI), Th(IV), Zr(IV), and Fe(III) were extracted to different extent from 0.1 to 3 M  $\text{HNO}_3$  solution by 0.1 M TOPO in cyclohexane solution using ELM [55]. Among these elements, only U(VI) and Th(IV) were found to be stripped from their organic phase by 0.1 M sodium citrate solution. On the other hand, cerium, copper, and cadmium were not extracted by TOPO under similar conditions. Forward permeation rate of uranyl ion was found to be mainly dependent on TOPO concentration and the concentration of U(VI) and  $\text{HNO}_3$  in the external phase was of little consequence.

### 31.2.3 SUPPORTED LIQUID MEMBRANES

Supported liquid membranes comprised the bulk of the published literature on the transport studies of metal ions across thin polymeric films [16,56–59]. Several literature reports on actinide transport across supported liquid membranes using various types of extractants viz., acidic extractants, neutral extractants and amine extractants are discussed below.

#### 31.2.3.1 Acidic Extractants as Carriers

Acidic extractants are commonly used as carriers for the pertraction of actinide ions across SLMs. Main feature of the acidic extractants is the inverse dependence of transport rates with the feed acidity. The various types of acidic extractants used as carriers for the separation of actinides are summarized in Table 31.5.

**TABLE 31.5**  
**Comparative Performances of Some Acidic Extractants Used as Carriers in SLM Studies**

Metal Ion	Carrier	Feed	Strip	Comments	References
U(VI)	Kelex 100	pH in the near neutral range	0.1 M HNO <sub>3</sub>	Recovery from seawater was possible without pretreatment	[60,61]
U(VI)	Cyanex-272	HNO <sub>3</sub>	HEDPA	Decontamination of Hanford site ground water containing U (>8000 ppb)	[79,80]
U(VI)	HDEHP	pH solutions	5 M H <sub>3</sub> PO <sub>4</sub>	Transport rates controlled by aqueous diffusion layer in Feed side	[67]
U(VI)	LIX 63	pH solution	0.1 M H <sub>2</sub> SO <sub>4</sub>	>99% U recovery was possible with DF exceeding 10 <sup>3</sup>	[84]
U(VI)	HDEHP + TOPO	5–6 M H <sub>3</sub> PO <sub>4</sub>	Fe(II)/H <sub>3</sub> PO <sub>4</sub>	Too low flux for any practical application	[75–77]
Am(III)	HPBI + TOPO	<1 M HNO <sub>3</sub>	1 M oxalic acid	>90% Transport was possible in <4 h	[63]
Am(III)	Cyanex-301	pH solution	0.1 M HNO <sub>3</sub> /0.1 M EDTA (pH 3.4)	Separation of Am(III) from Eu(III) was possible	[82,83]

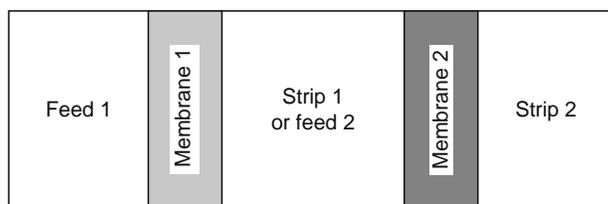

Akiba et al. investigated the carrier-mediated transport of uranium (VI) by a liquid membrane of 7-dodeceny-8-quinolinol (Kelex 100) [60]. The apparent rate constant of uranium transport was not affected significantly with the increase in the carrier concentration and the pH of the feed solution. They had also reported that uranium can be effectively recovered from seawater through the liquid membranes without any preliminary treatment. Compounds analogous to Kelex 100, with long-chain aliphatic linkages, have been used for this study [61].

Seguira et al. had used 2-thenoyl trifluoroacetone (HTTA) as the carrier for the transport of lanthanide ions [62]. The transport of Am(III) was investigated by Mohapatra et al. employing FSSLM technique using a synergistic mixture of 3-phenyl-4-benzoyl-5-isoxazolone (HPBI) and TOPO in *n*-dodecane as the carrier and 1 M oxalic acid as the strippant [63]. Apart from enhancing the flux due to synergistic extraction, TOPO also helped in the ligand solubility in the membrane phase. It was possible to achieve >90% transport of Am(III) in about 4 h with the feed acidity as 1 M HNO<sub>3</sub> and the carrier concentration as 0.1 M HPBI + 0.2 M TOPO. The major disadvantage was, however, the deterioration of the membrane with increasing acidity due to the formation of TOPO · HNO<sub>3</sub> adducts. This led to the blocking of the membrane pores, thereby decreasing the flux drastically.

Nakamura et al. investigated the permeation of lanthanide ions using an SLM impregnated with Versatic 10 (VA 10) alone in kerosene [64,65]. Separation factors obtained from the transport rates for lighter lanthanoids were larger than those for heavier lanthanoids. The separation factors for heavier lanthanoids were enhanced by the addition of citrate to the feed solution [65]. Several complexing agents have been used in the receiving phase by Chitra et al. [66] during their SLM studies on Eu with PC-88A and VA 10 as immobilized carriers. Under similar experimental conditions, the effect of complexing agents on permeation of europium was found as citric acid > succinic acid > malonic acid. Permeating coefficient of europium was found to be greater with PC-88A in comparison with that of VA 10.

A large number of reports are available in the literature on the pertraction of actinides and lanthanides using dialkyl phosphoric acid as the carrier. Kinetics of the coupled transport of U(VI) across SLM containing bis(2-ethylhexyl)phosphoric acid (HDEHP) in kerosene as a mobile carrier was investigated by Huang and Huang [67]. The transport rates of U(VI) from feed containing  $1.5 \times 10^{-4}$  to  $1.8 \times 10^{-3}$  M uranyl ion and 5 M phosphoric acid as the receiver phase were measured and were found to be controlled by chemical reaction and aqueous film diffusion, both of which occur at the feed–membrane interphase. The transport rate measured was found to be proportional to the concentration of U(VI) in the source phase and increased with the concentration of the HDEHP in the membrane liquid. Mikheeva et al. had investigated the membrane transport of Am under conditions of different redox potentials in aqueous phase using HDEHP as the carrier [68]. The various steps leading to the transport were explained on the basis of physicochemical model of the process including steps of americium oxidation in feed solution, extraction by membrane, partial reduction on membrane surface, transmembrane diffusion, and reextraction to strip solution. In another study, the coupled transport of Eu(III) ions through an SLM consisting of a porous polypropylene film immobilizing HDEHP solution in *n*-dodecane was studied [69]. While modeling the data, it was observed that the deviations from a pseudo-first-order rate law, often observed when measuring the coupled transport of metal species at low concentrations through SLMs, are due to a reasonable value of the distribution ratio at the membrane–strip interphase [70]. The study on tervalent elements in nitrate medium through a flat-sheet membrane comprising HDEHP in dodecane indicated that the transport rates of Ce and Gd decreased with increasing feed acidity. The transport of all the metals increased to some extent with increasing concentration of HDEHP in the feed. Conditions were established for separating the pairs Ce–Tm, Ce–Yb, and Ce–Sc [71].

Separation studies can be performed by a series of composite membranes (using two SLMs in parallel) containing either of the acidic carriers such as HDNNS or HDEHP with a neutral carrier such as a bifunctional neutral organophosphorous

**FIGURE 31.9** Schematic of a composite SLM cell comprising two parallel SLMs for the prevention of counter-transport of acid.

extractant such as CMPO in decalin [72]. The transport behaviors of  $\text{Am}^{3+}$  and  $\text{Eu}^{3+}$  were investigated from feeds containing 0.01 M HCl + 1.0 M NaCl (for HDEHP and CMPO composite membranes) and 0.2 M  $\text{HNO}_3$  + 3.0 M  $\text{NaNO}_3$  (for CMPO and HDNNS composite membranes) where the strip solutions were 0.2 M  $\text{HNO}_3$  + 3.0 M  $\text{NaNO}_3$  and 0.01 M HCl + 1.0 M NaCl, respectively, which on the other hand acted as the feed solution for the second membrane (Figure 31.9). This setup was used to prevent the counter transport of acid from the receiver to the feed side.

Recovery of uranium from WPPA is usually carried out by two extractants: (a) a mixture of HDEHP and TOPO (tri-*n*-octyl phosphine oxide) and (b) octyl-phenyl acid phosphate (OPAP). The first system preferentially extracts U(VI) [73] while the second extracts U(IV) [74]. The application of liquid membrane technology for the recovery of U from WPPA has been discussed in many reports where quantitative recovery is reported [75,76]. Sifniades et al. [77] have attempted to understand the transport behavior of U(VI) from 5 to 6 M phosphoric acid solution through an SLM containing HDEHP and TOPO in kerosene as the organic carrier into a receiver phase containing Fe(II) in  $\text{H}_3\text{PO}_4$ . They developed a model based on the uranium transport through the membranes and through quiescent layers of phosphoric acid and HDEHP/TOPO in kerosene. The average uranium flux from simulated solutions of WPPA at 90% uranium transport was estimated to be  $1.3 \times 10^{-11} \text{ M cm}^{-2} \text{ s}^{-1}$ , which was judged to be too low for SLMs to be competitive with liquid–liquid extraction processes for the recovery of U from WPPA. The SLM method required >10 days for quantitative transport of uranium from 5 to 6 M phosphoric acid solution taken in the feed compartment.

Nakamura and Akiba [78] have investigated the carrier-mediated transport of europium using an FSSLM impregnated with di-*iso*-decyl phosphoric acid (DIDPA) in kerosene as the carrier. Effective pertraction was observed from a feed containing 0.1 M  $\text{HNO}_3$  and a strip phase comprising 5 M  $\text{HNO}_3$ . Interestingly, the efficiency of stripping increased significantly in the presence of 10% 1-octanol added to the carrier phase. The europium flux was found to be proportional to the initial europium concentration at lower concentrations and remained unaffected beyond  $10^{-3}$  M.

Dialkyl phosphinic acids have been used as extractants of lanthanides and actinides. Di(2,4,4-trimethylpentyl)phosphinic acid (DTMPPA or Cyanex-272) has been used for the removal of uranium from contaminated ground water [79] after acidifying the ground water to pH 2. The strip solution contained 1-hydroxyethane-1,1-diphosphonic acid (HEDPA). This separation method was successfully employed for the decontamination of Hanford site ground water containing U concentration >8000 ppb which was brought down to <10 ppb (Table 31.6). This was later scaled up by the HFSLM method to achieve much higher DF values [80]. The transport of Eu(III) at pH 3 across a DTMPPA liquid membrane supported on porous polytetrafluoroethylene to a strip solution (0.1 M nitric acid) was investigated [81]. It was observed that the thio derivative of the ligand has a limited preference of Eu(III).

Separation of lanthanides and actinides is a challenging area of research in separation science. Impetus in this area of research has been provided by the need to develop safer and economically viable methodologies of HLW management. The

TRUEX as well as the DIAMEX processes developed during the last decade for actinide partitioning do not distinguish among trivalent lanthanides and trivalent actinides. Either of the two strategies being evolved for the HLW management, namely, vitrification followed by disposal in deep repositories or transmutation of long-lived actinide isotopes to short-lived fission products using high-energy high-flux reactors or accelerator-driven sub-critical systems, require the separation of Ln(III) from An(III). This is necessitated in view of the larger mass of lanthanides (30 times) over that of the minor actinides and high-neutron absorption cross section of some isotopes of lanthanides that may act as neutron poisons thereby rendering the transmutation process inefficient. It is desirable therefore to develop suitable complexing/separating agents, which can recognize trivalent lanthanides from trivalent actinides.

Although literature reports on liquid membrane separation of An(III) and Ln(III) are relatively scarce, some of them are discussed here. Bhattacharyya et al. carried out SLM studies using PP membranes containing 0.1 M bis(2,4,4-trimethylpentyl) dithiophosphinic acid (Cyanex-301) in *n*-dodecane as the carrier, pH 3.4 solution (sulfanilic acid buffer) as the feed, and 0.1 M EDTA as the receiver [82]. Though the quantitative transport (>99% in 20 h) of Am<sup>3+</sup> was observed, transport of Eu<sup>3+</sup> was negligible. Hoshi et al., on the other hand, observed the selective transport of Am<sup>3+</sup> across an SLM by using Cyanex-301 as a mobile carrier [83]. This extractant containing soft donor atoms exhibits strong affinity for actinoids, giving a large separation factor between trivalent Am and Eu. Americium was preferentially transported across the SLM and concentrated in product solution, while most of the Eu remained in the feed solution.

Uranium transport rates were also measured by Akiba and Kanno [84] using an SLM containing LIX 63 (5,8-diethyl-7-hydroxy-dodecan-6-one oxime) in kerosene as the carrier. Uranium transport was facilitated from a feed containing U(VI) at pH 4–5 to the receiver solution containing 0.1 M HNO<sub>3</sub>. The rate of transport was inversely proportional to the feed volume and was independent of U(VI) concentration. More than 99% of U was recovered and the final concentration ratio in the product to the feed exceeded 10<sup>3</sup>.

### 31.2.3.2 Neutral Donors As Carrier

#### 31.2.3.2.1 Alkyl Phosphates and Phosphine Oxides As Carriers

Tri-*n*-butyl phosphate is the work horse of the nuclear industry and is being used at various stages of nuclear fuel cycle. Apart from alkyl phosphates, tri-alkyl phosphine oxides are also used in many plant scale operations as well as in laboratory scale analytical separations. Minimizing their inventory in such separations through SLM methods though professed has not found industrial scale applications. Some of the laboratory scale applications of alkyl phosphates and tri-alkyl phosphine oxides as carriers in SLM will be discussed in this section (Table 31.7).

Similar to the transport behavior in BLM system (Section 31.2.1), several reports are available on the SLM-based transport studies of uranyl ion from feed containing nitric acid using TBP as the carrier. The nature of the species diffusing through the SLM phase is similar to the one given by Equation 31.1. Shukla and Mishra [27] have used 30% TBP in dodecane as the carrier and 1 M (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> as the receiver phase for their transport studies involving uranyl ion from a feed containing 2 M HNO<sub>3</sub>. Uphill transport was observed when both the F and R contained about 35 mg/L of U. In about 7 h, the U concentration in the receiver phase doubled suggesting the feasibility of the use of the SLM system for the preconcentration of the metal ion from dilute solutions. Chaudry et al. [85] have also investigated the transport studies of uranium using TBP in kerosene as the carrier. Permeation of the species of the type UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub> · 2TBP<sub>(o)</sub> was confirmed from the log *J*<sub>η</sub> vs. log [TBP], and log *J*<sub>η</sub> vs. log [HNO<sub>3</sub>] plots. The effect of temperature was also studied and was found to have a retarding effect on the metal ion permeation. It was observed that at higher concentration of nitric acid, TBP · *n*HNO<sub>3</sub> complexes (where *n* = 1 or 2) were also transported

TABLE 31.7

along with the  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP}_{(o)}$  complex [86]. They have calculated the diffusion coefficient ( $D$ ) for the  $\text{TBP} \cdot n\text{HNO}_3$  complexes from the Stokes–Einstein equation:

$$D = kT/6\pi R\eta \quad (31.9)$$

where

$k$  is the Boltzman constant

$\eta$  is the viscosity of the carrier solution

The diffusion coefficients are listed in Table 31.8. Transport of the  $\text{TBP} \cdot \text{HNO}_3$  complex was also reported in another study on a similar system [87]. However, based on the calculations made using the Stokes–Einstein equation, species of the type  $2\text{TBP} \cdot \text{HNO}_3$  is the more probable species diffusing through the organic layer. The difference between the experimentally observed and predicted values is attributed to the intermolecular interaction and tortuosity factors.

Based on the selective transport properties of TBP and its mixture with di-2-ethylhexyl phosphonate in benzene an uranyl ion selective membrane electrode was developed by Serebrennikova et al. [88]. This membrane electrode possesses higher selectivity as compared to the membrane electrode containing only di-2-ethylhexyl phosphonate in benzene [89]. Transport of  $\text{Pu}^{4+}$  from a feed containing 2 M  $\text{HNO}_3$  to a receiver phase containing 0.5 M ascorbic acid was investigated using Accurel 2E HF-PP flatsheet membrane containing 30% TBP in dodecane as the carrier [29]. Out of various strippants, namely, oxalic acid, ascorbic acid, hydroxyl amine hydrochloride, and sulfamic acid, ascorbic acid was found to be the most promising.

Changing the alkyl groups in TBP had shown interesting selectivities during solvent extraction studies [90,91]. Selective permeation of plutonium from aqueous nitrate medium was investigated using an SLM impregnated with tri-*iso*-amyl phosphate (TAP). More than 90% pertraction of plutonium could be easily accomplished in single run employing a feed solution consisting of about 1 mg/L Pu and 4 M  $\text{HNO}_3$ , at a carrier concentration of 0.8 M TAP/*n*-dodecane while the receiving phase was 0.5 M sodium carbonate or 0.5 M ascorbic acid [92]. Transport of U(VI) from aqueous nitrate solutions across an SLM, impregnated with tris(2-ethylhexyl) phosphate (TEHP), was investigated by Dharmapurikar et al. [93]. The permeability of U(VI) was evaluated as a function of  $\text{HNO}_3$  molarity in the feed phase (F), carrier concentration in the membrane phase, and chemical composition of the receiving phase (R). More than 90% extraction of U can easily be accomplished in single run employing about 0.2 g/L of U in 4 M  $\text{HNO}_3$  as the feed, carrier concentration of 0.6 M TEHP/*n*-dodecane while 0.5 M  $\text{Na}_2\text{CO}_3$  was used as the receiver.

Carrier (TOPO)-mediated transport of uranium(VI) has been studied by Akiba and Hashimoto [94] who have observed that uranium was extracted in the liquid membrane as  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TOPO}$  and stripped into the carbonate solutions as  $\text{UO}_2(\text{CO}_3)_3^{4-}$ . Using TOPO and HDEHP mixture, liquid membrane technique was applied for the recovery of uranium from WPPA [95]. Carrier-facilitated Pu(IV) pertraction through an SLM was standardized for its decontamination from oxalate wastes employing a commercially available Cyanex-923 (TOPO analog) in dodecane as the receptor [96,97]. More than 95% of plutonium could be easily recovered from Pu oxalate wastes solution during Pu reconversion operations.

Am(III)	TODGA	HNO <sub>3</sub>	Water	Good membrane stability was observed	[132]

Plutonium(III)-ion selective electrode consisting of phosphine oxides such as bis-(diphenylphosphoryl)-methane as an ionophore was developed by Kitatsuji et al. [98]. The Pu(III)-ISE prepared exhibited Nernstian response to the concentration of Pu<sup>3+</sup> in the sample solution. Interference of UO<sub>2</sub>(VI), U(IV), NpO<sub>2</sub>(V), and Pu(IV) was investigated. Cristau et al. [99] have carried out extraction as well as permeation studies of actinides such as neptunium, plutonium, and americium using polyphosphine polyoxides with (O)PCP(O) linkage, which exhibit very high selectivity.

#### 31.2.3.2.2 CMP and CMPO as Carriers

Current perception of radioactive waste management after operations involving the aqueous processing of the spent nuclear fuel materials involves minor actinide partitioning using exotic reagents as a key step. The recovery of alpha-emitting radioactive materials such as <sup>237</sup>Np, <sup>241</sup>Am, <sup>243</sup>Am, and <sup>245</sup>Cm from the HLW using novel bifunctional organophosphorous extractants such as CMP and CMPO has drawn the attention of many research groups [100–103]. A large number of publications have appeared using these reagents as carriers in the SLM studies. Many of the SLM studies have used lanthanides as surrogates (Table 31.9).

The transport of europium was studied by Nakamura and Akiba [104] through an SLM impregnated with di-*n*-hexyl-*N,N*-diethyl carbamoyl methyl phosphonate (CMP) from the perchlorate solution. The addition of 1-decanol improved the stripping process, and quantitative transport of europium was achieved. By combining the two SLM systems (Figure 31.10), consisting of di-*iso*-decylphosphoric acid and CMP, europium was transported from the feed solution (0.1 M HNO<sub>3</sub>) through the intermediate solution (1 M HClO<sub>4</sub> + 4 M NaClO<sub>4</sub>) to the product solution (0.1 M HNO<sub>3</sub>) and was effectively concentrated by a factor of about 20 [105].

Supported liquid membranes, consisting of an organic solution of *n*-octyl(phenyl)-*N,N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) and tributyl-phosphate (TBP) in decalin, were capable of selective separation and concentration of actinide and lanthanide ions from aqueous nitrate feed solutions and from synthetic nuclear wastes where the strip solution is a mixture of formic acid (FA) and hydroxylammonium formate (HAF) [106,107]. TBP is added to CMPO to improve its solubility in aliphatic diluents. Although low concentration of nitric acid was initially used as the strippant solution, a gradual

Feed 0.1 M HNO <sub>3</sub> 100 mL	SLM (1) 0.2 M (DIDPA) <sub>2</sub> + 10% decanol	Intermediate solution 1 M HClO <sub>4</sub> 4M NaClO <sub>4</sub> 20 mL	SLM (2) 0.1 M CMP + 10% decanol in kerosene	Product 0.1 M HNO <sub>3</sub> 5 mL
---	--	---	---	--

**FIGURE 31.10** Combination of two SLM systems consisting of DIDPA and CMP for the effective transport of Eu(III). (Reproduced from Nakamura, S. and Akiba, K., *Sep. Sci. Tech.*, 24, 1317, 1989. With permission.)

decrease in the transport rates due to the nitric acid transport led to the use of FA + HAF mixture as the strippant. The effectiveness of this strip solution was gradually reduced by the simultaneous transfer of HNO<sub>3</sub> in the strip solution. A possible way to overcome this drawback is to make use of a second SLM consisting of a primary amine that is able to extract only HNO<sub>3</sub> from the strip solution. The use of second liquid membrane in the synthetic nuclear waste/CMPO-TBP membrane/HCOOH-HAF strip solution/primary amine membrane/NaOH solution allowed the quantitative removal of actinide and lanthanide ions from the feed solution. Chiarizia et al. [108] used CMPO loaded membranes for analysis of Am in biological samples after leaching in nitric acid medium. Two membranes were used in the transport studies consisting of 0.25 M octyl(phenyl)-*N,N*-diisobutylcarbamoylmethylphosphine oxide (CMPO)/0.75 M TBP and primary aliphatic amine (PAA) (as a second membrane) for the selective extraction of actinides from nitric acid solutions. In another SLM study using CMPO as the carrier, Ramanujam et al. had used a mixture of citric acid, formic acid, and hydrazine hydrate as the receiving phase for partitioning of actinides from high-level waste of PUREX origin [109]. The studies indicated good transport of actinides such as neptunium, americium, and plutonium across the membrane from nitric acid medium. A high concentration of uranium in the feed retards the transport of americium, suggesting the need for early removal of uranium from the waste. The separation of actinides from uranium-lean simulated samples as well as from actual high-level waste was found to be feasible using the above technique.

Danesi et al. studied the kinetics of transport of Am(III) from aqueous nitrate solutions to formic acid aqueous solutions using an SLM, which consisted of a solution of a new (carbamoylmethyl)phosphine oxide in diethylbenzene (DEB) [110]. In an attempt to treat simulated low-level radioactive wastewater, Teramoto et al. [111] have used an SLM containing CMPO for the uphill transport of Ce(III) from aqueous solution containing a mixture of nitric acid and sodium nitrate. The simulated waste contained Ce(III), Fe(III), Cr(III), and Ca(II), while the strip solution contained water or sodium citrate solution. Though TBP has been used along with CMPO and *n*-dodecane as the carrier solution, it also facilitates the transport of HNO<sub>3</sub> to the strip side. The acid transport was significantly decreased when CMPO alone in 2-nitrophenyl octyl ether was used as the carrier solution.

### 31.2.3.2.3 Dialkyl Amides and Diamides As Carriers

With increasing concern for the environment protection, incinerable CHON or the green extractants are becoming more and more popular among chemists involved in separation science and technology. Among these dialkyl amides, pentaalkyl malonamides and tetraalkyl di-glycolamides are the most popular due to their innocuous hydrolytic and radiolytic degradation products and favorable DF values for actinide ions [112–117]. The SLM-related work carried out using amides and diamides as carriers is indicated in Table 31.9.

Di-*n*-hexyl octanamide (DHOA) was used by Patil et al. for effective transport of uranyl ion from 4 M nitric acid to a strip solution containing either 1.0 M Na<sub>2</sub>CO<sub>3</sub> or 0.01 M nitric acid [118]. Several newly synthesized monoamides such as di-butyl octanamide (DBOA), methylbutyldecanamide (MBDA), methyl butyl octanamide (MBOA), di-butyl decanamide (DBDA), di-*n*-octyl ethylhexyl amide (DOEHA), and di-hexyl octanamide (DHOA) were tested by Shukla et al. as carriers across SLMs for selective transport of Pu(IV) [119]. Of them, MBDA and DBOA proved to be quite suitable as ionophores from HNO<sub>3</sub> media providing >95% and >82% transport of Pu(IV) when operated for 7 h. Shailesh et al. [120] have used a sterically modified amide, di-2-ethylhexyl isobutyramide (D2EHIBA) in *n*-dodecane as the carrier for the selective transport of trace U(VI) in the presence of large excess of Th(IV). The decontamination factor obtained in this method is attributed to lower nitric acid transport rates as compared to TBP/*n*-dodecane system, which has much higher permeability coefficient as compared to D2EHIBA/*n*-dodecane system. This work is particularly interesting as it offers an alternative membrane-based separation method to the conventional TBP extraction-based separation methods.

Sriram et al. carried out SLM studies on the transport of Am<sup>3+</sup> from nitric acid medium using dimethyl dibutyl tetradecyl malonamide (DMDBTDMA) in dodecane as the carrier into 0.01 M nitric acid [121]. Significant transport of acid into the strip side resulted in relatively slower transport rate. It was observed that a mixture of 0.1 M DTPA, 0.4 M hydrazine, and 0.4 M formic acid led to highest transport rate (>60% in 8 h) when used as the stripping solution [122].

The effect of organic diluents on the extraction and hence the transport rates of Am<sup>3+</sup> were quantified by an empirical correlation using several diluents, namely, *n*-dodecane, toluene, *n*-hexane, cyclohexane, 1,2-dichloroethane, nitrobenzene, decalin, and diethyl benzene [123]. The extraction equilibria were not affected and the tri-solvate species were transported in all the cases as per the following extraction equilibrium:

The extraction (and hence the transport) efficiency depends on several diluent factors such as Schmidt empirical diluent parameter [124,125], the Swain's acidity and basicity parameters along with the Dimroth and Reichardt polarity indices [126], dielectric constant [127], refractive index [127] and viscosity [127], and the Hildebrand's solubility parameter [128]. The permeability coefficients ( $P_{\text{Am}}$ ) were computed from the Wlke-Chang, Scheibel, and Ratcliff [129,130] equations, which compared reasonably well with the experimentally determined values as shown in Table 31.10. Elhassadi and Do [131] have, on the other hand, taken into account only the viscosity and solubility effect of the diluent and the carrier immobilized in SLM. They have reported that these two factors influenced the transport rates significantly.

Source: Data from Sriram, S. and Manchanda, V.K., *Solv. Extr. Ion Exch.*, 20, 97, 2002. With permission.

Though tetraalkyl di-glycolamides (TODGA) are far superior as extractant as compared to CMPO or diamides, to our knowledge very little work on their use as carrier in SLM studies is reported so far. Ansari et al. [132] have studied the transport of Am<sup>3+</sup> from nitric acid medium into a receiving solution of distilled water using an SLM made from *N,N,N',N'*-tetraoctyl-3-oxapentane diamide (TODGA) in *n*-dodecane as the carrier inside microporous PTFE membranes. The transport of feed acid to the receiver phase was increased with the feed acidity, which influenced the transport rate of the metal ion at higher acidity (>2 M HNO<sub>3</sub>). Maximum transport was observed with a carrier concentration of 0.1 M and a feed acidity of 2 M HNO<sub>3</sub>. The membrane stability was remarkably good when tested for more than 20 days of continuous operation. The use of TODGA as a carrier in the polymer inclusion membrane (PIM) is discussed in Section 31.3 [133].

#### 31.2.3.2.4 Macrocyclic Carriers in Supported Liquid Membrane

Macrocyclic carriers such as crown ethers, cryptands, and calixarenes have been used as carriers for the transport studies involving alkali and alkaline earth metal ions [134–136]. There are a few reports on the use of these ligands as the carriers for the transport of lanthanide/actinides as well. Shukla et al. [137] studied the uranyl ion permeation fluxes, physical stability (loss of carrier), and chemical stability of SLMs using crown ethers in various aromatic and aliphatic diluents. They have concluded that the chlorinated hydrocarbons such as chloroform, 1,2-dichloroethane, dichloromethane afford much poor permeability compared to aromatic diluents such as toluene and *o*-dichlorobenzene. Plutonium transport could be achieved using 0.2 M DC18C6/toluene as carrier and sodium carbonate as strippant. By a combination of both BLM and SLM (using polypropylene filters), >90% transport of Pu was achieved using 0.2 M DC18C6 in toluene as the carrier into dilute sodium carbonate strippant in about 7–8 h without any contamination from fission products such as Ru-106, Cs-137, and Sb-125 [138]. The proven extractability and profound selectivity of dicyclohexano-18-crown-6 (DC18C6) have been exploited by selecting this crown ether as the ionophore in liquid membrane transport studies. Macrocyclic-facilitated transport of Pu(IV) and U(VI) against their concentration gradient from aqueous nitric acid solutions across SLM containing DC18C6 in toluene has also been investigated [139]. In the presence of 0.2 M DC18C6 in toluene as the carrier, uphill transport was observed when both the feed and receiver comprised of 0.8 mg/mL of Pu. The effect of radiation on the transport rates has indicated that the permeation of U(VI) and Pu(IV) was not affected when the membranes containing the carrier were subjected to a total dose of 80 kGy. On the other hand, dry membranes (Accurel HF-PP) became somewhat fragile beyond a total dose of 50 kGy though the transport behavior was not very much affected. The chemical stability of the membrane containing DC18C6 in toluene was satisfactory up to 12 h of continuous operation, beyond which a drop in the permeability coefficient was ascribed to the loss of carrier [140]. In another study involving the transport of Pu(IV), Shukla et al. have investigated the role of polymer support upon the performance and stability of an SLM using several solid supports such as polytetrafluoroethylene (TE-35, TE-36, TE-37), polypropylene (HF-PP), cellulose nitrate (BA-S-83) of different pore sizes and varying thickness, and DC18C6 in toluene as the mobile carrier [141]. Selectivity of plutonium transport from fission product contaminants such as Cs-137, Ru-103, and Ce-144 was found to be poor with large pore size (0.45 μm) support. Polytetrafluoroethylene supports, such as TE-35, TE-36, TE-37, and polypropylene HF-PP membranes, did not show any marked deterioration with nitric acid and organic solvents while cellulose nitrate membrane such as BA-S-83 was attacked by organic solvent. On the other hand, these membranes were found to have good radiolytic stability [142].

Almost no report is available on the membrane transport studies of trivalent actinide ions with macrocyclic carriers. However, there are some literatures available on trivalent lanthanide ions, which can be used as guidelines for any future studies. Brown et al. [143] and Zhu and Izatt [144] have used bis(1-hydroxyheptyl)DC18C6 as the membrane carrier and

attempted separation of Eu from trivalent lanthanide cations by reducing it to the +2 oxidation state. The online reduction was carried out by modifying the transport cell in such a way that the feed compartment contained a mercury pool that acted as the cathode, while a Pt coil worked as the anode. After reduction,  $\text{Eu}^{2+}$  behaved similar to  $\text{Sr}^{2+}$  and selective transport was observed as compared to other lanthanides such as  $\text{Nd}^{3+}$  (4 times lower flux than  $\text{Eu}^{2+}$ ) and  $\text{Gd}^{3+}$  (8 times lower flux than  $\text{Eu}^{2+}$ ). Tang and Wai [145], on the other hand, have studied the transport behavior of trivalent lanthanide ions using a lipophilic crown ether carboxylic acid, 2-(sym-dibenzo-16-crown-5-oxy) hexanoic acid using a surfactant membrane. The activation energies for the transport of lanthanides in the system were determined to be 3–4  $\text{kJ mol}^{-1}$  suggesting that the process is diffusion controlled. This surfactant membrane also shows a selectivity of  $\text{Lu}^{3+}/\text{La}^{3+}$  by 1.25 in the transport process.

Macrocyclic ligands, such as calixarenes, have the flexibility and favorable conformations to form stable complexes with uranyl ion [146–148]. The special structural features of the calixarenes make them selective ionophores for many lanthanide/actinide ions. Uranyl ion, in an aqueous sodium hydrogen carbonate solution of pH 4–8 (source phase), was simultaneously and selectively transported into a dilute sulfuric acid solution (receiving phase) through a membrane (chloroform, BLM) containing a lipophilic ion-associate of methyltrioctylammonium ion and hydroxycalix[*n*]arene-*p*-sulfonate ion,  $2_n$  ( $n = 6, 8$ ),  $\text{MTA}^+ - 2_n$ , as a metal carrier [149]. None of the other metal ions were transported, or obstructed the transport of uranyl ion, while the presence of large amounts of sodium hydrogen carbonate and sodium chloride in the source phase interfered by causing a delay in the start of transport. Ramakumar et al. [33] have used several calixarenes (Figure 31.8) along with neutral donors such as TOPO and 18 crown 6 for the selective transport of uranium from seawater. Calixarene II and IV were found to show very good transport behavior when used as the carrier. Using calixarene II and TOPO mixture in chloroform, they recovered >95% of uranium from seawater while the permeation of ions such as  $\text{Na}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{K}^+$ , and  $\text{Fe}^{3+}$  was negligible. A significant increase in the transport rates of alkali/alkaline earth ions was observed when 18 crown 6 was used as the synergist.

In the minor actinide partitioning by the TRUEX process, CMPO is used as the extractant for the recovery of trivalent actinides from nitric acid medium. A resorcinarene cavitand-based ligand, functionalized with CMPO (carbamoylmethylphosphoryl)-ligating moieties in 2-nitrophenyloctyl ether (NPOE), was utilized for the transport studies of Eu(III) by Boerrigter et al. [150]. The steric pre-organization of four CMPO moieties on the macrocyclic resorcinarene cavitand frame improved the efficiency and selectivity of the metal extraction processes as Eu(III) could be quantitatively removed from acidic solutions using SLM in about 8 h. They had also used the CMPO-functionalized resorcinarene cavitands for the transport studies of  $\text{UO}_2^{2+}$  [151]. Calix-4-arenes mono/bis-crown-6 bound to heteropolysiloxane matrix were used for the selective transport of radionuclides such as Cs-137 from a waste containing Am-241 [152]. Dozol et al. [153] synthesized several grafted membranes containing calixarenes linked to the polypropylene matrix, which were selective for the lanthanides and trivalent actinides. The data with SLM were compared with those obtained with the grafted membranes.

### 31.2.3.3 Basic Extractants as Carriers

Amines have been used as the extractants for the actinide-bearing anionic species. This is usually from high-acidic or high-ionic strength medium, which generally lead to very high decontamination factors. The precondition of their use in SLM-based separation methods is the inertness of the membranes toward high acidic or salt medium. As membranes made from polycarbonate or polyamide may not be very stable toward these medium, most of the reported work in this area is on PTFE or PP membranes.

Chaudry and Mohammad [154] had used tri-*n*-octyl amine (TOA) dissolved in xylene as the SLM in Celgard 2400 polypropylene filter for the transport of uranyl ions from nitric acid solutions to an alkaline aqueous phase. About 10 h were needed for the quantitative transport of uranyl ion from an aqueous feed of 6 M  $\text{HNO}_3$ . Several other tertiary amines along with TOA have been used as carriers in SLM studies by Sonawane et al. [155]. The diffusion-limited and amine-facilitated Pu(IV) cation permeation in nitric acid media across an SLM was investigated to quantify the membrane carrier type effects on its transport using basic extractants, namely, Primene JM-T (JMT) as primary, Amberlite LA-2 (Amb LA-2) as secondary, trilaurylamine (TLA) and triiso-octyl amine (TIOA) as tertiary, and Adogen-464 and Aliquat-336 as quaternary amines. Recovery of Pu steadily increased from primary to quaternary amines as it follows the order quaternary > tertiary > secondary > primary, similar to that generally observed in liquid–liquid distribution experiments. More than 95% pertraction of Pu(IV) was easily accomplished using tertiary or quaternary amine as carrier employing a feed solution containing about 5 mg/L Pu in 4 M nitric acid solution, while the receiving phase was 0.1 M  $\text{NH}_2\text{OH} \cdot \text{HCl}$  (in 0.3 M  $\text{HNO}_3$ ). On the other hand, plutonium permeation was found to plummet to about 49% on employing secondary amine, Amb LA-2, as the carrier [156].

Lakshmi et al. had investigated the transport of uranyl ion from HCl medium using 30% Aliquat-336 in  $\text{CHCl}_3$  as the carrier [157]. Significant amount of acid transport (about 15%) was observed which affected the metal ion transport though >90% transport of U was observed in about 3 h. In another study involving Alamine 336, the same authors had shown that aromatic solvents such as toluene or *t*-butyl benzene effect higher transport rates than solvents such as chloroform or hexane [158]. Subba Rao et al. had investigated the transportation of uranium from HCl medium by an SLM made from Aliquat-336 in xylene as carrier and observed that the flux values for HCl or for uranium were higher at lower carrier concentration, which was

explained based on the aggregation behavior of the carrier molecules in membrane phase [159]. Effect of phase modifier on uranium transportation from hydrochloric acid medium across SLM using Aliquat-336 as the carrier in xylene medium was investigated by them to understand the effect of degree of aggregation of carrier molecules [160]. In this study, reduction of uranium flux was observed at carrier concentration where viscosity effects were not dominant.

### 31.2.4 HOLLOW FIBER SUPPORTED LIQUID MEMBRANE

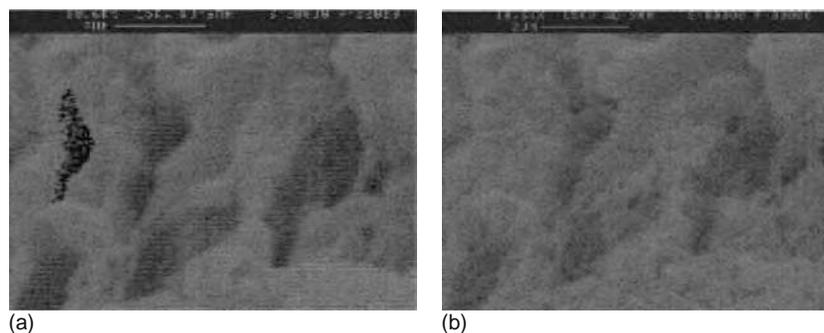

Several applications are envisaged in nuclear industry for the preconcentration of very lean solution of radioactive material, low- and intermediate-level wastes. There are, of course, reports on the application of HFSLM technique for high-level waste processing. Researchers at the plutonium facility at Los Alamos National Laboratory have studied the separation of actinides from waste solutions [161] using water soluble metal binding polymers (phosphonic acid derivative of polyethyleneimine). Kathios et al. [162] have investigated the use of HFSLM modules for process scale metal separations such as radioactive waste stream clean up and environmental remediation under simulated conditions (Nd was used for Am) using CMPO in di-*iso*-propyl benzene as the carrier. The major challenge in such case is to develop radiation resistant polymers.

Rathore et al. have studied the permeation of U(VI) and Pu(IV) in the presence of fission products from medium active acidic waste employing 30% TBP as a carrier through HFSLM and observed that recovery could be enhanced by using fresh strippant each time [163]. They have also used TBP as the carrier for the quantitative separation and recovery of Pu from nuclear waste solutions [164] using an HFSLM system. In the presence of various fission products, the selective permeation of Pu through the HFSLM was observed to be more than 90% into a stripping phase consisting of 0.1 M  $\text{NH}_2\text{OH} \cdot \text{HCl}$  in 0.3 M  $\text{HNO}_3$ . The membrane radiation stability was found to be good as shown by the scanning electron microscope (SEM) pictures of the irradiated and the nonirradiated membranes (Figure 31.11) even after exposure to 1 M Rad dose. A commercial tri-alkyl phosphine oxide, namely, Cyanex-923 was found to be far superior as the carrier as compared to TBP, as >94% transport was reported in 10 h using 0.1 M concentration of the carrier [97]. The permeation efficiency was found to increase from 75% to 90% by increasing the flow rate from  $3.0 \times 10^{-8}$  to  $1.4 \times 10^{-7} \text{ m}^3 \text{ s}^{-1}$ . Patil et al. have used dihexyl octanamide (DHOA) in normal paraffinic hydrocarbon diluent as the carrier in their HFSLM (operated in the nondispersive extraction mode) study [165,166]. From a feed solution comprising 8 g/L of U in 4 M  $\text{HNO}_3$ , transport was more facile into a strippant solution of 0.01 M  $\text{HNO}_3$  as compared to 1 M sodium carbonate.

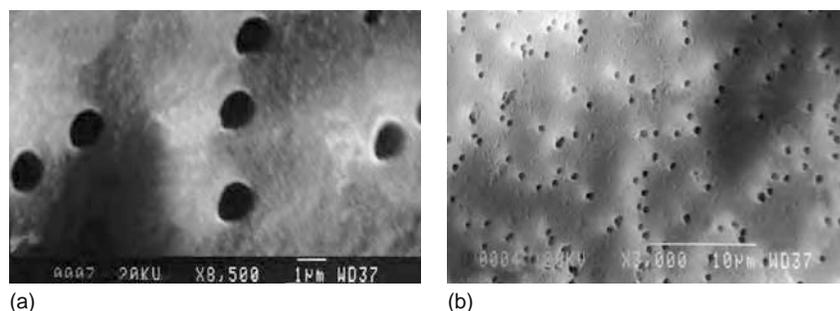

Transport of Pu(IV) from 3 M  $\text{HNO}_3$  solutions across Aliquat-336/Solvesso-100 by HFSLM was studied. Permeability of Pu(IV) through a bundle of hollow fibers made up with 20 lumens, of  $67 \text{ cm}^2$  surface area, 9 cm length, and operated at a flow rate of  $10^{-8} \text{ m}^3/\text{s}$  on recycle mode was examined. More than 80% Pu from oxalate bearing wastes generated during reconversion process could be transported through 10% Aliquat-336/Solvesso-100 into hydroxylamine hydrochloride strippant in about three runs [167].

HFSLM studies employing dialkyl phosphinic acid (Cyanex-272) were reported by Chiarizia et al. [80] for the decontamination of the severely contaminated Hanford site ground water. Their HFSLM experiments involved a hollow fiber module containing a total membrane area of  $9.8 \text{ cm}^2$  and the feed contained contaminated Hanford ground water at pH 2 (synthetic samples) circulated through the lumen side, while the strip containing 0.1 M HEDPA was circulated through the shell side. The U(VI) can be concentrated in the strip solution to about  $10^8$  times though significant amount of Fe(III) also gets cotransported.

Lanthanide-actinide separation was also attempted by HFSLM (operated in the nondispersive extraction mode) method using diphenyldithiophosphinic acid derivatives. Geist et al. have employed a synergistic mixture of bis(chlorophenyl)-dithiophosphinic acid and TOPO in a hollow fiber module for the lanthanide-actinide separation [168]. About 99.99% Am

(III) could be extracted by the contactor from 0.5 M nitric acid with about 33% of lanthanides such as Y, La, Ce, Pr, Nd, Sm, Eu, and Gd being extracted.

### 31.2.5 TRACK-ETCHED MEMBRANES

Track-etched membranes (TEM) are, in general, polymeric membranes with artificially made pores made after irradiating with a projectile of heavy ions followed by chemical etching. TEMs, which show a more precise distribution of pores with a known pore size, are used for the transport of ions [169]. Fleischer et al. [170] have used thin sheets of plastics, usually 10–20  $\mu\text{m}$  polycarbonates, perforated with collimated and diffused beams of heavy energetic ions. There is however a limitation on the thickness of the polymeric materials, which can be used for making membranes in view of the limitation of the projectile energy. As a consequence, these thin membranes are not rugged. These membranes with pore sizes in proportion to the energies of the charged particles are used for the investigations involving nonlinear theory in ionic transport [171]. It was reported that track-etched membranes with porosity up to 20% can be prepared using accelerated heavy ions. Pandey et al. [172] had used Makrofol track-etch membranes (after irradiating with 13 MeV Dy-161 ions and etching with 3 M NaOH) for the transport of Am(III) from a feed comprising 1.5 M ammonium nitrate and 0.5 M nitric acid to a strip phase consisting of 1 M oxalic acid using a mixture of 1.2 M TBP and 0.2 M CMPO as the carrier. Both the inner as well as outer diameters of the pores varied linearly with the etching time. The inner pore diameter as well as the porosity were found to govern the metal transport rates. The permeation across the SLM formed by using TEM with 17% porosity was found to be comparable to those SLMs formed by using commercial membranes with much higher porosities. The comparison of  $P$  (permeability coefficient) obtained by using TEMs with 29–30  $\mu\text{m}$  and 10  $\mu\text{m}$  thickness indicated that  $P$  decreased linearly with thickness and hence transport of Am(III) is diffusion controlled, and the extraction and stripping kinetics are fast. Removal of actinide ions from acidic solutions by carrier-mediated facilitated transport across mesoporous substrates with nanoengineered surfaces has been reported very recently [173]. The thiol self-assembled monolayer (SAM) modified with di(*tert*-butyl-phenyl) di(*iso*-butyl)CMPO was used for the selective transport of  $^{239}\text{Pu}$  and  $^{241}\text{Am}$  from a mixture containing fission products such as  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$ , which are not transported to any significant extent.

Nuclear track membranes with other materials, such as mica, oscillating quartz, PVDF, Kapton, and even polyster, have been found to be resistant to chemicals and acid. Figure 31.12 shows a typical representation of the holes formed in a polyster nuclear track filter after irradiation in accelerator and the subsequent etching with 6 M KOH and 0.1 Fw  $\text{KMnO}_4$  [174]. Vater has used track-etched mica filters for collecting the aerosols carrying radioactivity from the environmental air inside a nuclear reactor fuel elements production plant [175]. Ganz et al. [176] have, on the other hand, used Kapton track-etched microfilters (pore size: 3.8–13.4  $\mu\text{m}$  and porosity: 4%–12%) for the separation of  $^{237}\text{Np}$  from a feed containing 2 M  $\text{HNO}_3$ . About 0.5 M HTTA in xylene was used as the extractant, which formed emulsion with the aqueous phase and the Kapton membrane selectively allowed the organic phase to pass through.

## 31.3 POLYMER INCLUSION MEMBRANES

Although FSSLM- and HFSLM-based separation methods are getting increasingly popular, their only disadvantage is the stability, which is primarily due to the irreversible loss of carrier from the pores of the filters/lumens. As an alternative, polymeric films have been prepared along with the ligand and the diluent. These membranes termed as polymer inclusion membranes (PIM) have better membrane stability, although they are not suitable under high concentration of acid or alkali [177,178]. In general, the PIMs have relatively lower transport rates compared to the SLMs. Kim et al. [179] have shown that

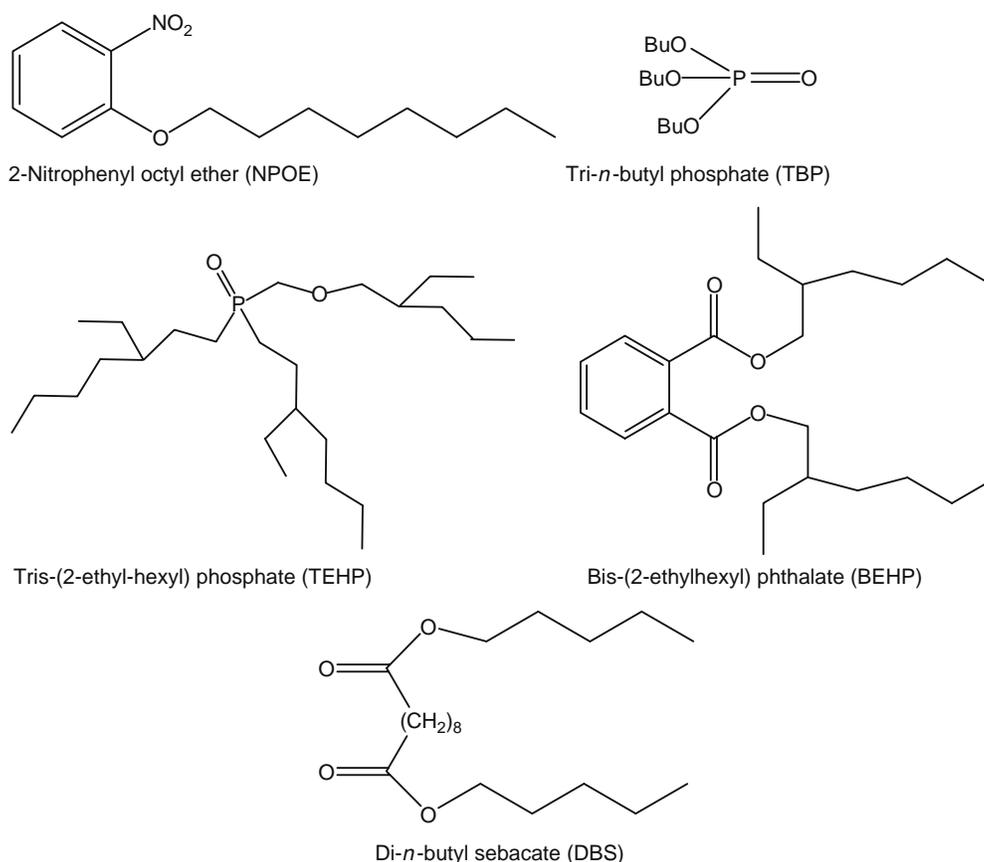

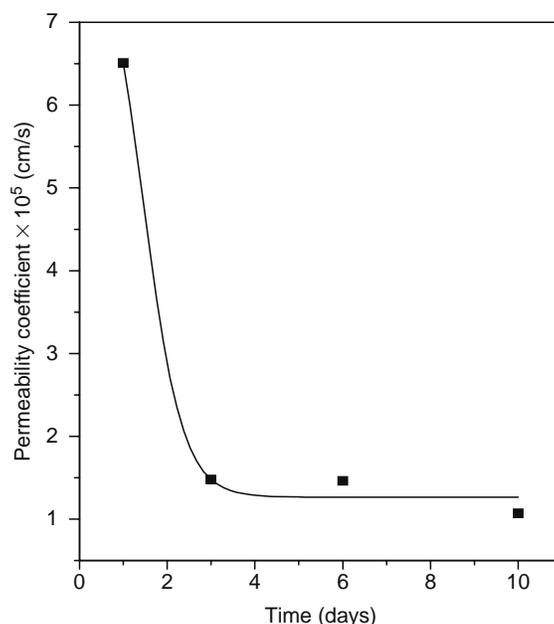

FIGURE 31.13 Structures of some plasticizers being used in the casting of PIM.

the flux in case of PIM is as high as 15 times higher than the corresponding SLM system. The carrier molecules crystallize inside the membrane and no new chemical bonds are formed within the polymer matrix [180]. CTA forms bulk of these types of membranes and is vulnerable to acid/alkali attack due to the possibility of hydrolysis of ester groups. It is understood that by increasing the chain length of the substituents the membranes could be made more acid/alkali resistant. Gardner et al. [181] attempted to vary the type of monomer by using cellulose acetate propionate (CAP), cellulose acetate butyrate (CAB), and cellulose tributyrates (CTB) and concluded that the flux decreases when the membranes were made more hydrophobic. The role of plasticizer is found to be extremely important in deciding the membrane stability and the overall flux of these membranes [182]. Figure 31.13 shows the structures of some of the plasticizers being used conventionally in PIMs. Sugiura [183] has used such membranes made from cellulose triacetate (CTA) with plasticizers such as 2-nitrophenyl octyl ether (NPOE) and tris(2-butoxyethyl) phosphate (TBEP), which enhance the membrane elasticity. He [184] has used  $\beta$ -isopropyl tropolone (HIPT) as the carrier trapped in these membranes for the transportation of lanthanide ions. Though there are many reports available [133,185–188] on the sorption/transport behavior of main group elements, very limited work is reported on the actinides using PIMs. Matsuoka et al. [189] have studied the uphill transport of uranium from nitric acid medium using a PIM containing CTA and TBP. In this case, TBP acted as both the carrier and the plasticizer, while  $\text{Na}_2\text{CO}_3$  was used as the stripping solution. An increase in U permeation (measured as  $D_1 = \Sigma([\text{UO}_2 - \text{X}_i]_{\text{TBP}}/[\text{UO}_2 - \text{X}_i]_{\text{HNO}_3})$ ) was observed with increasing aqueous phase acidity. On the other hand, the U release into the receiver phase (measured as  $D_2 = \Sigma([\text{UO}_2 - \text{X}_i]_{\text{TBP}}/[\text{UO}_2 - \text{X}_i]_{\text{Na}_2\text{CO}_3})$ ) decreased with increasing  $\text{Na}_2\text{CO}_3$  concentration. Significant loss of TBP into the aqueous phase was observed, which was similar to those observed in the case of SLMs. The loss of TBEP was also reported by an energy dispersive x-ray spectroscopic analysis [188]. No such loss of plasticizer is reported in the case of membranes made using NPOE as the plasticizer [190].

There are very limited reports available on the use of PIMs for the uptake/transport studies of trivalent actinides. There are some early reports, by Sugiura [191], on the transport behavior of trivalent lanthanides, which are considered as surrogates of the trivalent actinides. They have used NPOE as the plasticizer and investigated the effect of the alkyl chain length of some of polyoxyethylene *n*-alkyl ether on transport behavior of lanthanide ions and concluded that the flux decreased with an increase in the chain length. Bhattacharyya et al. have used a PIM containing TBP as the plasticizer and Cyanex-301 as the

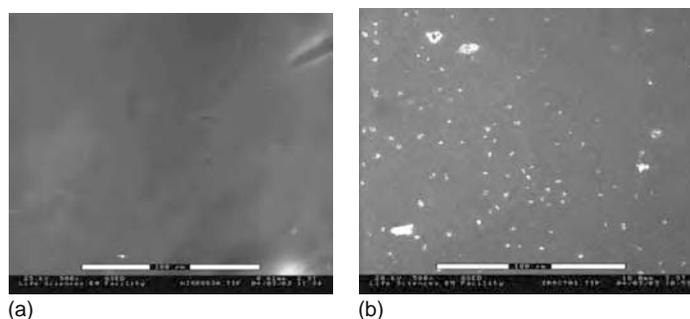

**FIGURE 31.14** Effect of radiation dose (200 kGy) on the subsequent decrease in the  $\text{Am}^{3+}$  permeability coefficient as a function of time.

carrier for the transport of  $\text{Am}^{3+}$  from an aqueous feed containing 1 M  $\text{NaNO}_3$  [192]. They have observed insignificant transport of  $\text{Eu}^{3+}$  thereby indicating the feasibility of the selective separation of trivalent actinides from lanthanides. However, the major problem of the PIMs is their stability against radiation. The sharp decline in  $\text{Am}^{3+}$  transport rates (Figure 31.14) is a consequence of the significant damaging of the plasticized membranes by gamma radiation (Figure 31.15). Kusumocahyo et al. have demonstrated facile transport of  $\text{Ce}^{3+}$  across a PIM containing TODGA, which was found to be far more superior as a carrier compared to CMPO [133].

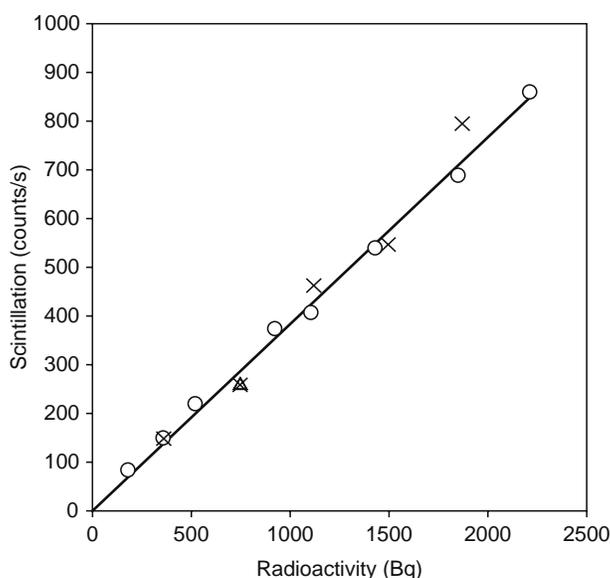

Sodaye et al. [193] have developed a scintillating PIM (S-PIM) containing HDEHP as the extractant, and PPO (diphenyl oxazole) and MSB (1,4-bis(2-methylstyryl)benzene) as fluors in plasticized CTA matrix for the assaying of actinide elements from aqueous samples (tap water and seawater). It was observed that the S-PIM could be made selective toward the tetravalent and hexavalent actinides at higher acidity ( $>0.25$  M), while the trivalent actinides could be trapped from pH solutions. The S-PIM could be made alpha-selective by pulse height discrimination. A linear response in a relatively wide range of radioactivity even in the presence of beta-emitting radionuclides such as  $^{154}\text{Eu}$  and  $^{147}\text{Pm}$  (Figure 31.16) underlines the applicability of this analytical method for the assaying of actinides.

### 31.4 SEPARATION OF RADIONUCLIDES FROM WASTE STREAMS

The use of membrane-based separation methods for gas separation is being routinely done in the industry. Reverse osmosis (RO) and ultrafiltration (UF) technologies are also very popular in treatment of industrial wastewater. Nevertheless, ultrafil-

**FIGURE 31.15** Effect of radiation dose (200 kGy) on polymer inclusion membrane stability. (a) SEM pictures of unirradiated PIM; (b) SEM pictures of irradiated PIM.

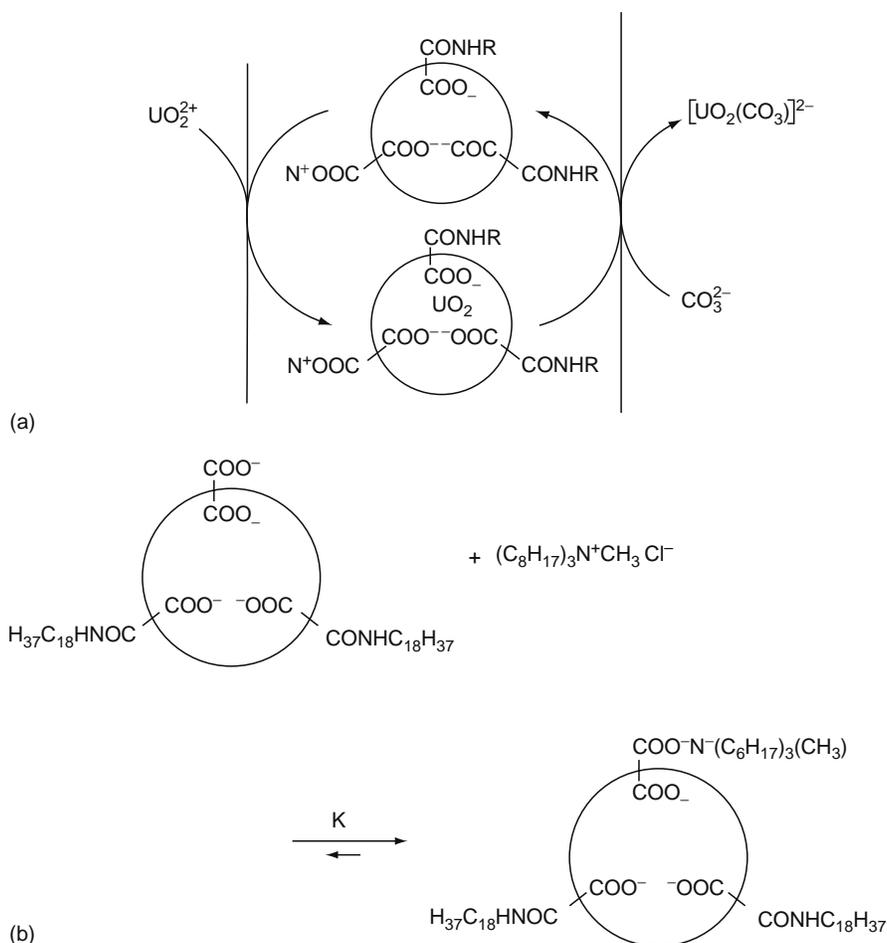

**FIGURE 31.16** Variation of  $\alpha$ -scintillation as a function of  $\alpha$ -activity of  $^{241}\text{Am}$  sorbed in the samples of S-PIM. The symbols ( $\Delta$ ), ( $\times$ ), and ( $\circ$ ) represent the S-PIM samples loaded with  $^{241}\text{Am}$ ,  $^{241}\text{Am}+^{147}\text{Pm}$ , and  $^{241}\text{Am}+^{154}\text{Eu}$ , respectively.  $\beta$ -activity = 1670 Bq; LLD = 4.5 V; amplifier gain = 50. Slope of the fit =  $0.386 \pm 0.013$ ; correlation coefficient = 0.994; S.D. = 29.44; number of data points = 13 (for  $^{241}\text{Am}+^{147}\text{Pm}$  and  $^{241}\text{Am}+^{154}\text{Eu}$ ). (Reproduced from Sodaye, S., Tripathi, R., Pandey, A.K., and Reddy, A.V.R., *Anal. Chim. Acta*, 514, 159, 2004. With permission.)

tration and reverse osmosis membrane technologies for treatment of radioactive liquid effluents are being applied in various nuclear plants [194]. These include the Nine Mile Point nuclear power plant, New York (RO), Comanche Peak nuclear power plant, Glen Rose, Texas (both RO and UF), Dresden nuclear power plant, Morris, Illinois (both RO and UF), Salem nuclear power plant, New Jersey (UF), AECL Chalk River Laboratory, Ontario, Canada (RO), etc. However, the application of liquid membrane-based separation methods for the removal of radionuclides from waste streams is at infancy stage and only a few reports are available. Americium removal from nuclear waste streams has been carried out at the Rocky Flats Plant (RFP) using SLM containing DHDECMP (dihexyl-*N,N*-diethyl carbamoylmethyl phosphonate) supported on Accurel polypropylene hollow fibers [195,196]. The waste from the Pu-purification cycle contained  $\text{HNO}_3$  concentration in the excess of 7 M, which was neutralized partially to yield >7 M nitrate and  $\sim 0.1$  M hydrogen ion concentration. More than 95% transport was observed into a stripping solution containing 0.25 M oxalic acid. The permeability coefficients were maximum up to  $1 \times 10^{-3}$  cm/s. Interference from Fe(III) was minimized by selective complexation.

Teramoto et al. [197] have used octyl(phenyl)-*N,N*-diisobutylcarbamoyl methyl phosphine oxide (CMPO) in diethyl benzene as a carrier and investigated the transport behavior to examine the feasibility of treating low-level radioactive wastewater using a stirred permeation cell. The transport rates were positively influenced by the addition of sodium citrate to the strip solution. For a simulated radioactive waste solution containing  $\sim 550$  ppm of Ce(III), at a treatment rate of  $1 \text{ m}^3$  per day (for >99.9% Ce removal) a membrane of  $3.3 \text{ m}^2$  surface area was recommended. Contaminated reactor pool water was reported to have been treated by SLM method, though the pertraction rates were very low [198]. Chiariasia has used liquid membranes containing three different commercially available long-chain aliphatic amines, namely, Primene JM-T (primary), Amberlite LA-2 (secondary), and triaurylamine (TLA, tertiary) for the treatment of synthetic Hanford site groundwater, where the strip solution was 1 M NaOH and *n*-dodecane was the diluent [199].

### 31.5 GRAFTED MEMBRANES FOR ACTINIDE SEPARATION

Uranium is present in the seawater as an extreme dilute solution. However, the total amount,  $4 \times 10^9$  tons, is ca. 1000-fold of the amount existing in the mines all over the world. Recovery of uranium from seawater is one of the most challenging problems in separation chemistry [200]. The separation methods using chelating resin [201] methods are limited by the low concentration of uranium ( $\sim 3$  ppb) and high concentration of other interfering ions. Kobuke et al. [202] have used a membrane-based separation method using a macrocyclic polycarboxylate ligand as the carrier. In the trial experiment, the feed contained uranyl acetate ( $3.3 \times 10^{-5}$  M) at pH 4–5, while the receiver phase contained 1.0 M  $\text{NaHCO}_3$ . The carrier (Figure 31.17) when modified with tri-*n*-octylmethyl ammonium chloride resulted in a significant enhancement in the transport rates. Selective transport rates of uranyl ion were observed in the presence of  $4.68 \times 10^{-1}$  M Na,  $5.3 \times 10^{-2}$  M Mg,  $1.0 \times 10^{-2}$  M K,

**FIGURE 31.17** Schemes of the highly selective ligand for uranium recovery from seawater. (a) The hexacarboxylate ligand; (b) after reaction with tri-octyl methyl ammonium chloride. (Reproduced from Tabushi, I., Kobuke, Y., Nakayama, N., Aoki, T., and Yashizawa, A., *Ind. Eng. Chem. Prod. Res. Dev.*, 23, 445, 1984. With permission.)

$1.0 \times 10^{-2}$  M Ca along with other ions. Out of these ions,  $\text{Ca}^{2+}$  was found to compete with the uranyl ion. However, due to favorable kinetic factors, a 300-fold increase in  $\text{Ca}^{2+}$  concentration decreased the uranyl ion transport rate only by 2.5 times.

Recently, the use of amidoxime grafted membranes for the recovery of uranium from seawater has shown great promise [203]. A research group at JAERI has proposed a method for the preparation of amidoxime (AO) grafted polyethylene and polypropylene membranes. The schematic of the grafting process is shown in Figure 31.18 wherein methacrylic acid (MAA) and 2-hydroxyethyl methacrylate were cogenerated with acetonitrile onto polyethylene fibers by radiation-induced graft polymerization. The amidoxime group density and water content determined the U sorption onto the membranes. The AN (acrylonitrile)/MAA ratio of 60:40 was found to be optimum and over a period of 20 days contact time showed a maximum uptake of 0.9 g of U/kg. The preconcentration of uranium from dilute solution is extremely slow and is possibly due to kinetic factors, which decide the slow diffusion of uranyl ion into the polymer matrix [204]. Sriram et al. [205] have also investigated the transport of uranyl ion across amidoxime incorporated polypropylene membranes. The feed consisted of 0.5 M  $\text{Na}_2\text{CO}_3$  solution at pH  $\sim 8$ , while the receiver phase was 0.1 M HCl. Using a 38% grafted membrane, they have observed 70% U sorption onto the PP-AN membrane. However, it was relatively difficult to leach out the sorbed U from the membrane ( $\sim 20\%$  with even 10 M HCl). On decreasing the percentage grafting to about 22%, 66% sorption was possible in 6 h and 70% stripping was possible using only 2 M HCl.

### 31.6 STABILITY OF LIQUID MEMBRANES

Despite the many advantages of liquid membranes, which include selectivity and ligand economy, they are not yet applied in industrial scale that is ascribed to their low stability [206]. The common reasons for the instability of liquid membranes are

constant and low solubility in water for the SLMs to be highly stable and permeable. Chiarizia [199] has investigated membrane stability using flat-sheet supports containing long-chain aliphatic amines as the carriers. The following order of stability was measured: tertiary > secondary > primary. This is the reverse order of the interfacial tension lowering at a water-*n*-dodecane interface. The water solubility of the amines also seems to play an important role in determining the membrane stability. This can be improved significantly by presaturating the aqueous phases with organic phase [214]. The performance of the SLM has also been reported to be affected by pore-blocking or fouling. Chiarizia [215] and Mohapatra et al. [63] observed such membrane fouling in their studies using amine and beta-diketone carriers, respectively. Nitrate · trilauryl amine salts and TOPO·HNO<sub>3</sub> complex are the causes for precipitation and subsequent blocking of pores of the membranes in these cases. There are several other mechanisms of membrane degradation and will not be discussed here. In general, the stability of SLM can be increased by increasing the membrane thickness, decreasing the pore size, and enhancing the lipophilicity of the carrier.

Polymer inclusion membranes are reported to have better stability as compared to the SLMs [177]. However, PIMs made from plasticizing agents such as TBP or TBEP (tris-butoxy ethyl phosphate), which have significant solubility in water can degrade with time. Salazar-Alvarez et al. [188] have shown using energy dispersive X-ray scans (EDS) that significant degradation of the membranes containing TBEP as the plasticizer do occur which could be suppressed by the addition of a small quantity of ethanol to the monomer plasticizer mixture prior to the membrane casting.

### 31.7 FUTURE PERSPECTIVES

Membranes have been used extensively for the separation of radionuclides from liquid effluents generated in different nuclear facilities such as fuel fabrication plant, fuel reprocessing plant, and nuclear reactors. These separations, based on size exclusion, are invariably pressure driven and are not useful for the recovery and purification of a specific element present in a mixture where solvent extraction has a distinct advantage. However, liquid membrane techniques offer the advantages of both solvent extraction as well as membrane separations. Liquid membrane separations provide an efficient and excellent opportunity to explore novel and exotic extractants such as calixarenes, crown ethers, thiophosphinic acids, diamides, and carbamoyl methyl phosphine oxides which are of vital interest to the separation scientists engaged in the development of new strategies for the safe management of high-level radioactive waste. Low inventory of the extractants needed for membrane-based techniques makes them attractive not only from cost considerations but also from the ease of disposal of secondary wastes.

Although ELM technique is quite efficient essentially due to the thinness of the membrane, large-scale application of this technique is limited in view of the difficulties encountered in the demulsification step needed for the recovery of the trapped metal ion. On the other hand, promise of the SLM technique has been demonstrated in the lab scale experiments. Large-scale applications of SLM require additional work in the area of stability/reusability of the membranes. Apart from the selective extraction, there is a need to develop the membranes that are compatible with the diluent/solvent mixture with respect to physical properties such as surface tension and viscosity. In addition, chemical/radiation environment of the feed/strip solution to which these membranes are subjected over long duration is an area of particular concern. Additional stability can be obtained by developing chemically grafted membranes.

Recently, emphasis has been shifted to hollow fiber contactors as well as hollow fiber nondispersive solvent extraction technique, which can have surface to volume ratio as high as 10,000 m<sup>2</sup>/m<sup>3</sup>. Hollow fiber modules that offer a continuous means for large-scale separation applications need to be designed and developed keeping in mind the nature of solvent, feed, and strippant. Apart from the design parameters, such as lumen length/diameter, shell length/diameter, and number of lumens, one needs to ensure the compatibility of materials used for making these modules. Nature of adhesives used and microstructures of the polymers used for making lumens also need attention.

## 32.1 INTRODUCTION

The applications of membrane technology have grown significantly in the last decade. Some advantages of membrane technologies are continuous performance, low energy consumption, modular structure, and easy installation or automation. Due to this, nowadays membrane processes have become an ideal complement or even a suitable replacement of conventional separation processes (evaporation, chemical precipitation, ion exchange, etc.).

Some areas of application are the nuclear industry and the treatment of radioactive liquid wastes, with two main purposes: reduction in the waste volume for further disposal, and reuse of decontaminated water. Pressure-driven membrane processes (microfiltration, ultrafiltration, nanofiltration, and reverse osmosis [RO]) are widely used for the treatment of radioactive waste.

Some research groups worldwide are currently working on the application of membrane technology to the treatment of radioactive liquid wastes with different levels of activity, from low to high activity waste. Research is mainly focused on wastes from the nuclear industry. However, the nuclear industry is not the only source of radioactive wastes; medical and research applications of radioisotopes also generate radioactive wastes.

Since 1995, the Chemical and Nuclear Engineering Department of the Polytechnic University of Valencia in Spain has been working on the application of membrane technology to the treatment of low and medium level radioactive liquid wastes. In this chapter, we describe two practical cases of radioactive liquid waste treatment using membrane processes: the treatment of  $^{137}\text{Cs}$ -contaminated water generated after a radioactive incident in a stainless steel production factory, and the treatment of  $^{125}\text{I}$  liquid wastes from nuclear medicine services at hospitals.

## 32.2 ORIGIN OF RADIOACTIVE WASTES

Radioactive wastes are generated in the following activities: generation of electric power from nuclear fuel; applications of radioisotopes in medicine, industry, and research; and dismantling of nuclear and radioactive installations. With respect to waste volume and specific activity, the activities that generate the highest amounts of waste are those related to electric power generation.

### 32.2.1 WASTES FROM THE ELECTRIC POWER GENERATION CYCLE

This group includes the wastes generated during all the stages of the power production cycle in a nuclear power plant. First, the wastes from uranium mining, concentrate manufacturing, conversion to uranium hexafluoride, uranium enrichment, and fuel manufacturing. Second, the wastes generated during the operation of the nuclear power plant. This includes equipment and devices used for the purification and cleaning of the cooling systems, and other radioactive wastes like tools, working cloths, laundry wastes, papers, etc. Finally, the spent fuel rods that are produced on the completion of the energy production cycle; these elements are temporarily stored in swimming pools or in dry sites in the nuclear power station itself.

### 32.2.2 WASTES FROM MEDICINE, INDUSTRY, AND RESEARCH

In medical installations, the use of radioactive isotopes for diagnosis and therapy has significantly increased in the past years. Nonencapsulated radioactive elements are used for different purposes such as in diagnosis by tracers, treatment of thyroid or blood disorder, and in medical research. These activities produce some solid radioactive wastes like cotton, rubber gloves, syringes, etc., as well as liquid wastes, mainly scintillation liquids. Another type of waste is the encapsulated sources that are used for cancer treatment; these elements must be changed when their activity decays below a certain level.

In industry, radioisotopes are used in encapsulated sources, generally of low activity, for the continuous measurement of level, humidity, density, or thickness. Gamma radiation-encapsulated sources are also used in nondestructive tests in metallic constructions (gammagraphies) and in industrial sterilization.

In the nuclear research centers, the wastes are obtained from research and experimental reactors, hot cells, pilot plants, and decontamination services. These wastes have varying physical, chemical, and radioactive nature due to the great diversity of isotopes used and the wide range of processes in which they are applied.

### 32.2.3 WASTES FROM THE DISMANTLING OF NUCLEAR AND RADIOACTIVE INSTALLATIONS

The dismantling of a nuclear or radioactive installation, when its useful life is finished, generates the following radioactive wastes: reactor vessel and the components inside biological shield, external parts of the biological shield (heat exchangers, circulation pumps, pipes, etc.), activated and contaminated concrete, and auxiliary systems and building structures. Furthermore, some secondary wastes such as decontamination liquids and gas filters are also generated.

## 32.3 CASE STUDIES

This section describes some case studies carried out by the authors, which are related to radioactive liquid waste treatment using membrane processes: a study about the influence of radiation on reverse osmosis membranes, a practical case about concentration of  $^{125}\text{I}$  radioactive liquid wastes by ultrafiltration and reverse osmosis processes, and a practical experience about decontamination of  $^{137}\text{Cs}$  liquid waste by reverse osmosis, including a study of radiological protection during the treatment.

### 32.3.1 RADIATION INFLUENCE ON MEMBRANE PERFORMANCE

The influence of radiation on the transport properties of different reverse osmosis composite membranes was studied by Chmielewski and Harasimowicz [1]. Reverse osmosis membranes were irradiated with a  $^{60}\text{Co}$  source, with a linear accelerator, and were also immersed in a  $^{137}\text{Cs}$  high activity solution, reaching absorbed dose values around 40 kGy. The results of some tests with the irradiated membranes showed that aromatic polyamide composite membranes are highly radiation resistant. This allows these membranes to be used in radioactive solutions with an activity below  $3.7 \times 10^{12} \text{ Bq/m}^3$ , which corresponds to absorbed dose values around 30 kGy.

**TABLE 32.1**  
**Permselective Performance of Gamma-Irradiated Membranes**

Absorbed Dose (Gy)	$J_v$ (L/[m <sup>2</sup> h])	$R$ (%)
0.25	28.0	97.0
0.50	26.7	98.5
1	30.5	98.6
2	31.0	98.7
5	28.5	98.9
10	24.0	98.9
20	20.0	97.7
Nonirradiated	21.6	97.5

Similar studies were carried out by Nakase, who determined the effect of radiation on some mechanical and thermal properties of the polysulphone film of composite membranes. After a complete experimental and microscopic study, the author concluded that polysulphone film almost keeps transport properties and stability up to dose values of 2 MGy [2].

Following these studies, the authors assessed the influence of different kinds of radiation on reverse osmosis composite membranes, applying radiation doses within the range of values that are expected to be absorbed by membranes in the treatment of low and medium radioactive wastes. Samples of reverse osmosis composite membranes were irradiated with gamma radiation using a <sup>60</sup>Co source, in an absorbed dose range between 0.25 and 20 kGy; and with electron radiation using a linear accelerator, in an absorbed dose range between 5 and 25 Gy [3].

The irradiated membranes were then tested in a pilot plant with a plate-and-frame module with capacity for two membranes with an effective area of 90 cm<sup>2</sup> each. Permselective results of irradiated membranes were compared to those of nonirradiated membranes [3]. It was observed that the performance of the samples irradiated with electronic or gamma radiation was very similar to that of the nonirradiated membranes. Tables 32.1 and 32.2 show the results of permeate flux and retention index for gamma- and electron-irradiated membranes, respectively.

The differences in permselective performance between some irradiated and nonirradiated samples cannot be associated with radiation effects, but with membrane structural dispersion. This is because the membrane samples were taken from a spiral wound module; therefore, the differences observed can be due to the lack of homogeneity in the membrane structure and its characteristics along the module. This fact can be illustrated by the dispersion of the experimental results of the nonirradiated samples.

Figure 32.1 shows the permeability obtained for all the nonirradiated samples. The average value of all these samples is  $J_{v,av} = 21.6$  L/m<sup>2</sup>h. The highest value of the statistical dispersion is  $J_{v,av} + 2\sigma = 38.8$  L/m<sup>2</sup>h, and the lowest value is  $J_{v,av} - 2\sigma = 4.4$  L/m<sup>2</sup>h. On the other hand, Figures 32.2 and 32.3 show the permeability of the gamma- and electron-irradiated samples, respectively. As it can be seen, in both cases the dispersion values of permeability are within the limit values of the nonirradiated dispersion, proving that the variability in the results is not the consequence of radiation, but of membrane non-homogeneity.

**TABLE 32.2**  
**Permselective Performance of Electron-Irradiated Membranes**

Absorbed Dose (Gy)	$J_v$ (L/[m <sup>2</sup> h])	$R$ (%)
5	20.0	97.2
10	26.7	97.5
15	18.7	97.4
20	14.0	97.0
25	20.0	97.4
Nonirradiated	21.6	97.5

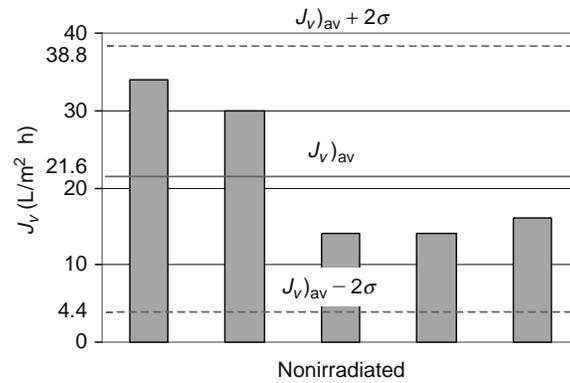

FIGURE 32.1 Permeate flux of nonirradiated membranes.

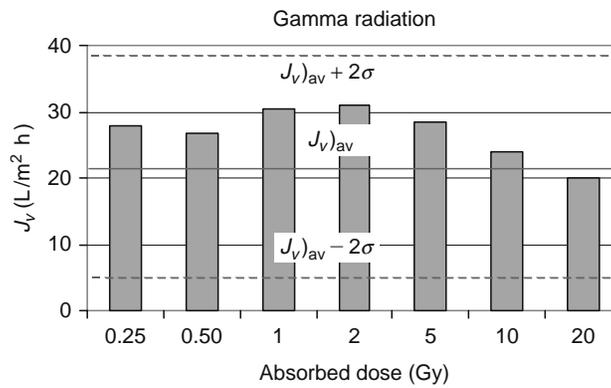

FIGURE 32.2 Permeate flux of gamma-irradiated membranes.

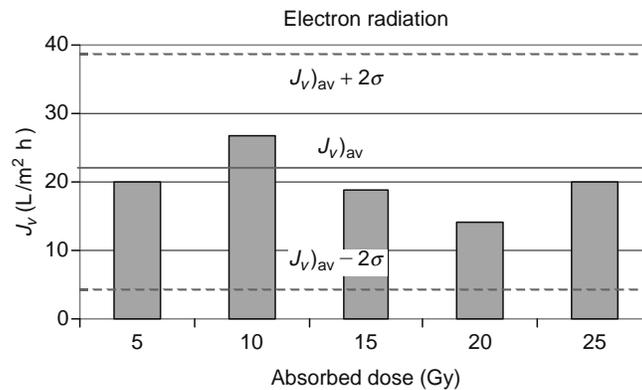

FIGURE 32.3 Permeate flux of electron-irradiated membranes.

With regard to selectivity, Figure 32.4 shows the results of the retention index for all the nonirradiated samples. The average value of all these samples is  $R_{av} = 97.6\%$ . The highest value of the statistical dispersion is  $R_{av} + 2\sigma = 98.1\%$ , and the lowest value is:  $R_{av} - 2\sigma = 97\%$ . On the other hand, Figures 32.5 and 32.6 show the selectivity of the gamma- and electron-irradiated samples, respectively. As it can be seen, the dispersion of selectivity in the electron-irradiated membranes is within the limit values of the nonirradiated dispersion, proving that the variation in the results is not caused by radiation.

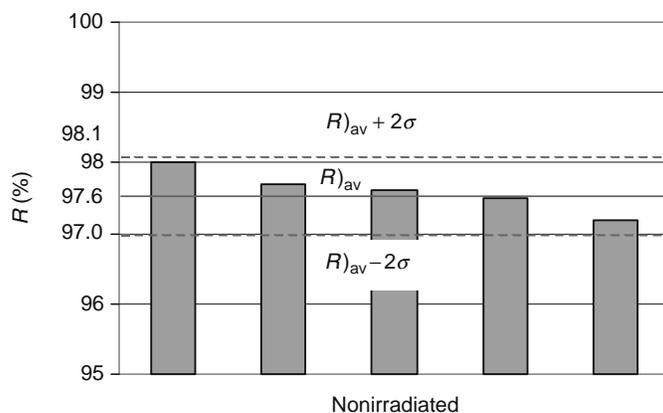

FIGURE 32.4 Retention index of nonirradiated membranes.

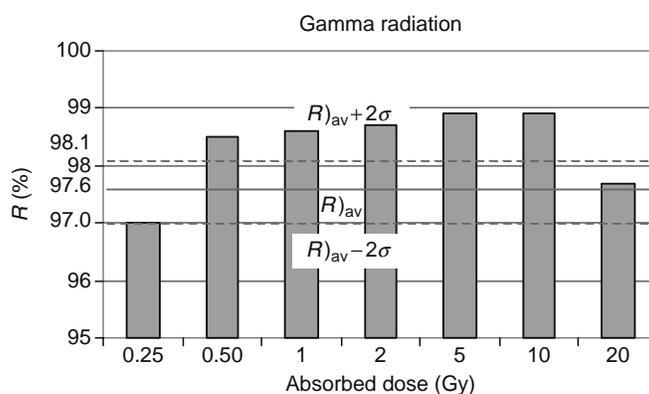

FIGURE 32.5 Retention index of electron-irradiated membranes.

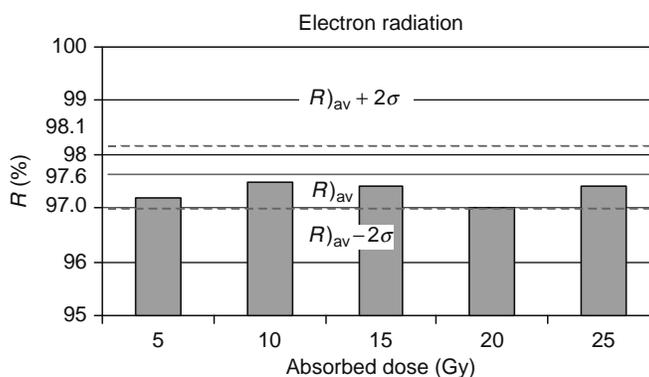

FIGURE 32.6 Retention index of gamma-irradiated membranes.

For gamma-irradiated membranes, the values of experimental selectivity are higher than the upper limit of the nonirradiated dispersion, so it can be said that gamma radiation can even have a beneficial effect on membrane selectivity.

As a conclusion of this study about the influence of electron and gamma radiation on reverse osmosis composite membranes, it can be stated that radiation does not affect membrane performance in a range of absorbed dose values up to 25 Gy, approximately. Therefore, reverse osmosis composite membranes are suitable for use in the treatment of low and medium activity levels, as the values of the radiation absorbed by the membranes will be lower than those assessed in this case study.

### 32.3.2 TREATMENT OF $^{125}\text{I}$ LIQUID WASTES BY ULTRAFILTRATION AND REVERSE OSMOSIS

#### 32.3.2.1 Description of the Problem

Radioimmunoassay (RIA) is used in nuclear medicine for measuring very low levels (concentrations below  $10^{-11}$  g/mL) of some biological compounds in corporal fluids, by means of the combination of radioisotopes and antibodies. The most common radioisotope used in this technique is  $^{125}\text{I}$ , a gamma-emitting radioisotope with a half-life of 60 days, which is used for labelling compounds of interest.

RIA techniques generate great amounts of radioactive liquid wastes whose composition depends on the specific assays that are carried out in each laboratory. Liquid wastes from RIA techniques are usually composed of different types of proteins (some of them radioactively labelled), preservative solutions, several low-molecular-weight organic compounds, and inorganic salts—all in aqueous solutions. These wastes are classified as low and medium radioactive, but they are also potentially infectious since they can contain pathogens from patient's blood [4]. Sometimes, the infectious risks of these wastes can be much more dangerous than the risks associated with radioactivity.

At present, these radioactive wastes are temporarily stored in the sanitary center for partial activity decay. Then, the wastes are disposed of by an officially designated company depending on their radioactivity levels and other biological and chemical risks. Reduction of RIA waste volume would mean an important decrease in waste disposal costs, and would diminish the problems of waste storage in hospitals. Furthermore, an appropriate treatment of RIA liquid wastes would remove pathogens and chemicals that otherwise would remain in the wastes.

#### 32.3.2.2 Treatment Description

Figure 32.7 shows the scheme of the solution proposed by the authors for treating radioactive liquid wastes from RIA laboratories. Since part of the radioisotope is in ionic form [5], reverse osmosis can be used for radioisotope removal. But before the application of reverse osmosis, a pretreatment is required. It consists of the following two stages:

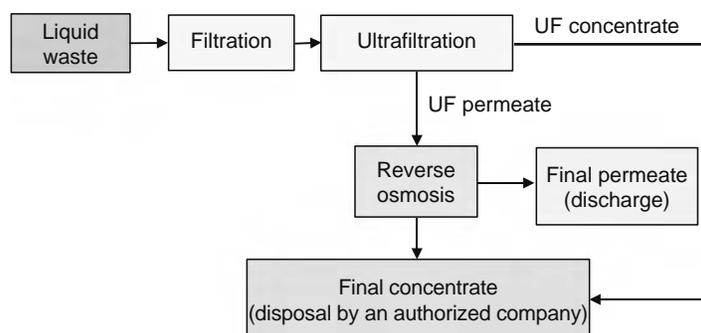

- Filtration in cartridges for removal of suspension solids that could damage the membranes.
- Ultrafiltration membranes are suitable for the treatment of radioactive liquid wastes, especially as reverse osmosis pretreatment [6]. Therefore, ultrafiltration is used for the removal of the radioactivity associated with the proteins and high-molecular-weight organic compounds, as these species can reduce reverse osmosis performance.

The purpose of the treatment is to reduce waste volume for further disposal by an authorized company, and to obtain an organic matter and pathogens-free permeate with an activity level below the legal discharge limit.

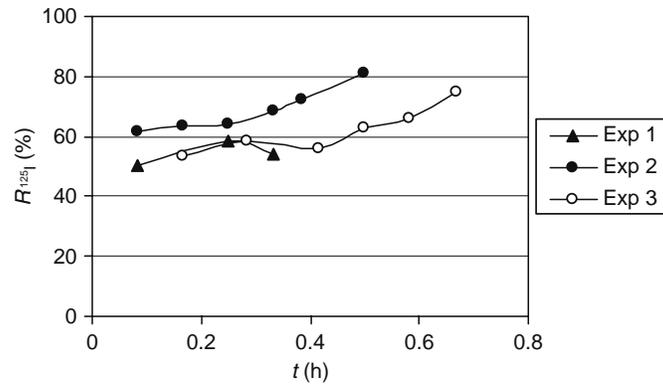

#### 32.3.2.3 Experimental Test

Some experiments were carried out with wastes from nuclear medicine services (RIA laboratories). Wastes with different storing periods were used, with activity values between 10 and 1000 kBq/L, depending on their storage time.

The experiments consisted of a first stage of ultrafiltration, after which the UF permeate was treated by reverse osmosis, according to the scheme presented in Figure 32.7. If the RO permeate showed an activity higher than the environmental background level in the treatment area, it was again treated by RO, and so on until reaching an activity level in the permeate close to background levels.

**FIGURE 32.7** Scheme of the RIA liquid waste treatment. (Courtesy of Radiation Protection Dosimetry, Oxford University Press, Oxford. With permission).

**FIGURE 32.8** Radioactivity removal by UF membranes in the RIA waste treatment. (From Arnal, J.M., Campayo, J.M., Lora, J., Sancho, M., Iborra, I., and Alcaina, I., *Desalination*, 129, 101, 2000.)

During the treatment, periodical measurements of flow and conductivity of the permeate and feed were taken for calculating the permselective parameters of the membranes ( $J_v$ ,  $R$ ). In addition, samples of the feed and permeate were periodically taken for measuring radioactivity. Then, the retention index to  $^{125}\text{I}$  was calculated using the following expression:

$$R_{125\text{I}} (\%) = \frac{A_F - A_P}{A_F} \times 100 \quad (32.1)$$

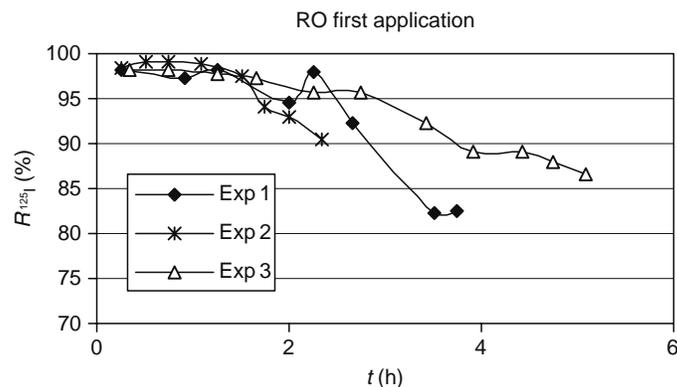

where  $A_F$  and  $A_P$  are the activities of feed and permeate (Bq/L), respectively.

#### 32.3.2.4 Radioactivity Removal by Membranes in the Treatment of $^{125}\text{I}$ Wastes

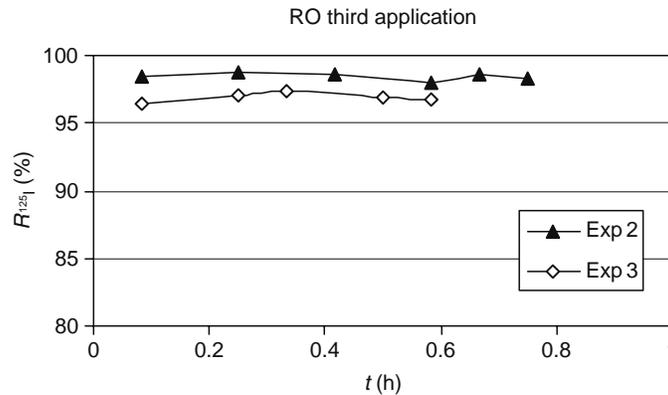

In the experiments performed on real wastes, ultrafiltration played an important role in the partial reduction of radioactivity. Figure 32.8 shows the evolution of the retention index to  $^{125}\text{I}$  with time in some of the UF experiments. Most of the time, radioisotope rejection by UF membrane was higher than 50%, even reaching maximum values of about 80%. This fact proves that part of the radioisotope remains labelled to proteins and other organic compounds, most of which are removed in the UF stage [7]. The rest of the radioactivity, associated with low-molecular-weight organic compounds and ionic solutes, will be removed in the RO stages.

In reverse osmosis, radioactivity removal gives two types of results: the results of the first RO application after the UF stage, in which the ultrafiltrate was treated; and the results of the subsequent RO applications, in which an RO permeate of an earlier stage was treated.

Figures 32.9 and 32.10 show the evolution with time of the retention index to  $^{125}\text{I}$  in the first RO application carried out in three experiments, and in the third RO application performed on experiments 2 and 3, respectively. It can be observed that in the first RO application, the retention index to  $^{125}\text{I}$  decreased progressively during the treatment due to an increase of feed activity as a result of concentrate recirculation to the feed tank. Anyway, in this application  $R_{125\text{I}}$  was higher than 90% most of

**FIGURE 32.9** Radioactivity removal by RO membranes in the treatment of UF permeate. (From Arnal, J.M., Campayo, J.M., Lora, J., Sancho, M., Iborra, I., and Alcaina, I., *Desalination*, 129, 101, 2000.)

**FIGURE 32.10** Radioactivity removal by RO in the treatment of an earlier RO permeate. (From Arnal, J.M., Campayo, J.M., Lora, J., Sancho, M., Iborra, I., and Alcaina, I., *Desalination*, 129, 101, 2000.)

the time. On the other hand, in the subsequent RO applications (Figure 32.10), the retention index to  $^{125}\text{I}$  remained quite constant with values above 95% in all the experiments. This was due to lower feed activity values and lower feed activity variation.

Table 32.3 shows the values of feed and permeate activity evolution in one of the experiments, representative of a typical treatment process. It can be seen how it is possible to obtain a permeate with a level of activity below the legal discharge limits by means of successive reverse osmosis applications.

### 32.3.2.5 Treatment Procedure

According to the experimental results, the most suitable procedure for RIA waste treatment was defined. This procedure consists of the following stages:

- *Ultrafiltration.* In this stage, high-molecular-weight organic compounds as well as biological contaminants are removed, and the activity is reduced to an average of 50%–60%.
- *First Stage of Reverse Osmosis.* Almost all the organic and biological compounds that were not eliminated previously by ultrafiltration are removed in this stage.
- *Second Stage of Reverse Osmosis.* Salt concentration is reduced below running water levels (lower than 1 g/L).
- *Third Stage of Reverse Osmosis.* After this stage, a permeate with an activity below 100 Bq/L is obtained.

The following options are suitable for the disposal of the final permeate:

- Direct discharge to the sink by dilution, if authorized by the appropriate official institution.
- Temporary storage and further discharge to the sink after checking that the activity is below the legal limit. It must always be authorized by the appropriate entity.

The final concentrate, which includes UF and RO concentrates, should be disposed of by an authorized company, considering not only waste radioactivity levels but also chemical and biological contaminations, specially in the ultrafiltration concentrate since it contains most of the pathogens of the original waste.

**TABLE 32.3**  
**Radioactivity Removal in RO Experiments**

RO Stage	$A_F$ (Bq/L)	$A_P$ (Bq/L)
RO1	117,400	15,360
RO2	15,360	720
RO3	720	70

### 32.3.3 TREATMENT OF $^{137}\text{Cs}$ -CONTAMINATED WATER BY REVERSE OSMOSIS

#### 32.3.3.1 Description of the Problem

In 1998, a  $^{137}\text{Cs}$  source was accidentally melted in a stainless steel production factory in Spain. As a consequence of this accident, the cooling system of one of the ovens became radioactively contaminated. The decontamination process produced  $40\text{ m}^3$  of  $^{137}\text{Cs}$  contaminated water, with an average activity above  $300\text{ kBq/L}$ .

The authors, in collaboration with LAINSA company, developed the project for decontaminating the radioactive liquids, by means of a reverse osmosis plant. The aim of the treatment was to remove the  $^{137}\text{Cs}$  radioisotope from the treated liquid and to reduce the volume of the solution for further immobilization.

#### 32.3.3.2 Treatment Description

Figure 32.11 shows a scheme of the RO plant for the treatment of the  $^{137}\text{Cs}$ -contaminated liquids. It was equipped with two kinds of spiral wound reverse osmosis membranes: high-pressure (HP) and low-pressure (LP) membranes. Before flowing through the membranes, the feed was pretreated using  $5\text{ }\mu\text{m}$  sleeve filters and  $0.45\text{ }\mu\text{m}$  cartridge filters.

The treatment was divided into two stages. At the first stage, both types of membranes were used, recirculating all the concentrates to the feed tank. The second stage began when the permeate resulting from the first stage was out of the specifications, and then the two reverse osmosis lines were separated. The low-pressure membranes treated the first-stage permeate, while the high-pressure membranes continued treating the concentrate.

The decontamination process by reverse osmosis took about 1 month. After this period,  $36\text{ m}^3$  of liquid was decontaminated from the original  $40\text{ m}^3$ . Later, evaporation was applied to get an additional concentration of the final waste; the volume of concentrate liquid was reduced from  $4$  to  $1\text{ m}^3$ .

#### 32.3.3.3 Reverse Osmosis Performance in the Treatment of $^{137}\text{Cs}$ Liquid Wastes

During the treatment, samples of the permeate, the concentrate, and the feed were taken periodically for measuring radioactivity. The retention index to  $^{137}\text{Cs}$  was calculated by an expression that is analogous to Equation 32.1.

Figure 32.12 shows the results of the retention index to  $^{137}\text{Cs}$  obtained at the two RO treatment stages. From these results, it can be stated that

- At the first RO treatment stage, the retention index to  $^{137}\text{Cs}$  was higher than 98% in most cases.
- At the second RO treatment stage, the retention index values in the high-pressure membranes were slightly lower, but always above 96%.
- At the second RO treatment stage, the retention index to  $^{137}\text{Cs}$  in the low-pressure membranes was always higher than 98%, and above 99.5% in most cases.

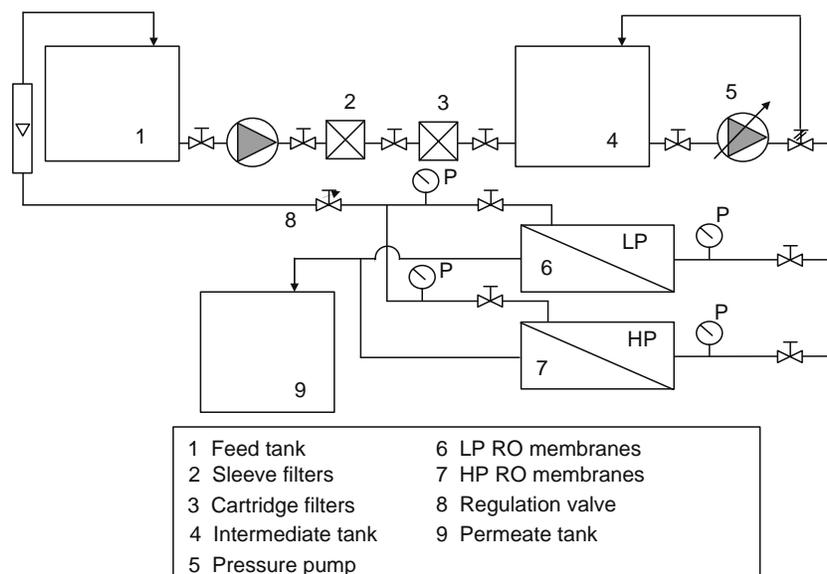

FIGURE 32.11 Scheme of the  $^{137}\text{Cs}$  liquid waste treatment plant.

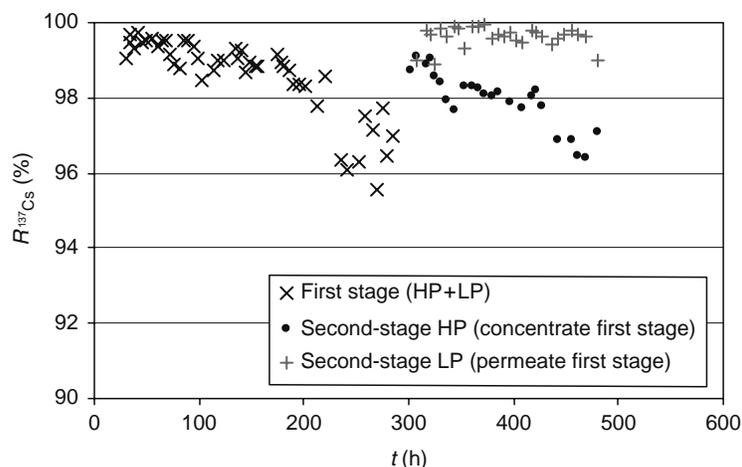

FIGURE 32.12 Retention index to  $^{137}\text{Cs}$  of the RO membranes. (Courtesy of M. Balaban, Desalination, Italy. With permission.)

The progressive decrease of the retention index values at the first stage of the RO treatment and in the high-pressure membranes during the second stage is due to two main factors. On one hand, to the increase in feed concentration as a result of concentrate recirculation, and on the other hand, to the increase in membrane fouling. However, in the low-pressure membranes in the second RO treatment stage high values of retention index were obtained because the permeate of the first stage was treated, so the activity values were much lower (below 100 kBq/L in comparison with values higher than 1500 kBq/L in the other two situations).

In spite of the successful  $^{137}\text{Cs}$  selectivity results, permeability values were not as good as expected; in fact, the low permeability caused the RO treatment to last more than planned. This was mainly due to a lack of knowledge about the characteristics of the solution to be treated; as a result, it was not possible to design a specific pretreatment, and filtration was not enough to avoid severe fouling in the RO membranes.

As a summary, the following conclusions can be drawn from the treatment of  $^{137}\text{Cs}$ -contaminated liquids [8]:

- The application of reverse osmosis was highly successful, decontaminating more than 90% of the original volume.
- The selectivity values confirm the potential of reverse osmosis composite membranes in the treatment of effluents that contain radioactive isotopes.
- The decrease in membrane permeability was caused by membrane fouling. This could have been partially avoided with an appropriate pretreatment design.

### 32.3.4 RADIOLOGICAL PROTECTION IN THE TREATMENT OF RADIOACTIVE LIQUID WASTES

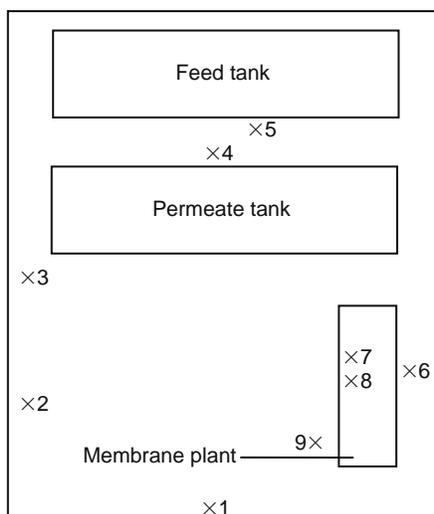

During the RO treatment of  $^{137}\text{Cs}$ -contaminated liquid, dose levels were measured at different sites in the working area with the purpose of following dose evolution and taking the appropriate radiological protection measures [9].

Figure 32.13 shows a scheme of the treatment area, in which the measuring points are indicated by numbers whose description is presented in Table 32.4. Environmental doses were measured at boundary points (1, 2, and 3); in all other points contact, doses were measured. Measures were taken approximately every 12 h in both cases.

The following figures show the dose evolution with time of the points indicated in the scheme shown by Figure 32.13. Figure 32.14 shows radiation evolution at the boundary points. The three points show no significant radiation values, although point 3 has slightly higher values than points 1 and 2 because it is closer to the tanks containing radioactive liquid.

Figure 32.15 shows the radiation evolution in the surroundings of the permeate and feed tanks (points 4 and 5). Near the permeate tank (point 4), dose variation is not very significant since the permeate has a low activity level [10]. However, the radiation evolution near the feed tank (point 5) shows quite high dose values. This is because the liquid inside this tank has much higher activity than the liquid inside the permeate tank. Dose increase around the feed tank is due to progressive concentration of the liquid feed as a result of membrane concentrate recirculation to this tank [11].

Figure 32.16 shows the radiation evolution of the main elements of the membrane treatment plant. Among these elements, the filtration unit showed the highest dose values, particularly the sleeve filters (point 7) with top values around 140  $\mu\text{Sv/h}$ . This high dose is because these filters are the first element through which the feed flows, so they are in contact with a high activity liquid. The dose values at the cartridge filters (point 8) are lower than the values of the sleeve filters, though they are also fairly high, between 10 and 30  $\mu\text{Sv/h}$ , approximately.

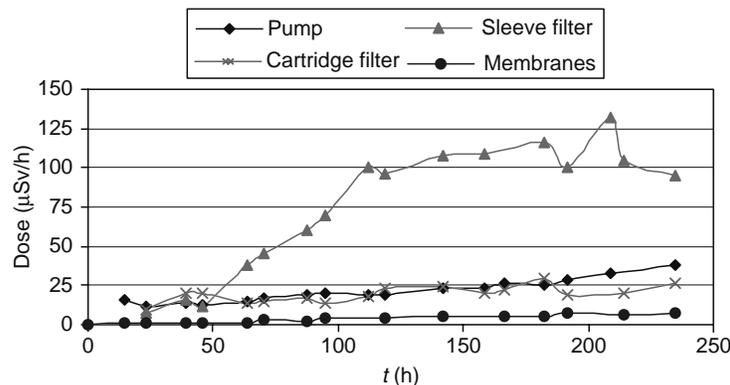

**FIGURE 32.15** Radiation level evolution around the permeate and feed tanks. (From Arnal, J.M. *Tratamiento de Residuos Radiactivos Líquidos y Sólidos Contaminados con Cs-137 Mediante Sistemas Combinados de Separación por Membranas, Lixiviación y Precipitación Química*, 1st ed. Valencia, Spain: Servicio de Publicaciones UPV, 2003.)

Another important point with regard to radiation level at the treatment plant is the intermediate tank in which the liquid is stored after filtering, and the pump placed beside that tank (point 6). The high values at this point, around  $40 \mu\text{Sv/h}$ , are due to the high activity values of the liquid stored in the intermediate tank.

Finally, the point that represents membrane modules (point 9) shows quite significant dose values, which increase progressively as the feed concentrates. From the analysis of radiation evolution in the treatment area, the following conclusions can be stated:

- Most relevant points from the viewpoint of radiological protection are the filtration unit and the intermediate tank, with the highest dose values.
- Filtration unit is a point of necessary and frequent access to change filters. In future treatment plants, it should be isolated to facilitate a safe access to the other elements of the plant.
- Intermediate tank should not be placed in the surroundings of any element that needs frequent access. The pump also has to be placed far from the elements with high dose values, if it requires regular maintenance.
- Membrane modules reach dose values that cannot be ignored. Although they are not as high as the doses reached at the elements mentioned above, membrane modules are points of continuous manipulation, so they have to be considered from the point of view of radiological protection.
- Dose values at the area around the feed tank are fairly high, but it is not an important problem since this tank is not of frequent access.

**FIGURE 32.16** Radiation level evolution at the membrane plant. (From Arnal, J.M. *Tratamiento de Residuos Radiactivos Líquidos y Sólidos Contaminados con Cs-137 Mediante Sistemas Combinados de Separación por Membranas, Lixiviación y Precipitación Química*, 1st ed. ## 32.4 FUTURE TRENDS IN RADIOACTIVE LIQUID WASTE DISPOSAL

With regard to future trends in the radioactive and nuclear fields, an increasing use of radioisotopes for medical, industrial, and research purposes is expected soon. As a result of this, there will be an increase in the amount of low and medium radioactive wastes.

The benefits of these activities are well known, but design of waste disposal strategies for volume reduction and liquid decontamination is essential, to optimize waste storage installations and reduce waste disposal costs. Among these strategies, the application of an appropriate treatment is essential for suitable waste disposal.

Membrane technologies have a great potential in the treatment of radioactive liquid wastes, as it has been proved throughout this chapter. In this sense, it is expected a growing use of the membrane processes in the radioactive field, with different possibilities: alone, combined between them (microfiltration or ultrafiltration and reverse osmosis) or combined with other conventional processes like evaporation or ion exchange. Furthermore, some special membrane processes, like membrane distillation or liquid membranes, could be applied for the specific treatment of radioactive wastes.

In relation to future trends of the membrane treatments described in this chapter, they are expected to be applied for medical and research wastes of low-medium activity contaminated with  $^{125}\text{I}$ ,  $^{137}\text{Cs}$ , or other radioisotopes with similar characteristics. Furthermore, membrane treatment has been proved as an efficient and quick treatment in an incident that generates low-medium radioactive wastes.

## ACKNOWLEDGMENTS

Authors would like to express their gratitude to the people from La Fe Hospital and LAINSA company of Valencia for their contribution to the research described in this chapter.

We would also like to thank the R & D & I Linguistic Assistance Office at the Universidad Politécnica of Valencia for their help in revising this paper.

## 33.1 INTRODUCTION

Membrane-based processing of nuclear plant radioactive waste and radioactive liquids in general is rapidly gaining acceptance within the nuclear industry. Whereas early membrane systems were limited by unreliable hardware and inconsistent performance; modern systems have proven to be both cost effective and superior to conventional processing technologies. In specific installations, the conversion to membrane-based processing has produced significantly pure water, with less secondary waste generation and lower operator radiation exposure [1]. The possible applications of membranes in nuclear programmes are (1) treatment of radioactive liquid effluents, (2) separation and concentration of useful radionuclides, and (3) separation of gaseous streams containing radioactive species.

Membrane processes have been introduced on pilot plant scale in the reprocessing plant of the Bhabha Atomic Research Centre (BARC) to treat various low-active streams. The following case studies are discussed in brief.

## 33.2 REMOVAL OF ACTIVITY FROM VARIOUS WASTE STREAMS USING ULTRAFILTRATION AND REVERSE OSMOSIS

### 33.2.1 ACTIVITY REMOVAL FROM FUEL POND WATER

The primary function of ultrafiltration (UF) systems is to remove colloids and other particulate foulants from feed streams. Activity from fuel pond water is currently removed via ion-exchange columns. Among the drawbacks of ion-exchange purification is the production of substantial amounts of secondary waste during regeneration of the ion-exchange bed. Hence, ultrafiltration was thought to be an attractive alternative for treating fuel pond water [2]. We undertook a pilot study at our reprocessing plant. The typical composition of fuel pond and delay tank waters for the plant is shown in Table 33.1. The spiral-wound module used for the UF and reverse osmosis (RO) studies is detailed in Table 33.2, and the basic flow diagram through the spiral-wound membrane is shown in Figure 33.1. The setup of the UF membrane pilot plant is shown in Figure 33.2.

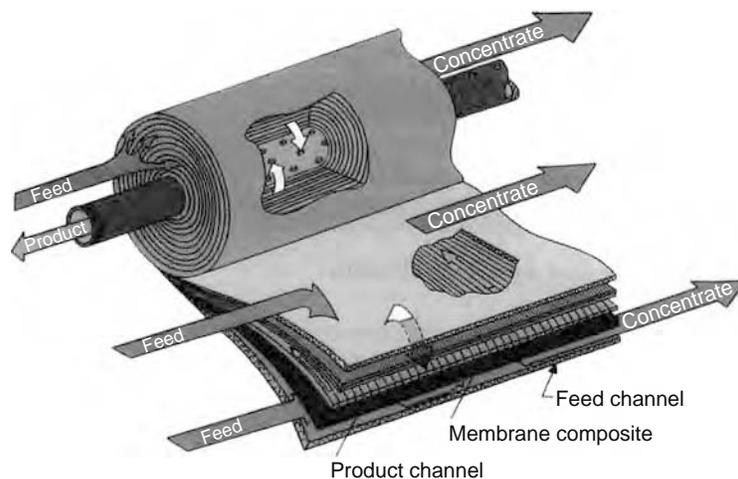

**TABLE 33.1**  
**Composition of Fuel Pond and Delay Tank Solutions**

Fuel Pond Water		Delay Tank Water	
pH	6.8 to 7.8	pH	6 to 8
Total dissolved salts (TDS)	28 ppm	TDS	1700 ppm
Turbidity	0.3 NTU	Gross alpha	$2.8 \times 10^{-5}$ mCi/L
Gross alpha	$4.6 \times 10^{-6}$ mCi/L	Gross beta/gamma activity	$3.5 \times 10^{-4}$ mCi/L
Gross beta/gamma activity	$3.2 \times 10^{-4}$ mCi/L		

*Note:* mCi/L stands for millicuries per liter.

Membrane pore size	100 Å	5–10 Å
Operating pressure	1 bar	15 bar

**FIGURE 33.1** Spiral wound module.

The results of the pilot plant study, summarized in Table 33.3, are very positive: 12,000 L of fuel pond water were successfully treated, providing decontamination factor (DF) (Chapter 29) values for alpha and beta of 4 and 5, respectively. The final product obtained from UF had a turbidity of ca. 0.1 NTU (feed turbidity: 0.3 NTU). The flux value was reduced by 15%, which was attributed to possible membrane fouling. The UF module was backflushed with pH 2 solution (HNO<sub>3</sub>), and the original flux value of the permeate was restored. A long-term performance evaluation study was conducted by monitoring the permeate quality (DF value) and radiation dose on the module. No hot spot generation was observed during a pilot run of UF with fuel handling area (FHA) water.

### 33.2.2 REMOVAL OF ACTIVITY FROM DELAY TANK SOLUTIONS USING AN RO UNIT

Adapting RO technology will help to achieve the ALARA concept, which will be beneficial for the environment. In recent years, RO systems have been used to replace or augment existing evaporation or ion-exchange technology due to their lower

FIGURE 33.2 UF membrane setup utilized in fuel handling area.

operating costs [1,3]. The final discharge of low-level active waste (i.e., a mixture of evaporator condensate, ammonium diuranate filtrate, hand washings, etc. from the reprocessing plant) is carried out from the delay tank, which temporarily holds low-active waste. We thus evaluated RO for the removal of alpha activity, beta activity, nitrates, and total dissolved salts (TDS) from delay tank water at the pilot plant.

The specifications of the membrane module, which was supplied by the Desalination Division of the BARC (Mumbai), are listed in Table 33.2. The RO setup installed at the delay tank site is shown in Figure 33.3. The delay tank water composition is given in Table 33.1. The module was operated at a pressure of 15 bar, which was adjusted by a throttle valve placed on the reject line. The experiments were performed both in once-through and recirculation modes. The alpha and beta activities, and nitrate and TDS levels were periodically monitored by sampling the feed, permeate, and reject solutions using standard analytical methods.

The results of the RO studies are summarized in Table 33.4. The DF values for alpha range from 6–10, and for beta, from 6–15. Nitrates and TDS were also strongly rejected by RO. The results from the permeate solution show that after passing 25,000 L, the performance of the pilot plant was quite promising. Furthermore, the same RO setup was used for a delay tank solution containing moderate alpha and beta activity. The DF values (Table 33.4) obtained for alpha are 12–15, which are slightly higher than those obtained for solutions with lower activity. This is because the feed input alpha activity was higher. In recirculation mode, good permeate quality was maintained, whereas alpha and beta activities of the concentrate reached  $10^{-4}$  and  $10^{-3}$  mCi/L, respectively, and TDS levels surpassed 15,000 ppm. The results of the RO studies are summarized in Table 33.5.

**TABLE 33.3**  
Typical Analytical Results of UF Pilot Plant Studies Conducted for Fuel Pond Water

Sample at	Feed Activity (mCi/L)		DF		Permeate NTU	TDS (ppm) <sup>a</sup>	
	Alpha	Beta/Gamma	Alpha	Beta/Gamma		Feed	Permeate
500 L	$2.8 \times 10^{-6}$	$3.5 \times 10^{-4}$	5	4	0.05	28	<10 (45 ppm) <sup>b</sup>
2000 L	$3.8 \times 10^{-6}$	$4.5 \times 10^{-4}$	4	3	0.1	22	<10 (38 ppm)
4000 L	$1.4 \times 10^{-6}$	$5.8 \times 10^{-4}$	4	4	0.1	22	<10 (42 ppm)
8000 L	$2.4 \times 10^{-6}$	$3.9 \times 10^{-4}$	4	4	0.1	35	<10 (54 ppm) <sup>c</sup>
12000 L	$5.2 \times 10^{-6}$	$3.4 \times 10^{-4}$	4	4	0.1	35	<10 (53 ppm) <sup>c</sup>

Note: mCi/L stands for millicuries per liter.

<sup>a</sup> TDS values within the brackets belong to concentrate.

<sup>b</sup> The alpha and beta/gamma activity of concentrate was found to be  $2.2 \times 10^{-5}$  and  $5.5 \times 10^{-3}$  mCi/L, respectively.

<sup>c</sup> The alpha and beta/gamma activity of concentrate was found to be  $3.9 \times 10^{-5}$  and  $3.5 \times 10^{-3}$  mCi/L, respectively.

### 33.3 ELECTRODIALYSIS FOR THE DECONTAMINATION AND CONCENTRATION OF LOW-ACTIVE WASTE

Low-active liquid waste (i.e., condensate, regenerant, and detergent) generated in reprocessing plants is subjected to electro dialysis for concentration of radioactive cations into a very small volume, thus rendering a large portion of the waste disposable and environment friendly ( $5 \times 10^{-5}$  mCi/L gross beta activity). For this purpose, an electro-membrane cell containing an ion-exchange membrane in its central compartment was designed and fabricated in the BARC laboratory (Figure 33.4). The electro dialysis (ED) cell was used to further reduce the volume of concentrated stream generated during electro dialysis. The study employed a laboratory model electrolyzer unit (Figure 33.5) that had 41 pairs of vertically alternating cation- and anion-exchange membranes ( $200 \times 80$  mm<sup>2</sup> effective size). The membranes were obtained from M/s. Thermax Ltd. (Pune, India). The interpolymer membranes are composed of high-density polyethylene, polystyrene and divinyl benzene, and functionalized with sulfonic acid, in cation-exchange membranes, and with quaternary ammonium, in anion-exchange membranes [4].

About 5 L each of regenerant and detergent liquid waste were recirculated through the ED cell at the rate of 16 L/h. Samples were collected after each pass and analyzed for fission product activities. Results from a typical test run are given in Tables 33.6 and 33.7. The concentrated stream generated during electrolytic treatment of different waste streams was subjected to electrochemical ion concentration. The electrochemical ion concentrator is composed of three chambers. The central chamber is filled with cation-exchange resin (Zeocarb 225), and is separated from the adjacent cathode and anode chambers by cation-exchange membranes. The electrodes used are made of titanium-expanded sheet metal coated with oxides of precious

Note: Voltage per cell pair: 1–2 V; current density: 20 mA/cm<sup>2</sup>; flow rate: 16 L/h; volume of feed: 5 L; volume of concentrated waste: 0.5 L; VRF: 10; mCi/L stands for millicuries per liter.

metals such as palladium. Inlets and outlets were provided for each chamber. The catholyte and anolyte are fed at the bottom, which overflows from the top. The feed flows into the top of the central chamber and flows out of the bottom. The ions, under the influence of the electric field, move perpendicular to the flow of the solutions. Feed acidity was maintained at 0.01 M HNO<sub>3</sub>. Flow rates for anolyte and catholyte were maintained at about 300–350 bed vol/h. The elutriant in all the experiments was passed at a constant rate of 23 bed vol/h. Samples were drawn at regular intervals and analyzed for Cs-137 activity using a high purity germanium detector coupled with a 4 K multichannel analyzer. Electrochemical ion concentration [5,6] operation involved simultaneous loading and electroelution of cations into the catholyte stream, keeping the effluent activity in the range from  $1 \times 10^{-5}$  to  $1 \times 10^{-4}$  mCi/L. A volume reduction factor (VRF) of ca. 35–40 was easily obtained in this step. An overall VRF of ca. 350–400 was obtained by ED coupled with an ion concentrator.

The main contributors to the radioactivity of the effluent were Cs-137, Cs-134, and Ru-106. Most of the radioactivity from the low-level radioactive effluents could be removed by ED. Greater DF was achieved for cesium than for ruthenium due to the nonionic nature of the latter [12]. The degree of decontamination increased with the number of electrodialysis stages performed. Salt content and radionuclide concentration did not have any marked influence on the decontamination factors of these nuclides [7]. The concentrate streams generated during electrodialysis contained 0.005–0.05 mCi/L of Cs-137, and the VRF achieved in the electrodialysis operation was ca. 10.

### 33.4 APPLICATION OF A PERFLUORINATED MEMBRANE IN FUEL REPROCESSING

Uranous nitrate [U(NO<sub>3</sub>)<sub>4</sub>] solution is used for the quantitative reduction of plutonium from loaded tributyl phosphate (TBP) phase [8]. Membrane cell technology was investigated for the production of 100% uranous nitrate solution [9], which is to be used in the partition cycle of the PUREX process in the fuel reprocessing plant. The membranes used hitherto have suffered from mechanical instability. A study was carried out at the BARC to obtain 100% uranous nitrate solution using a membrane-based electrolytic cell. The membrane used in this study was a thin polymer film reinforced with a Teflon fabric. The film was used as a separator between the anolyte and catholyte chambers, which are made of perfluorinated polymers, thus offering high thermal and chemical stability.

Nafion-perfluorinated membranes are manufactured from copolymers of tetrafluoroethylene and perfluorinated monomers and contain sulfonic groups on one side and carboxylic acid groups on the other. The membranes, originally designed for use in

Material of construction	Perspex, PVC, Neoprene
Capacity of each chamber	100 mL
Total volume of catholyte feed	5 L
Catholyte composition	Uranyl nitrate, 280 gm/L; Hydrazine, 0.5 M; Nitric acid, 3.0 M
Anolyte volume	3 L
Anolyte composition	1.0 M HNO <sub>3</sub>
Membrane	Nafion-900 series
Current density	50 mA/cm <sup>2</sup>

caustic soda production membrane cells, have the extraordinary chemical and thermal stability of Teflon resins but, unlike Teflon, which is among the most hydrophobic substances known, Nafion is among the most hydrophilic. Nafion resins rapidly absorb water at room temperature. The rate of water absorption depends on the number of resin-bound sulfonic and carboxylic groups. We used the cell with different pairs of electrodes to produce a 100% U(NO<sub>3</sub>)<sub>4</sub> solution. Details of the cell are given in Table 33.8, and a schematic of the cell is provided in Figure 33.6. The current efficiency in each case was calculated from measured values (Table 33.9). The membrane was used for over 3 years in nitric acid and hydrazine medium without any apparent damage. It offered high chemical resistance and mechanical strength. In each batch operation, the percentage conversion to uranous nitrate was 100%. The membrane has an established life span of 128 A h/cm<sup>2</sup> with no loss in electrochemical performance. A ca. 10% dilution in product was observed due to electroosmosis. The 100% uranous nitrate solution generated was utilized for the plant process. Several kilograms of uranous nitrate have been produced in the reprocessing plant using this technique.

### 33.5 NONDISPERSIVE SOLVENT EXTRACTION FOR THE SEPARATION, REMOVAL, AND CONCENTRATION OF ACTINIDES

As a part of our comprehensive programme on membrane technology, we evaluated nondispersive solvent extraction (NDSX) with a hydrophobic microporous hollow fiber contactor (HFC) for the separation and removal of actinides [1,10–12]. As the separation and recovery of actinides from different sources is paramount to radiotoxicity, there is a constant need for advances in the field. Among recently developed technologies, membrane extraction using microporous hollow fibers is particularly

**FIGURE 33.6** Schematic diagram of electrolyzer used for uranous production.

<sup>a</sup> TSIA stands for titanium substrate insoluble anode.

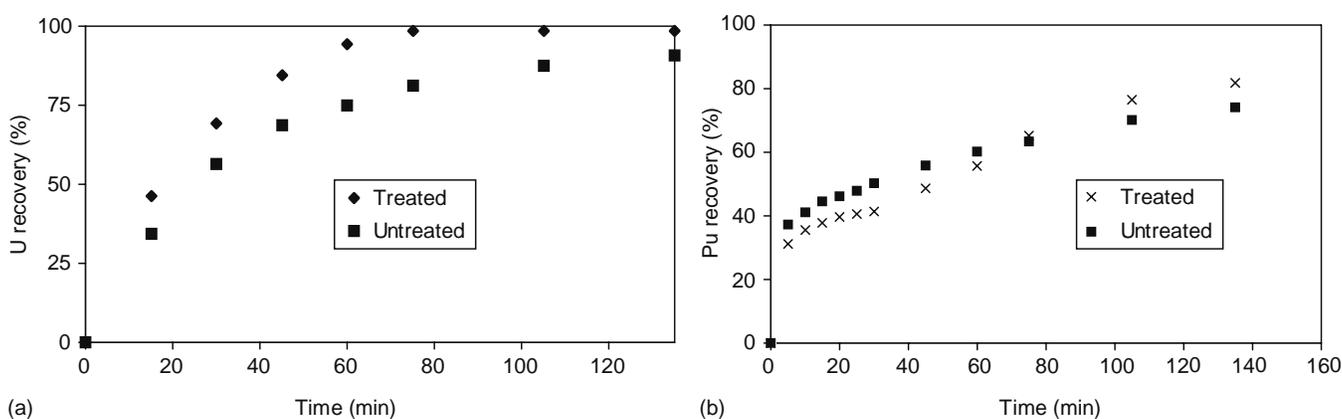

interesting because of its versatility and the fact that it overcomes problems encountered in conventional liquid–liquid extraction [10,13,14]. NDSX is simply liquid–liquid extraction performed in an HFC, which involves the use of a standard commercial hollow fiber module to bring aqueous and organic phases into contact without dispersion, thereby minimizing the possibility of forming emulsions, third phases, or crud with the extractant. A second module is then used to strip the solute from the loaded organic phase.

### 33.5.1 SEPARATION OF URANIUM AND PLUTONIUM FROM OXALATE SUPERNATANT

Plutonium is recovered by first precipitating out plutonium nitrate as plutonium oxalate, then extracting the oxalate supernatant, which contains milligram levels of plutonium. The typical composition of oxalate supernatant waste is Pu: 25 m/dm<sup>3</sup>, U: 5 gm/dm<sup>3</sup>, Ru<sup>106</sup>: 0.0032 mCi/dm<sup>3</sup>, Cs<sup>137</sup>: 0.003 mCi/dm<sup>3</sup>, HNO<sub>3</sub>: 3M, and H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>: 0.1 M. The separation of uranium and plutonium in presence of fission products from this waste was investigated using 30% TBP/nph. The uranium extraction was quantitative (>99%) from this aqueous waste. Removal of plutonium is more important being a strategic metal and can reduce the load of extraction cycle to achieve high recovery of plutonium. The results from plutonium extractions using acidic, pure plutonium tracer solutions are summarized in Figure 33.7, and were compared to known data for typical plutonium extraction methods. Based on these data, we studied the recovery of U(VI) and Pu(IV) from oxalate supernatant using 30% TBP/*n*-dodecane as extractant, and without addition of nitric acid. The experiments were performed in counter-current recirculation mode with the A/O ratio at 1 using treated (C<sub>2</sub>O<sub>4</sub><sup>2-</sup> ions destroyed by KMnO<sub>4</sub>/H<sub>2</sub>O<sub>2</sub>) and untreated (in presence of C<sub>2</sub>O<sub>4</sub><sup>2-</sup> ions) wastes separately. The results (Figure 33.8) clearly indicate that the recovery of Pu(IV) from untreated waste was >70%, and from treated waste, was >80% whereas uranium recovery was more than 99% from treated oxalate supernatant waste. The same technique was also used to extract and concentrate Pu(IV) from the aqueous phase. We evaluated solutions of uranous nitrate and of hydroxylamine hydrochloride as strippants for the back-extraction of the Pu. The strippants were run through the tube side, and the loaded organic phase was run through the shell side. Extraction of Pu(IV) was not affected by the presence of fission products such as Cs<sup>137</sup>, Ru<sup>106</sup>, and Eu<sup>154</sup>; no Cs, Ru, or Eu was extracted. This may be due to insignificant DF values (partition coefficient for extraction) for such fission products under these conditions [15].

**FIGURE 33.7** Effect of extractant concentration on % Pu(IV) extraction. Feed acidity: 3.0 M HNO<sub>3</sub>; feed concentration:  $1 \times 10^{-5}$  mol/dm<sup>3</sup>; extractant: tributyl phosphate (TBP)/*n*-dodecane; A/O ratio: 1 (200 cm<sup>3</sup> of each). ### 33.5.2 EXTRACTION OF MACRO-QUANTITIES OF URANIUM

In the reprocessing plant, macro-quantities of uranium can be separated from several streams. To apply NDSX to the macro-concentration, we first evaluated NDSX for macro-quantities of uranium(VI) using an HFC in recycling mode with tri-*n*-butylphosphate (TBP) in *n*-dodecane as extractant under different chemical and hydrodynamic conditions. A schematic view of the membrane is shown in Figure 33.9. The extraction mechanism of U(VI) through HFC is shown in Figure 33.10. An increase in TBP concentration from 5%–50% led to an increase in U(VI) extraction. However, to ensure economical plant scale operation, we chose 30% TBP as the optimum concentration to evaluate further parameters. A total recovery of >98% was achieved in three consecutive runs using fresh extractant and without adjusting the feed acidity [16]. In studying the effects of U(VI) concentration (ranging 16–116 g/L) on extraction, we observed that for 16 g/dm<sup>3</sup> uranium, 81% extraction was achieved within 135 min (Figure 33.11). However, when the U(VI) concentration was increased to 116 g/dm<sup>3</sup>, the extraction decreased to 51%. This could be due to the limited surface area of the module. U(VI) was stripped from the loaded organic phase using 0.05 M HNO<sub>3</sub> [17].

### 33.5.3 EXTRACTION OF AMERICIUM FROM ACIDIC MEDIA

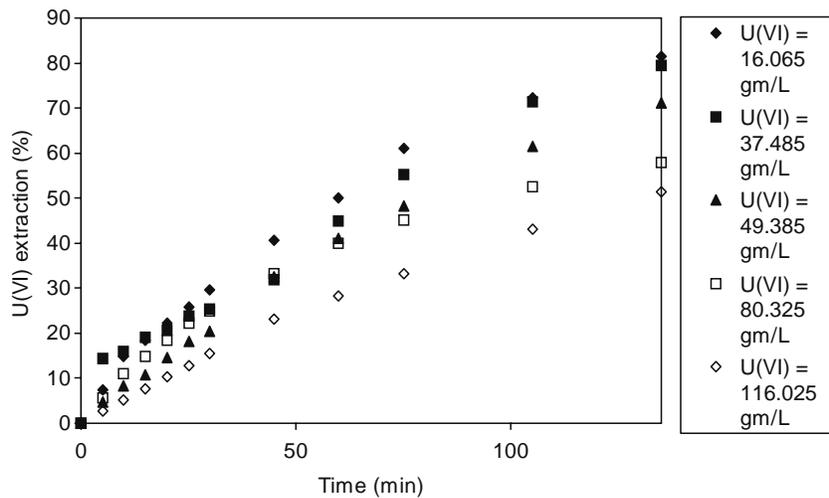

Since the effluents from nuclear fuel reprocessing plants also contain Am(III), we studied NDSX of Am(III) using the HFC module [17,18], and the acidic extractant PC-88A (2-ethylhexylphosphonic acid mono-2-ethylhexyl ester). The results of the studies are summarized in Figure 33.12. At 30% PC-88A concentration, a maximum extraction of 90% was achieved. Am(III)

**FIGURE 33.12** Influence of extractant concentration on Am(III) extraction. Extractant: Varying concentration of PC-88A/*n*-dodecane (v/v); feed acidity: 0.001 M HNO<sub>3</sub>; feed Am(III) concentration:  $6 \times 10^{-7}$  M; volume of aqueous/organic: 200 cm<sup>3</sup>; flow rate of aqueous: 5.83 cm<sup>3</sup>/s, flow rate of organic: 1.53 cm<sup>3</sup>/s.

was stripped from the loaded organic using 4.0 M HNO<sub>3</sub>. This technique could be used to pre-concentrate Am(III) from low-active waste using single HFC and maintaining lowest volume of strippant and passing large volume of feed without replacing strippant solution.

## 34.1 INTRODUCTION

There are over 1000 drinking water treatment plants in the United States that use alum,  $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$  as a coagulant for the efficient removal of particulate solids and colloids from surface water supplies [1,2]. For alum, the process of coagulation works best in the pH range 4.5–8.0. Similarly, for ferric chloride, another coagulant used in the water treatment plants, the optimum pH range is between 4 and 12. Alum is converted during the process into insoluble aluminum hydroxide, a major component (25%–50%) of solids in water treatment residuals (WTR). Water treatment plants in the United States produce over 2 million tons of aluminum-laden disposable WTR every day [3], which are bulky, gelatinous, and biologically inert slurry composed of suspended inorganic particles, natural organic matter (NOM), trace amounts of heavy metal precipitates, and aluminum hydroxide. The total solids content of the residuals normally ranges from 2% to 10% in mass per unit volume [4,5]. A typical composition of water treatment plant residuals is shown in Table 34.1 [6]. Due to regulatory changes in the recent past, WTR now have to be disposed in landfills or through land application [3,6]. And due to the magnitude and pervasiveness of the problem, the prospect of alum recovery from WTR has received considerable attention in recent years. The toxicity of free and complexed aluminum species toward various aquatic species and benthic organisms has been the focus of several studies [7,8]. Some researchers have linked aluminum ion's contributory influence to occurrence of Alzheimer's disease [9]. It is therefore recognized that the disposal of aluminum-laden solids from water treatment plants will receive a closer scrutiny in the coming years [10]. Ideally, a simple-to-operate process, which can recover alum selectively from the sludge, will significantly reduce the amount of disposable solids. However, the recovered alum has to be sufficiently pure to be reused as a coagulant at the front-end of water treatment. Such a process will truly combine pollution prevention with resource recovery, thus reducing stress on the environment.

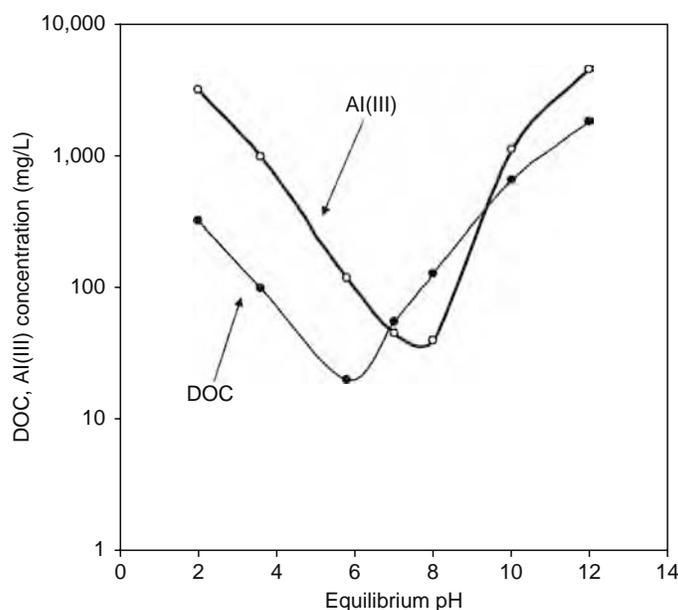

### 34.1.1 PAST STUDIES ON ALUM RECOVERY

When WTR are sufficiently acidified with sulfuric acid ( $\text{H}_2\text{SO}_4$ ), insoluble aluminum hydroxide in the solution is converted to aluminum sulfate, which is soluble in the aqueous medium. The stoichiometry of this reaction can be written as follows:

**TABLE 34.1**  
**Typical Composition of WTR**

Substance	Amount (mg/L)
Total suspended solids	100,000–150,000
Total Al(III)	1,000–3,000
Total iron	100–300
Total calcium	<30
Total copper	<10
Total zinc	<20
pH	7.0–7.2
Arsenic	<0.3
Total dissolved organic carbon (DOC)	100–300

**FIGURE 34.1** Variation of DOC and aluminum ion concentration with pH for WTR from the Allentown Water Treatment Plant (AWTP), Pennsylvania.

Equation 34.1 provides the underlying concept of the *acid digestion process*, which has been tried both at laboratory and at pilot-scale levels [11,12]. The basic concept of the process is simple but the following shortcomings limit the possibility of reusing the recovered liquid alum as a coagulant. The process is nonselective i.e., along with alum it also recovers all other substances that are soluble under highly acidic conditions or that exist as colloids. Thus, naturally occurring organic material (humates and fulvates), which are generally removed quite well by alum coagulation, will be present in the recovered alum. Should this recovered alum be reused as a coagulant, trihalomethane formation potential (THMFP) in the treated water upon chlorination would tend to increase significantly. Trihalomethanes are suspected carcinogens and are regulated by the United States Environmental Protection Agency (USEPA) [13–15].

Since aluminum oxide is amphoteric, alum could theoretically be recovered from the WTR under alkaline conditions as well. Figure 34.1 shows both dissolved organic carbon (DOC) and Al(III) concentration in Allentown, Pennsylvania under water treatment plant conditions. Since a high concentration of dissolved organic matter is very undesirable in recovered alum due to its THMFP, even the *alkali digestion process* is unable to achieve selective alum recovery.

*Liquid ion exchange (LIE)* [16] can concentrate aluminum ions up to 4000 mg/L from an initial 1000 mg/L. But in the stripping stage of LIE, entrainment issues are always a concern, because LIE involves separating aluminum ions from an organic phase into which it is dissolved in the first stage. Since this separation cannot be 100% ideal, one can expect organics being carried over into the alum solution.

*Ultrafiltration* is another technique that can be employed following acid treatment. However, this process suffers from the demerits of fouling, decreased membrane life due to pressure differential, and a decrease in flux with continued deposition [17].

*Two-step composite membrane process* [18] involves selective sorption of aluminum ions from an aqueous phase (containing dissolved aluminum ions in acidified WTR) onto a membrane phase in the first step followed by desorption or regeneration of the composite membrane in a  $H_2SO_4$  solution in the second step with the release of aluminum ions. This patented process was developed in the Department of Civil and Environmental Engineering at Lehigh University. It overcomes many of the shortcomings of the previous processes in that it selectively recovers aluminum ions and prevents passage of natural organic material, heavy metals, and manganese into the recovered alum. However, composite ion-exchange materials are not available in sizes appropriate for large-scale applications.

### 34.1.2 DONNAN MEMBRANE PROCESS: NEW APPROACH TO ALUM RECOVERY

During the last two decades, pressure-driven membrane processes namely reverse osmosis (RO), nanofiltration (NF), and ultrafiltration (UF) have found increased applications in water utilities and chemical industries. Unlike RO, NF, and UF, the Donnan membrane process (DMP) or Donnan dialysis is driven by an electrochemical potential gradient across an ion-exchange membrane. Theoretically, the DMP is not susceptible to fouling because particulate matter or large organic molecules do not concentrate on the membrane surface, as commonly observed with pressure-driven membrane processes. DMP has been used in the past in hydrometallurgical operations [19,20], for concentration of ionic contaminants [21,22] and for separation of

acids from salts [23,24]. Although information on several applications of DMP is available in the open literature, no work is reported on the use of DMP to treat a sludge or slurry with high concentrations of suspended solids or high organic content molecules. It was conceived that a single-step DMP could selectively recover alum, a widely used coagulant, from water treatment plant sludge or WTR.

It is also true that many water treatment plants use ferric chloride as a coagulant in water treatment operations. Ferric ions are trivalent cations, much like aluminum ions. Since the DMP is driven by an electrochemical potential, it is thought that it might be possible to apply it to WTR generated from iron-based coagulants. It was therefore conceived that a single-step DMP could selectively recover ferric ions as well.

### 34.1.3 SCOPE OF THIS CHAPTER

In writing this chapter, the central theme is to detail the readers of the applicability of the DMP for recovering coagulants from WTR. This includes verifying the quality of the recovered alum and studying its usage in coagulation processes. The response of the process to various operating conditions including those of membrane fouling is also discussed. The parameters of study include (1) total coagulant recovery, (2) selectivity of recovered coagulants, (3) effectiveness of recovered coagulants, (4) Donnan exclusion of DOC, (5) feed/sweep solution strength and their volumetric ratio, (6) feed/sweep ion type, (7) membrane area, (8) feed solution turbidity, (9) agitation of solutions, (10) membrane fouling, and (11) settling efficiency of residual WTR. The efficacy of the process for recovery of ferric ions from ferric chloride-based residuals is also discussed briefly.

The other important subject is the comparison of effectiveness of the process in alum recovery for two types of ion-exchange membranes, namely heterogeneous and homogeneous membranes.

In addition, a model has been formulated to predict the self-diffusion coefficient of diffusing species, which are hydrogen and aluminum ions. The interdiffusion coefficient value for the coupled transport of these two ions is also determined for the two types of membranes.

The process of diffusion dialysis is also mentioned briefly, as an attempt to recover spent acid from WTR, after alum recovery. The objective of this process is to estimate the efficacy of the process in (a) raising the pH of the treated WTR and (b) lowering the pH of the fresh WTR before undergoing alum recovery in the DMP.

## 34.2 DONNAN MEMBRANE PROCESS: THEORY

The DMP has been a widely recognized ion-exchange membrane separation process that can be applied to selectively remove ions from a dilute feed solution and to simultaneously enrich them in a sweep solution. The ion of interest (feed ion) in the feed solution is transported to the sweep solution with a counter transport of a driving ion (the sweep ion) from the sweep solution to the feed side. This coupled transport takes place across an ion-exchange membrane until conditions of Donnan equilibrium are achieved. The process utilizes an electrochemical potential gradient that exists between the feed and the sweep solution and requires no external field or pressure gradient to accomplish this transport. The DMP is based on the Donnan co-ion exclusion principle [25], by which negatively charged cation-exchange membranes do not allow anions to pass through the membrane and the positively charged anion-exchange membranes do not allow cations to cross over.

### 34.2.1 DONNAN MEMBRANE PROCESS: BASICS

A fundamental understanding of the DMP requires knowledge of both the ion transport through an ion-exchange membrane and the Donnan equilibrium, the latter indicating the maximum allowable transfer of ions that can take place. The underlying concept can be better explained through an example. This example is also relevant in the context of the objectives of the research, which is alum recovery from water treatment plant residuals [26].

Let us consider aluminum sulfate and sulfuric acid solutions in a Donnan membrane cell divided into two chambers by a cation-exchange membrane that allows only cations to migrate from one side to the other but rejects any passage of anions according to Donnan's co-ion exclusion principle. At equilibrium, the electrochemical potential of aluminum ( $\text{Al}^{3+}$ ) ion ( $\bar{\mu}$ ) in the electrolyte solution on the left hand side (LHS) of the membrane will be the same as that in the electrolyte solution on the right hand side (RHS) i.e.,

$$\bar{\mu}_{\text{Al}}^L = \bar{\mu}_{\text{Al}}^R \quad (34.2a)$$

or

$$\mu_{\text{Al}}^o + RT \ln a_{\text{Al}}^L + zF\phi^L = \mu_{\text{Al}}^o + RT \ln a_{\text{Al}}^R + zF\phi^R \quad (34.2b)$$

where

superscripts “o,” “L,” and “R” refer to standard states of  $\bar{\mu}$ , LHS, and RHS, respectively

$\bar{\mu}$ ,  $a$ ,  $F$ , and  $\phi$  denote electrochemical/chemical potential, chemical potential, activity, Faraday constant, and electrical potential, respectively

$R$  is the universal gas constant

$z$  refers to the charge of the diffusing ion

which is 3 for trivalent aluminum ion  $\text{Al}^{3+}$ . Equation 34.2 gives the following equality for aluminum ions on two sides of the membrane:

$$\frac{F(\phi^L - \phi^R)}{RT} = \ln \left( \frac{a_{\text{Al}}^R}{a_{\text{Al}}^L} \right)^{1/3} \quad (34.3)$$

In a similar way, it can be shown for hydrogen ions that

$$\frac{F(\phi^L - \phi^R)}{RT} = \ln \left( \frac{a_{\text{H}}^R}{a_{\text{H}}^L} \right) \quad (34.4)$$

Since both the feed and the sweep solutions are of similar order of electrolyte strength, it may be assumed that the nonideality effects are about the same on both sides of the membrane, and activities can therefore be replaced by molar concentrations. Equations 34.3 and 34.4 then yield the following:

$$\left( \frac{C_{\text{Al}}^R}{C_{\text{Al}}^L} \right) = \left( \frac{C_{\text{H}}^R}{C_{\text{H}}^L} \right)^3 \quad (34.5)$$

If the ratio  $C_{\text{H}}^R/C_{\text{H}}^L$  is 10, it means  $C_{\text{Al}}^R$  is 1000 times greater than  $C_{\text{Al}}^L$ . Thus, by maintaining high hydrogen ion concentration on the RHS of the membrane, aluminum ions can be driven from the LHS to the RHS even against a positive concentration gradient i.e., from a lower concentration region to a higher concentration one, the impact being more for a higher valent species. For example,  $\text{Al}^{3+}$  will concentrate more than  $\text{Na}^+$ . This example can be extended to any system of coupled transport, a general expression for which would be:

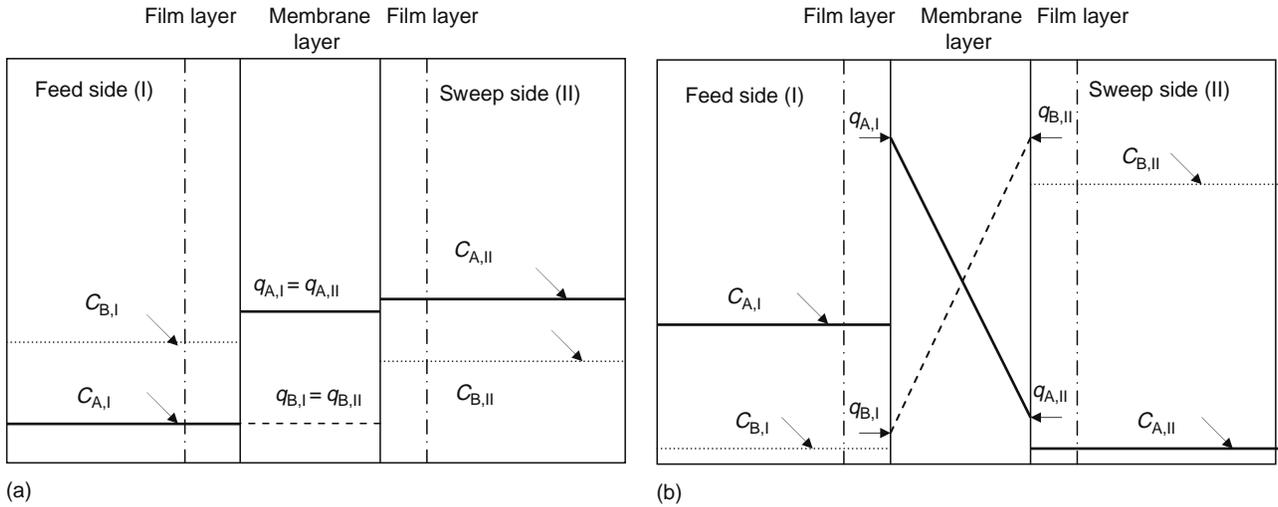

$$\left( \frac{C_i^R}{C_i^L} \right)^{z_i} = \left( \frac{C_j^R}{C_j^L} \right)^{z_j} \quad (34.6)$$

where  $i$  and  $j$  refer to the exchanging ionic species and  $z_i$  and  $z_j$  refer to the valence of these two species.

### 34.2.2 DONNAN MEMBRANE PROCESS: CONCENTRATION PROFILE INSIDE MEMBRANES

A Donnan membrane setup can be divided into two cells by a cation-exchange membrane. Cell I or the feed side solution primarily consists of the feed cation A with a charge  $z_A$  while cell II or the sweep side solution predominantly consists of the sweep cation B, which has a charge  $z_B$ . At the start of the separation process, the concentration of the feed ion A is several folds higher than of sweep ion B in cell I. The cation-exchange membrane has certain selectivity for feed ion A over B. The corresponding selectivity coefficient  $K_B^A$ , described later, relates the preference of the membrane for a particular ion with respect to another ion. A higher selectivity coefficient for A over B in cell I would mean a concentration  $q$  (expressed in moles per cubic millimeter) of cation A on the membrane surface in cell I. In other words,  $q_{A,I}$  will be much higher than  $q_{B,I}$ . The situation is reversed on the sweep side, where there will be a higher concentration of B on membrane surface II, as there is a surplus of sweep ion B in solution. That is to say,  $q_{B,II}$  is much higher than  $q_{A,II}$ . The concentration  $q$  is always less than or equal to the ion-exchange capacity  $Q$  of the membrane. The sum total of the equivalent concentration of the ionic species A and B is equal to the ion-exchange capacity of the membrane, which is defined as the number of ionogenic groups per specified amount of the ion exchanger. For the present case, it is the total number of exchangeable cations per unit volume of the membrane. Exchange capacity determination is discussed in detail, later in this chapter.

The DMP is represented in Figure 34.2a. It can be seen from this figure that the ionic transport is initiated by a concentration gradient across the membrane. It can also be inferred from this figure that the transport process is one of coupled transport, where the movement of feed ion A from the membrane surface in cell I to the membrane surface in cell II is compensated for in the other direction by the sweep ion B. For any amount of ion A transferred to cell II, an equivalent amount of ion B is transferred to cell I, so that the electroneutrality of each solution is maintained. This leads to a change in the fractional concentration of individual species in both cell I and cell II. The resultant change in the membrane phase is a drop in

**FIGURE 34.2** (a) Instantaneous ion concentration in the liquid phase and within the membrane under intramembrane transport limited conditions. Note that despite an apparent discontinuity in the concentration of ions at the solution–membrane interface, the chemical potential remains the same in the two phases due to instantaneous equilibrium. (b) Ion concentration at Donnan equilibrium in the liquid phase and within the membrane under intramembrane transport limited conditions. Note that despite an apparent discontinuity in the concentration of ions at the solution–membrane interface, the chemical potential remains the same in the two phases due to instantaneous equilibrium.

$q_{A,I}$  and  $q_{B,II}$  concentration and a simultaneous rise in  $q_{A,II}$  and  $q_{B,I}$  concentration. This leads to a decrease in the gradient. At conditions of Donnan equilibrium,  $q_{A,I} = q_{A,II}$  and  $q_{B,I} = q_{B,II}$ . This situation is represented in Figure 34.2b. The concentration gradient for each ion (A and B) is zero at equilibrium. In addition, species A is concentrated several times over on the sweep side of the Donnan membrane cell at Donnan equilibrium.

### 34.2.3 DONNAN EQUILIBRIUM CONDITION

The conditions of Donnan equilibrium derived in Equation 34.6 can be understood in a slightly different way. For the coupled transport described previously, the heterogeneous exchange of cation A in the aqueous phase and cation B in the membrane phase is represented by the following equation:

The species in the membrane phase have been shown by a bar sign.

The thermodynamic equilibrium  $\hat{K}_B^A$  [27] for this equation can be written as:

$$\hat{K}_B^A = \frac{\bar{a}_A^{z_B} a_B^{z_A}}{a_A^{z_B} \bar{a}_B^{z_A}} \tag{34.8}$$

where  $a$  refers to the activity of the species. For cell I and cell II of the Donnan membrane setup, in contact with the two different surfaces of the membrane, it can be said that

$$\hat{K}_B^A = \frac{\bar{a}_{A,I}^{z_B} a_{B,I}^{z_A}}{a_{A,I}^{z_B} \bar{a}_{B,I}^{z_A}} = \frac{\bar{a}_{A,II}^{z_B} a_{B,II}^{z_A}}{a_{A,II}^{z_B} \bar{a}_{B,II}^{z_A}} \tag{34.9}$$

When the system is in equilibrium, the activity of A and B will be uniform throughout the membrane and there will be no flux. This implies the following:

$$\bar{a}_{A,I} = \bar{a}_{A,II} \tag{34.10}$$

$$\bar{a}_{B,I} = \bar{a}_{B,II} \tag{34.11}$$

Therefore, Equation 34.9 now becomes

$$\frac{a_{B,I}^{z_A}}{a_{A,I}^{z_B}} = \frac{a_{B,II}^{z_A}}{a_{A,II}^{z_B}} \tag{34.12}$$

Since both sides have high electrolyte strength, the activity coefficient term can be assumed identical for a given species in the two solutions, in accordance with the correlation based on modified Debye-Huckel theory proposed by Davies [28]. Therefore, the concentration term can replace the activity coefficient term and the condition for Donnan equilibrium becomes

$$\left(\frac{C_{A,II}}{C_{A,I}}\right)^{z_B} = \left(\frac{C_{B,II}}{C_{B,I}}\right)^{z_A} \quad (34.13)$$

This equation is the same as the one derived in Equation 34.6. It is also worthwhile to point out that for the purpose of our study; the thermodynamic coefficient has been equated to selectivity coefficient, which strictly speaking, takes into account the concentration term of each species and not the activity term. Pellicer et al. [29] have observed in their experimentation that for strong-acid fixed-charge group membranes, the ratio of activity coefficient in the membrane and the aqueous phase approaches unity for strong-acid fixed-charge groups of membranes and for high-ionic strength external solutions. It can therefore be assumed that for the present work, which includes sulfonic acid functional group membranes, the activity coefficient values in both the membrane and the aqueous phase will be close to each other and will cancel out. Therefore, it is assumed that the thermodynamic equilibrium constant can be equated to the selectivity coefficient. Equation 34.8 can therefore be rewritten as

$$K_B^A = \frac{q_A^{z_B} C_B^{z_A}}{C_A^{z_B} q_B^{z_A}} \quad (34.14a)$$

The selectivity coefficient alone will be used throughout this chapter. For the current work, the ions of interest are feed ions ( $Al^{3+}$ ) and sweep ions ( $H^+$ ) and the selectivity of  $Al^{3+}$  with respect to  $H^+$  is defined as

$$K_H^{Al} = \frac{q_{Al}^{z_H} C_H^{z_{Al}}}{C_{Al}^{z_H} q_H^{z_{Al}}} \quad (34.14b)$$

#### 34.2.4 KINETICS OF THE DONNAN MEMBRANE PROCESS

The DMP is an electrochemical-driven process and the driving force is an electrochemical potential gradient that exhibits itself as a passive gradient across the membrane. The coupled transport has been discussed using the Nernst–Planck equation [30]. The DMP involves ion exchange, in which the fluxes of the two species are coupled with one another. The most important feature that distinguishes ion exchange from isotopic exchange is the electric coupling of the ionic fluxes. For conservation of electroneutrality, the fluxes of the exchanging counter ions must be equal in magnitude, since otherwise a net transfer of electric charge would result. The regulating mechanism, which enforces the equality of the fluxes, is the electric field (diffusion potential) set up by the diffusion process. The faster counter ion tends to diffuse at a higher rate. However, any excess charge transfer by the faster ion builds up a space charge, which slows down the faster ion and accelerates the slower ion, and electroneutrality is preserved. These considerations are included in the Nernst–Planck equation. Thus, for any ionic species  $i$ , the flux can be described by the following set of equations:

$$J_{\text{electrical}} = -\left(\frac{\bar{D}_i F}{RT}\right) (z_i) \left(C_i \frac{\partial \phi}{\partial x}\right) \quad (34.15a)$$

$$J_{\text{diffusional}} = -D_i \left(\frac{\partial C_i}{\partial x}\right) \quad (34.15b)$$

$$J_{\text{net}} = J_{\text{electrical}} + J_{\text{diffusional}} \quad (34.15c)$$

The resulting net flux of the species is known as the Nernst–Planck equation, and it holds in ideal systems, for all mobile species present. The set of Nernst–Planck equations must be solved under the appropriate conditions. In derivation of the Nernst–Planck equation, convection and gradients of pressure and activity coefficients are not included.

#### 34.2.5 TRANSPORT EQUATIONS

The fundamental conditions for coupled transport have been discussed in several papers [31,32]. The Nernst–Planck equation can now be applied to the ionic species  $A^{z_A}$  and  $B^{z_B}$ . This flux can be described by a contribution of driving forces:

$$J_A = -\bar{D}_A \left( \frac{\partial q_A}{\partial x} + z_A \right) (q_A) \left( \frac{F}{RT} \right) \left( \frac{\partial \phi}{\partial x} \right) \quad (34.16a)$$

$$J_B = -\bar{D}_B \left( \frac{\partial q_B}{\partial x} + z_B \right) (q_B) \left( \frac{F}{RT} \right) \left( \frac{\partial \phi}{\partial x} \right) \quad (34.16b)$$

where

$J$  and  $q$  are the flux and the concentration of ions in the ion-exchange membrane, respectively  
 $F$ ,  $R$ ,  $T$ , and  $\phi$  are Faraday's constant, gas constant, temperature, and electrical potential, respectively  
 $x$  is the distance in the membrane, perpendicular to the plane of the membrane surface  
 $\bar{D}$  is the self-diffusion coefficient of the diffusing ions

As a special case, when the ions of interest are  $Al^{3+}$  and  $H^+$ , these equations become

$$J_{Al} = -\bar{D}_{Al} \left( \frac{\partial q_{Al}}{\partial x} + z_{Al} \right) (q_{Al}) \left( \frac{F}{RT} \right) \left( \frac{\partial \phi}{\partial x} \right) \quad (34.16c)$$

$$J_H = -\bar{D}_H \left( \frac{\partial q_H}{\partial x} + z_H \right) (q_H) \left( \frac{F}{RT} \right) \left( \frac{\partial \phi}{\partial x} \right) \quad (34.16d)$$

where Al and H refer to  $Al^{3+}$  and  $H^+$  ions.

By the principle of electroneutrality, the concentration of all counter ions is equal to those of fixed ions, namely the exchange capacity ( $Q$ ) throughout the membrane including its two surfaces, as represented by Equation 34.17:

$$z_A q_A + z_B q_B = Q \quad (34.17a)$$

For the case of  $Al^{3+}-H^+$  coupled transport, this translates to

$$z_H q_H + z_{Al} q_{Al} = Q \quad (34.17b)$$

where

$z$  refers to the charge on the ion  
 $Q$  is the exchange capacity of the membrane

Because of the condition of zero current, the sum of the flux of feed ions  $J_A$  and that of the driving ions  $J_B$  is zero:

$$z_A J_A + z_B J_B = 0 \quad (34.18a)$$

For the  $Al^{3+}-H^+$  system, this is represented as

$$z_H J_H + z_{Al} J_{Al} = 0 \quad (34.18b)$$

Using Equations 34.16 through 34.18, the transfer of feed ion A can be described by

$$J_A = -\bar{D}_A \bar{D}_B \left( \frac{z_A^2 q_A + z_B^2 q_B}{z_A^2 q_A \bar{D}_A + z_B^2 q_B \bar{D}_B} \right) \frac{\partial q_A}{\partial x} \quad (34.19a)$$

which for the case of  $Al^{3+}-H^+$  pair is given by

$$J_{Al} = -\bar{D}_H \bar{D}_{Al} \left( \frac{z_H^2 q_H + z_{Al}^2 q_{Al}}{z_H^2 q_H \bar{D}_H + z_{Al}^2 q_{Al} \bar{D}_{Al}} \right) \frac{\partial q_{Al}}{\partial x} \quad (34.19b)$$

Diffusion processes are often described by Fick's first law [33]. For coupled transport, Fick's law can be written as

$$J_A = -\bar{D}_{A,B} \left( \frac{\partial q_A}{\partial x} \right) \quad (34.20a)$$

which describes the coupled interdiffusion of A and B in terms of one diffusion coefficient:

$$\bar{D}_{A,B} = \bar{D}_A \bar{D}_B \left( \frac{z_A^2 q_A + z_B^2 q_B}{z_A^2 q_A \bar{D}_A + z_B^2 q_B \bar{D}_B} \right) \quad (34.20b)$$

This “interdiffusion coefficient” parameter  $\bar{D}_{A,B}$  for the  $Al^{3+}-H^+$  ion pair system can be represented as

$$\bar{D}_{Al,H} = \bar{D}_{Al} \bar{D}_H \left( \frac{z_H^2 q_H + z_{Al}^2 q_{Al}}{z_H^2 q_H \bar{D}_H + z_{Al}^2 q_{Al} \bar{D}_{Al}} \right) \quad (34.20c)$$

Another important point in this mathematical treatment is that the total equivalent strength of the feed and the sweep solution remains conserved in the transfer, as shown

$$z_A C_{A,I} + z_B C_{B,I} = C_{T,I} \quad (34.21a)$$

$$z_A C_{A,II} + z_B C_{B,II} = C_{T,II} \quad (34.21b)$$

where  $C_T$  refers to the total equivalent strength of solution expressed in moles per cubic millimeter.

Once again, the equation can be extended to the  $Al^{3+}-H^+$  ion pair as follows:

$$z_{Al} C_{Al,I} + z_{H,I} C_{H,I} = C_{T,I} \quad (34.21c)$$

$$z_{Al} C_{Al,II} + z_{H,II} C_{H,II} = C_{T,II} \quad (34.21d)$$

Another important term in this discussion is the equivalent ionic fraction of  $Al^{3+}$  which can be written as

$$x_{Al} = \frac{z_{Al} C_{Al}}{C_T} \quad (34.22a)$$

$$y_{Al} = \frac{z_{Al} q_{Al}}{Q} \quad (34.22b)$$

They will be different in cell I and cell II. Equation 34.14b, used to define the selectivity coefficient, can now be rewritten in terms of the equivalent ionic fraction as follows:

$$K_H^{Al} = \left[ \frac{y_{Al}^{z_H}}{(1 - y_{Al})^{z_{Al}}} \right] \left[ \frac{(1 - x_{Al})^{z_{Al}}}{x_{Al}^{z_H}} \right] \left[ \frac{C_T^{(z_{Al} - z_H)}}{Q^{(z_{Al} - z_H)}} \right] \quad (34.23)$$

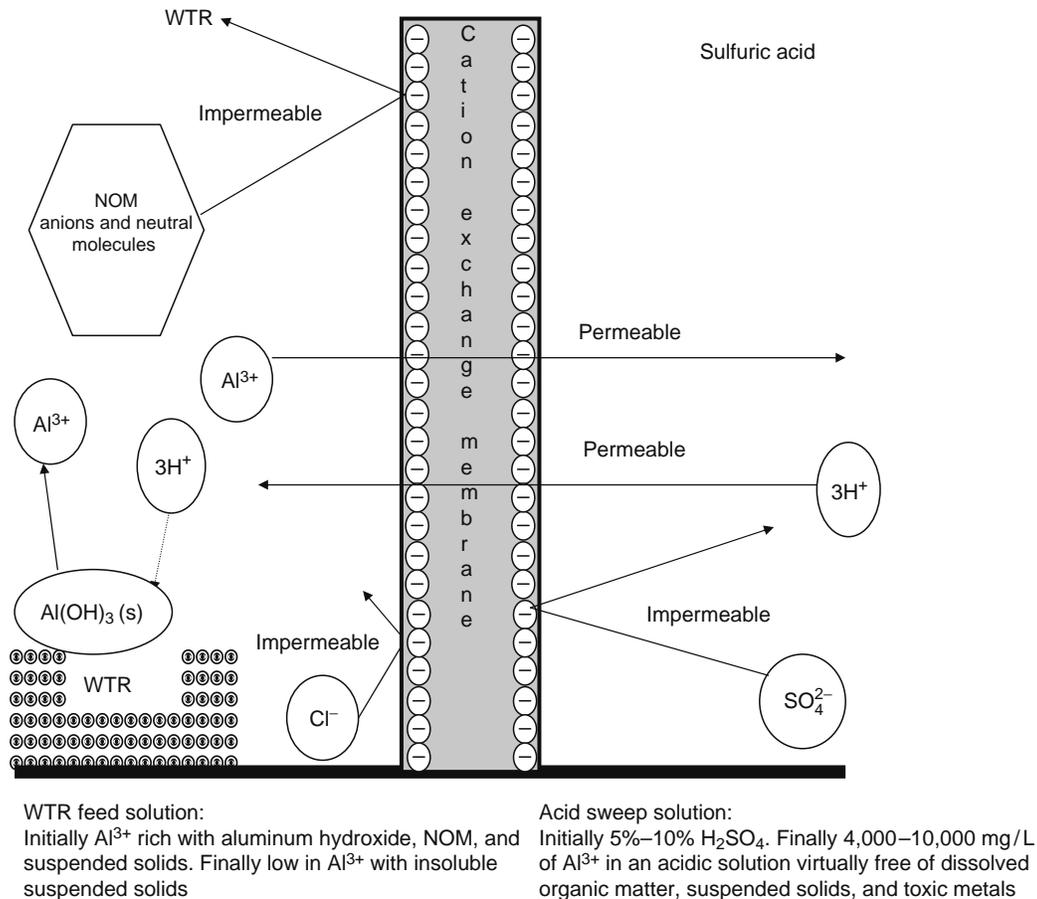

### 34.2.6 DONNAN MEMBRANE PROCESS: ASSUMPTIONS

The following assumptions have been made in the DMP treatment:

1. Diffusional resistance under experiment conditions lies entirely in the membrane phase i.e., intramembrane solute transport is the rate-limiting step [34].
2. Amount of co-ions (anions) in the membrane is negligibly small compared to its ion-exchange capacity. i.e., Donnan co-ion exclusion principle is valid.
3. Local equilibrium is assumed at the membrane–water interface.
4. Due to equilibrium conditions at the interface, the electrochemical potential of the electrolyte solution is the same as that of the membrane surface contacting it.
5. Amount of ions in the membrane is negligible compared to the amount in the solution.

### 34.2.7 FUNDAMENTALS OF ALUM RECOVERY

The alum recovery process can be conceptualized as in Figure 34.3. Initially, some amount of acid is added to the WTR, to dissolve a portion of the residuals in the aqueous phase and to release  $Al^{3+}$  ions from the solid phase. The resulting solution

**FIGURE 34.3** Schematic of the DMP illustrating the underlying principles.

constitutes the feed side of the membrane. The sweep side consists of sulfuric or hydrochloric acid (HCl), which supplies hydrogen ions for counter transport. The salient features of the process, as can be seen from this figure are

- $\text{H}_2\text{SO}_4$  or HCl sweep solution allows both dissolution of  $\text{Al}(\text{OH})_3(\text{s})$  and selective  $\text{Al}^{3+}$  recovery through the semipermeable cation-exchange membrane. No pressure differential is required across the membrane.
- Anions (chloride, sulfate, and dissolved organic molecules) cannot permeate through the membrane, and therefore their concentrations on each side remain practically unchanged. The cation-exchange membrane also rejects large-sized neutral organic molecules.
- Process does not have any moving parts and is, therefore, operationally simple. The cation-exchange membranes are chemically stable over the entire range of pH and mechanically strong.
- Since pressure is not the driving force in this process, a high concentration of solids in WTR does not foul the membrane or affect its performance.

The only expendable chemical used in the DMP is  $\text{H}_2\text{SO}_4$  or HCl. It is hypothesized that the application of this process in plants would be beneficial in

- Concentrating aluminum ions in the recovered solution
- Achieving near-complete rejection of NOM or DOC
- Reducing carryover of heavy metals such as copper, zinc, etc., into the recovered alum by offering greater transport to trivalent aluminum ions over these bivalent ions
- Reusing recovered alum as a coagulant in the same plant without the possibility of THM formation upon chlorination
- Reducing the volume of the residuals and the cost of its disposal

A practical application of this process could be in setting up a counter-current flow of acidified water treatment residual feed against an acid sweep solution through a stack of cation-exchange membranes. The process schematic is shown in Figure 34.4 [35].

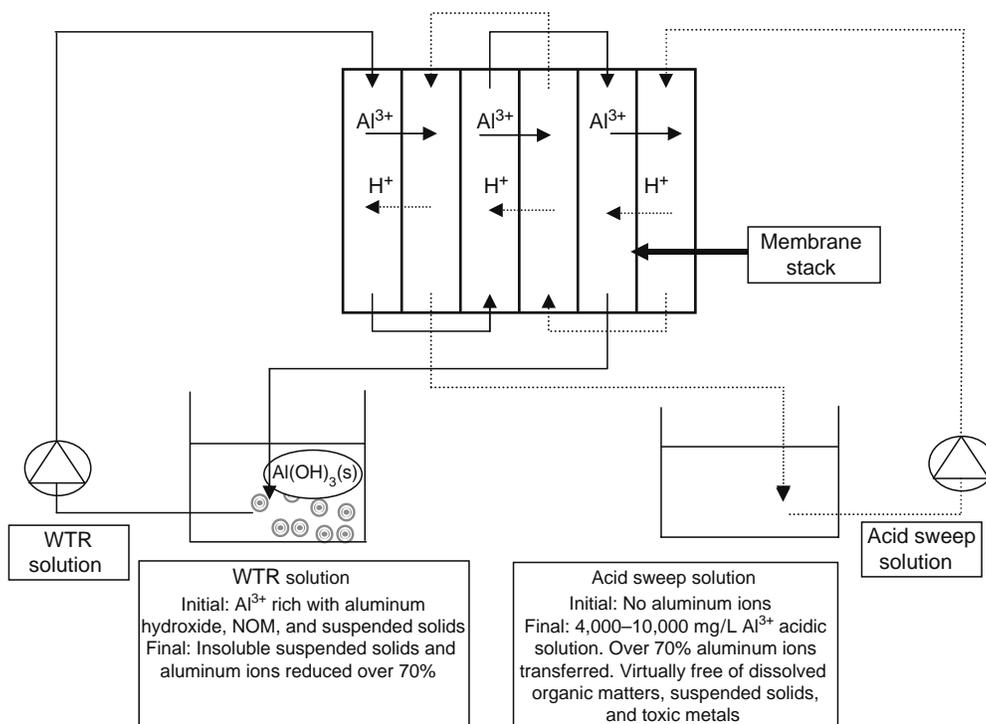

FIGURE 34.4 Process flow diagram for a DMP unit.

### 34.2.8 SOLVED EXAMPLE FOR DMP APPLICATION

Consider a situation with the following initial conditions:

$$\begin{aligned} \text{Cell I volume: } & 6 \text{ L} \\ \text{Cell II volume: } & 2 \text{ L} \\ C_{\text{H},\text{I}}: & 0.001 \text{ M} \\ C_{\text{Al},\text{I}}: & 0.074 \text{ M} \\ C_{\text{H},\text{II}}: & 2.000 \text{ M} \\ C_{\text{Al},\text{II}}: & 0.000 \text{ M} \end{aligned}$$

If  $m$  moles of  $\text{Al}^{3+}$  were transferred from cell I to cell II until Donnan equilibrium was achieved, it would mean that  $3m$  moles of  $\text{H}^+$  would be transferred from cell II to cell I, as the number of equivalents will be preserved in both the cells to maintain zero current conditions. This transfer would satisfy the conditions of Equation 34.5. Substituting for the valence term in this equation,  $m$  can be calculated. It would lead to the following values at equilibrium:

$$\begin{aligned} C_{\text{H},\text{I}}: & 0.221 \text{ M} \\ C_{\text{Al},\text{I}}: & 0.001 \text{ M} \\ C_{\text{H},\text{II}}: & 1.343 \text{ M} \\ C_{\text{Al},\text{II}}: & 0.219 \text{ M} \end{aligned}$$

From this example, it can be concluded that over 98% of  $\text{Al}^{3+}$  ions are recovered in the sweep solution and the sweep-to-feed concentration ratio  $C_{\text{Al},\text{II}}/C_{\text{Al},\text{I}}$  equal to 220 suggests that the recovered ion is also concentrated.

### 34.2.9 STEPWISE MODELING PROTOCOL

Experimental results from our previous studies [26] demonstrated that the diffusional resistance in the liquid phase is negligible under representative experimental conditions and intramembrane transport is the rate-limiting step for the alum recovery process. The following provides a stepwise protocol for the determination of self-diffusion coefficient values and the alum recovery rate for the DMP.

*Step 1: Ion-exchange capacity and  $Al^{3+}/H^+$  isotherm data*

The ion-exchange capacity of the membranes is determined using the standard protocols [36]. Equilibrium data for equivalent ionic fractions of  $Al^{3+}$  and  $H^+$  in the aqueous phase and the corresponding fraction in the membrane phase are then experimentally determined for a given total ionic concentration  $C_T$  expressed in eq/m<sup>3</sup>. Average selectivity value is subsequently generated using Equation 34.14b.

*Step 2: Determination of aluminum flux*

A 24 h experiment (Run 1) is performed for a given feed and sweep solution to generate concentration values of  $Al^{3+}$  in the two solutions at different times. From these concentration values, the average flux data between time  $t_1$  and  $t_2$  can be generated using the following equation:

$$J_{Al} = \frac{(C_{Al,sweep,t_2} - C_{Al,sweep,t_1})V_{sweep}}{(t_2 - t_1)A} \quad (34.24)$$

where

$A$  is the membrane area of exchange

$V_{sweep}$  is the volume of sweep solution

*Step 3: Determination of interdiffusion coefficient*

Once the flux data are available, the average interdiffusion coefficient during that time is given by Equation 34.25 as

$$J_{Al} = -\bar{D}_{Al,H} \left( \frac{q_{Al,I} - q_{Al,II}}{L} \right) \quad (34.25)$$

Local equilibrium is assumed at the membrane–water interface. Thus,  $q_{Al}$  values at both the feed surface ( $q_{Al,I}$ ) and the sweep surface ( $q_{Al,II}$ ) can be computed using the computed average selectivity coefficient value in Step 1 and the known aqueous phase compositions from Step 2. Since  $J_{Al}$ ,  $q_{Al,I}$ ,  $q_{Al,II}$ , and the membrane thickness  $L$  are known, the interdiffusion coefficient  $\bar{D}_{Al,H}$  can be calculated. Note that  $\bar{D}_{Al,H}$  is not constant and it changes with time with the change in membrane composition.

*Step 4: Determination of membrane phase self-diffusion coefficient values*

Equation 34.20c can be arranged as follows:

$$\frac{1}{\bar{D}_{Al,H}} = \frac{1}{\bar{D}_{Al}} + \frac{\bar{D}_{Al} - \bar{D}_H}{\bar{D}_H \bar{D}_{Al}} \left[ \frac{1}{1 + \left( \frac{z_H^2}{z_{Al}^2} \right) \left( \frac{q_H}{q_{Al}} \right)} \right] \quad (34.26)$$

Considering  $z_H = 1$ ,  $z_{Al} = 3$ , and  $y_{Al} + y_H = 1$ , Equation 34.26 becomes

$$\frac{1}{\bar{D}_{Al,H}} = \frac{1}{\bar{D}_{Al}} + \frac{\bar{D}_{Al} - \bar{D}_H}{\bar{D}_H \bar{D}_{Al}} \left[ \frac{1}{1 + \frac{1}{9} \left( \frac{1 - y_{Al}}{y_{Al}} \right)} \right] \quad (34.27)$$

From experimental data, the values of  $\frac{1}{\bar{D}_{Al,H}}$  are plotted against  $\frac{1}{1 + \frac{1}{9} \left( \frac{1 - y_{Al}}{y_{Al}} \right)}$ . Since the membrane has a high selectivity for trivalent

aluminum ion over monovalent hydrogen ion,  $H^+$  ions are essentially the minor species within the membrane phase. The intercept of Equation 34.27 can be used to calculate  $\bar{D}_{Al}$  and it can be substituted in the expression for slope to obtain  $\bar{D}_H$ . This approach can only be applied as a first approximation, as overall interdiffusion coefficient has been used to represent the interdiffusion coefficient value on a membrane surface. This assumption is not true, since interdiffusion coefficient is a function of ionic distribution and is unique at each point across the membrane. It is hypothesized in this model that while the true value of self-diffusion coefficient  $\bar{D}_{Al}$  and  $\bar{D}_H$  needs to be calculated separately from the model, the relative deviation from the true value in the linear regression approach described in Equation 34.27 is the same for both  $Al^{3+}$  and  $H^+$ . Therefore, the ratio  $\bar{D}_{Al}/\bar{D}_H$  determined from the plot for Equation 34.27 is the same as the ratio for the true values obtained from the model.

*Step 5: Aluminum ion concentration profile*

A numerical integration technique is applied to calculate the aluminum ion concentration at intermediate times. The input parameters are (1) initial concentration of the ions in the feed and the sweep solutions,  $C_{Al,feed}$ ,  $C_{Al,sweep}$ ,  $C_{H,feed}$ , and  $C_{H,sweep}$ , (2) volume of the two solutions,  $V_{feed}$  and  $V_{sweep}$ , (3) area of exchange  $A$ , (4) self-diffusion coefficient  $\bar{D}_{Al}$  and  $\bar{D}_{Al}/\bar{D}_H$  determined from Step 4, and (5) wet membrane thickness,  $L$ . Two sets of equations are generated from the isotherm plot for

feed and sweep conditions, relating the ionic fraction of  $\text{Al}^{3+}$  in the membrane phase to that in the aqueous phase. These equations coupled with the Nernst–Planck equations discussed in the theory are applied in a model that uses  $\bar{D}_{\text{Al}}$  as an operating parameter to predict  $\text{Al}^{3+}$  concentration profile in the feed and sweep solutions.

#### Step 6: Osmosis effect

To incorporate dilution effect, a separate experiment is carried out with known concentration of NaCl on the sweep side and deionized water on the feed side of the membrane to determine the osmosis of water. Water flux is related to the difference in electrolyte strength of the two solutions and has been validated in previous studies [37]. For the current work, it can be assumed that the water flux  $\hat{J}_{\text{osmosis}}$  ( $\text{m}^3/\text{m}^2 \text{ h}$ ) is proportional to the difference of ionic concentration in the two solutions.

$$\hat{J}_{\text{osmosis}} = K_{\text{osmosis}} \Delta C \quad (34.28)$$

where

$$\Delta C = C_{\text{sweep}} - C_{\text{feed}}$$

$C$  is the summation of molar concentration of all ionic species in the given solution

$k_{\text{osmosis}}$  is the proportionality constant or the “osmosis parameter”

The value of  $k_{\text{osmosis}}$  was determined from this experiment as  $1.13 \times 10^{-7} \text{ m}^4/\text{mol h}$  and was used in the modeling program.

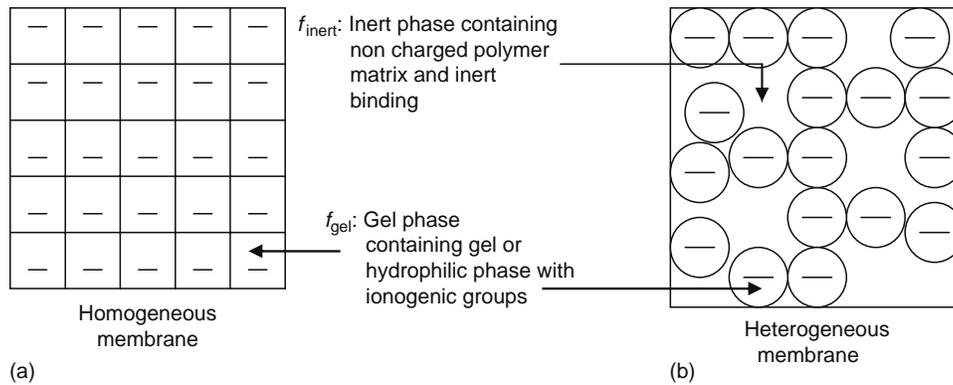

### 34.3 ROLE OF MEMBRANE STRUCTURE

An investigation into the transport of exchanging ions in the DMP application for alum recovery should consider the structure of the membrane, as the transport of ions is related to the resistance offered in the membrane phase. On the basis of the structure and method of preparation, two different types of ion-exchange membranes have been identified. Homogeneous membranes are coherent ion-exchanger gels. Heterogeneous membranes consist of colloidal ion-exchanger particles embedded in an inert binder. Methods of preparing these membranes are different and are available in the open literature [38].

Several researchers have studied the influence of nonuniformity of ion-exchange membranes on various transport properties of membranes such as electrical conductivity, transport numbers, and diffusion permeability [39–41]. A membrane may be considered to be a system of two or more phases. Timashev [42] proposed a two-phase model with a hydrophobic backbone and a hydrophilic ion-exchange group, including sorbed water. Zabolotsky and Nikonenko [43] suggested that a membrane could be represented as a combination of a conducting phase and a nonconducting phase. The conducting phase or the gel phase comprised a relatively uniform distribution of ionogenic groups, hydrophilic parts of the matrix polymer chains, and an electroneutral solution filling the interstices between these elements in the gel phase. The nonconducting phase or the inert phase formed from the hydrophobic parts of the polymer matrix or from the inert binder introduced during the synthesis stage. It can therefore be stated that the membrane morphology is represented by two constituents or phases:

1. Conducting fraction  $f_{\text{gel}}$  that includes the conducting gel or hydrophilic phase with ionogenic groups
2. Nonconducting fraction  $f_{\text{inert}}$  that includes the nonconducting polymer matrix and inert binding without ionogenic groups

In a homogeneous membrane, the nonconducting fraction  $f_{\text{inert}}$  is much lower than in a heterogeneous membrane. Homogeneous membranes are therefore coherent ion-exchanger gels and heterogeneous membranes consist of colloidal ion-exchanger particles embedded in an inert binder. Conceptually, this information can be represented in Figure 34.5a and 34.5b. Figure 34.5a depicts the distribution of the ionogenic groups within a homogeneous membrane while Figure 34.5b represents the same inside a heterogeneous membrane. It may be noted that the nonconducting inert fraction  $f_{\text{inert}}$  is significantly greater within the heterogeneous membrane. Under nonequilibrium conditions, a diffusing cation hops from one charged site to the next within the membrane and that constitutes the primary ion transport mechanism for homogeneous membranes as illustrated in Figure 34.6a. For heterogeneous membranes, the nonconducting or inert fraction offers resistance to ion transport in the following two ways: first, tortuosity or the path length of ion transfer through the membrane is increased; and second, the stagnant inert phase with minimal or no ionogenic groups is always less conducive to transport of ions. For counter transport of aluminum and hydrogen ions in a heterogeneous membrane, Figure 34.6b illustrates the foregoing effects of the inert phase. In this study, a homogeneous cation-exchange membrane, Nafion 117 from DuPont, Delaware, and a heterogeneous membrane, Ionac MC 3470 from Sybron Chemicals, New Jersey, were used. A series of laboratory experiments were carried out to compare the alum recovery from WTR using these two membranes.

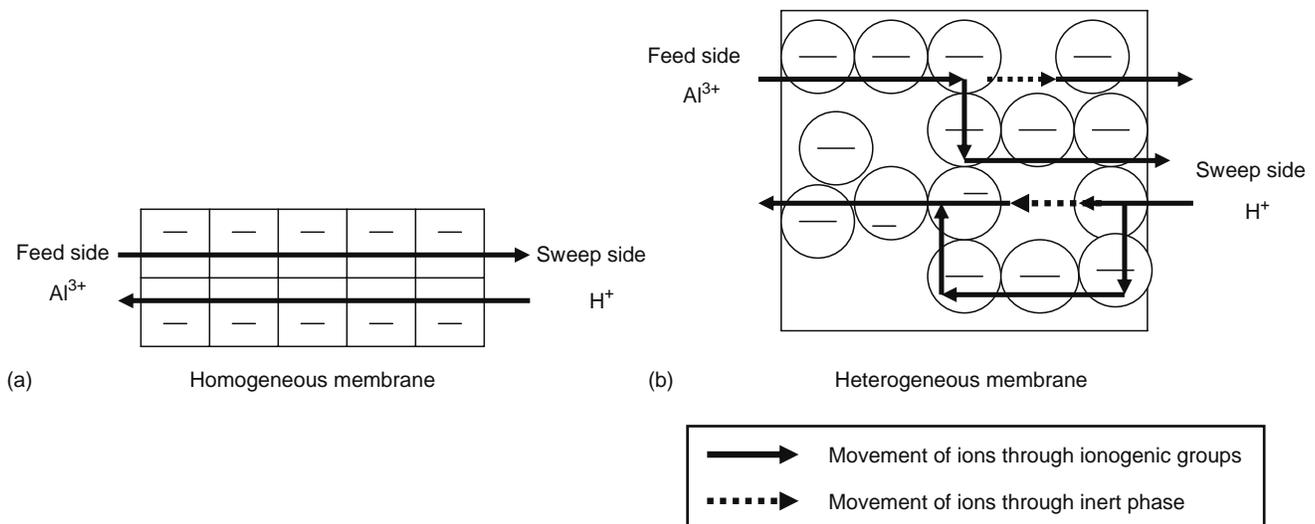

**FIGURE 34.5** Conceptualized distribution of ionogenic groups within cation-exchange membranes for (a) homogeneous membrane and (b) heterogeneous membrane.

#### 34.4 DIFFUSION DIALYSIS: RAISING pH OF RESIDUAL WTR

The residual feed, low in  $\text{Al}^{3+}$  content, has a low pH. Its pH needs to be raised before the residuals are discharged. While an obvious solution is to add lime to raise the pH, in the current research work, a novel application of another membrane process, diffusion dialysis, was tried. Diffusion dialysis has been applied earlier to recover spent acid [23,24]. It was first applied during the 1950–1960s [44–46]. In this process, an anion-exchange membrane separates an acid-rich solution from an acid-deficient solution. The anion-exchange membrane is impermeable to all cations except  $\text{H}^+$  ions. They leak through the membrane as neutral acid molecules under the influence of a chemical potential gradient. It is hypothesized that if diffusion dialysis process is applied in a process in which posttreatment residual feed is separated from fresh WTR solution using anion-exchange membranes, the acid molecules will leak from the residual feed side to the fresh feed side. In the process, the pH of the residual feed will rise and the fresh feed pH will drop, thereby dissolving aluminum ions locked up in the solid phase. Operationally, this process is similar to the DMP shown in Figure 34.5, except that a stack of anion-exchange membranes replaces the cation-exchange membranes and the transport process entails movement of neutral acid molecules from residual feed solution (emerging from a recently completed DMP) to a solution of fresh feed, which is later treated in the DMP. The two processes can be combined together conceptually, as shown in Figure 34.7.

Diffusion dialysis relies on the difference in chemical potential of species on either side of a membrane and external power is only required to circulate the solutions. The separation of acid from its electrolyte solution is achieved by using an anion-exchange membrane. The membrane allows the selective transport of anions across the membrane, while ideally remaining impermeable to cations other than protons. Proton leakage takes place due to its high mobility. This migration takes place by both diffusion and by transfer from a water molecule to another through a mechanism referred to as the Grotthius mechanism [47]. The goal of the diffusion dialysis process is to raise the pH of the residual feed before its disposal and to simultaneously

**FIGURE 34.6** Counter transport of (a)  $\text{Al}^{3+}$  and (b)  $\text{H}^+$  through homogeneous and heterogeneous membranes.

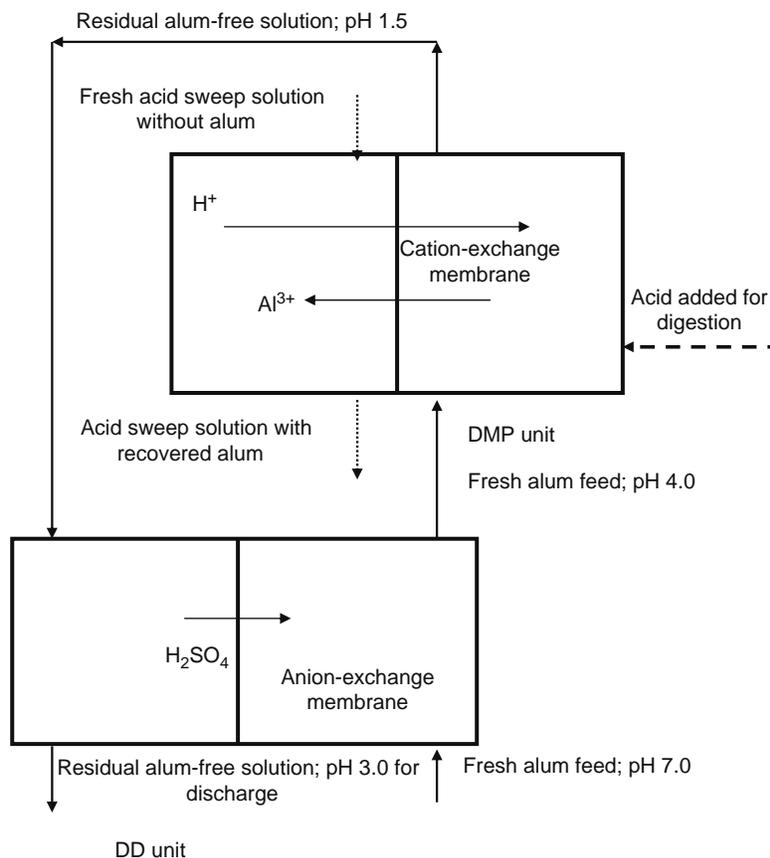

FIGURE 34.7 Integrated process comprising a DMP unit and a diffusion dialysis unit.

dissolve  $Al^{3+}$  ions in the fresh feed. This implies that the acid should diffuse fast enough through the anion-exchange membrane. The kinetics of the process plays an important role. It therefore depends on the choice of the acid used in the diffusion dialysis process and the choice of membrane. Some acids tend to diffuse faster than others and some membranes offer lower resistance to the diffusion process. A parameter often employed to determine the transfer kinetics is the dialysis coefficient,  $U$ .

### 34.4.1 DIFFUSION DIALYSIS COEFFICIENT

The dialysis coefficient  $U$  for a given component in solution in diffusion dialysis cell is given by the amount of the component that is transported per unit active membrane area, per unit time, and per unit concentration difference of the component. This translates into the following equation:

$$U = \frac{W}{(AtM)} \tag{34.29a}$$

where

- $W$  is the amount of the component transported in moles
- $A$  is the active membrane area in square meters
- $t$  is the time in hours

For specific acids, it can be expressed as

$$U_{H_2SO_4} = \frac{W_{H_2SO_4}}{(AtM_{H_2SO_4})} \tag{34.29b}$$

$$U_{\text{HCl}} = \frac{W_{\text{HCl}}}{(AtM_{\text{HCl}})} \quad (34.29c)$$

where  $M$  is the log-mean concentration difference expressed as

$$M = \frac{(C_{f,0} - C_{p,t} - C_{f,t})}{\ln\left(\frac{C_{f,0} - C_{p,t}}{C_{f,t}}\right)} \quad (34.29d)$$

where

$C_{f,0}$  is the concentration of the feed solution at time 0

$C_{p,t}$  is the concentration of the permeate solution at time  $t$

$C_{f,t}$  is the concentration of the feed solution at time  $t$  [48]

The numerator term is not equal to zero because of volume changes that occur in cell chambers caused by water transport across the membrane during the experiment. The selectivity of the membrane for one acid over another can be described as

$$K_{\text{HCl}}^{\text{H}_2\text{SO}_4} = \frac{U_{\text{H}_2\text{SO}_4}}{U_{\text{HCl}}} \quad (34.30)$$

Knowledge of the selectivity and diffusion dialysis coefficient can be used to determine the membrane that offers lower resistance to acid diffusion. It also helps in determining the faster-diffusing acid.

## 34.5 MATERIALS AND METHODS

### 34.5.1 FEED AND RECOVERY SOLUTIONS

The feed consisted of WTR collected from the Allentown Water Treatment Plant (AWTP) (Allentown, Pennsylvania) and the Baxter Plant (Philadelphia, Pennsylvania). The former uses alum as a coagulant and the latter applies ferric chloride in the coagulation process. Total suspended solids content of the WTR obtained from the AWTP varied between 2% and 4% mass per volume. In some experiments, synthetic feed solutions were prepared using aluminum sulfate (Fisher Scientific, Bethlehem, Pennsylvania) and ferric chloride (Sigma Chemicals, Bethlehem, Pennsylvania). The recovery side solution consisted of 10% (2N)  $\text{H}_2\text{SO}_4$  purchased from E M Science, Bethlehem, Pennsylvania. To investigate the effect of turbidity on solute flux and membrane fouling, fine (<200 mesh size) inert glass powder (Potters Industries, Valley Forge, Pennsylvania, Product number: 6000) was used as the source of turbidity.

### 34.5.2 DONNAN MEMBRANE CELL

The Donnan membrane cell was made of Plexiglas, partitioned into two chambers, as shown in Figure 34.8 with dimensions  $L = 30$  cm,  $W = 7$  cm, and  $H = 40$  cm. Fixed volumes of feed (WTR) and recovery (acid) solutions were used for every run;

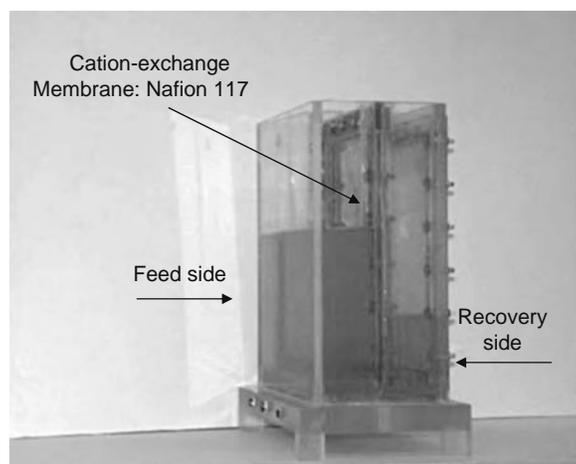

FIGURE 34.8 Laboratory setup for a variable volume Donnan membrane cell.

the ratio of WTR volume to acid volume could be adjusted independently in the test cell. Solutions in both chambers were agitated using instrument quality compressed air at 1 psi g.

### 34.5.3 EXCHANGE MEMBRANE

The cation-exchange membranes used in the experiments were the homogeneous Nafion 117 from Dupont and the heterogeneous Ionac MC 3470. Pertinent details are provided in Table 34.2. The exchange capacity data were determined in the laboratory following standard experimental protocols [31,36].

### 34.5.4 EXPERIMENTAL PROCEDURE AND ANALYTICAL TECHNIQUES

The feed was allowed to exchange aluminum ions with hydrogen ions from the recovery solution for a period of 10–72 h, depending on the objective of each experiment. Samples were collected at regular intervals from both feed and the recovery side. Aluminum was analyzed using UV-VIS spectrophotometer. This analysis involved the eriochrome cyanine R method described in Ref. [49]. Other metals such as iron, copper, magnesium, arsenic, and zinc were analyzed with an atomic absorption spectrometer (Perkin Elmer: Model AA100 and Perkin Elmer: Model SIMAA 6000). The DOC was measured using a TOC Analyzer (Dohrman: Model DC-190) and sulfate ions were analyzed for Donnan exclusion using a dionex ion chromatograph (Model 4500i).

### 34.5.5 JAR TESTS: EVALUATION OF RECOVERED ALUM AS A COAGULANT

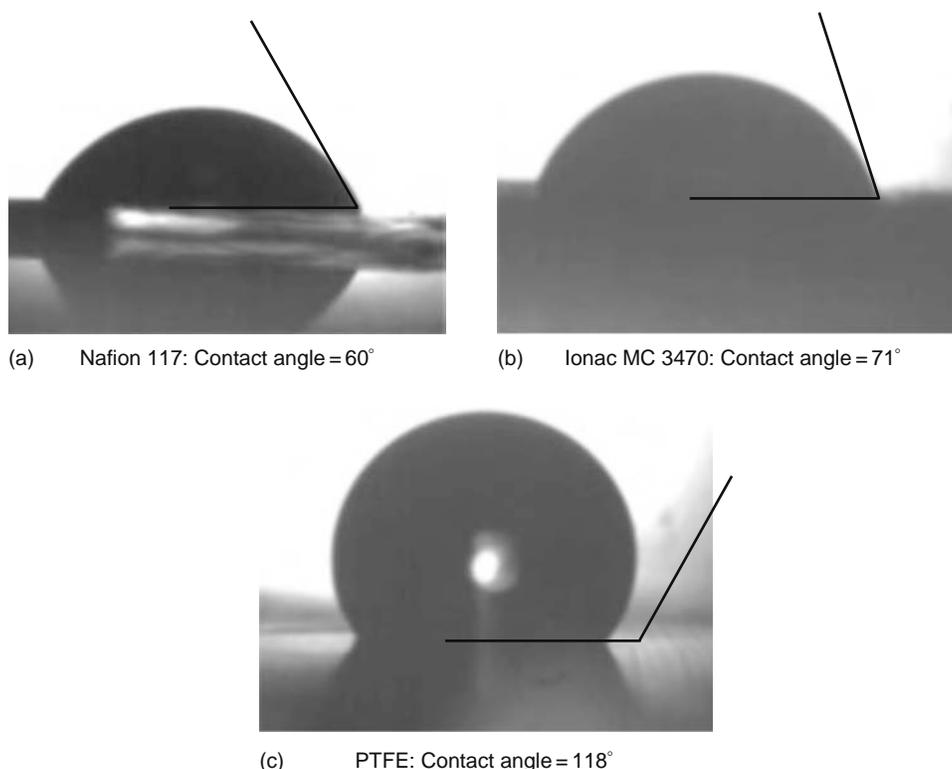

Jar tests were conducted to evaluate the coagulation efficiency of the recovered alum. For the purpose of comparison, commercial alum obtained from AWTP and mixed alum (50% recovered alum and 50% commercial alum) were employed as coagulants in jar tests. The water from the Little Lehigh River, which is the primary water source of the AWTP, was used to examine the coagulation efficiency of recovered alum. During the jar tests, predetermined doses (for a typical water treatment plant) were added into beakers, which contained 1.0 L of the AWTP water. After stirring and subsequent settling, samples of water were collected from the top (within 2 in. from the surface) of every beaker and analyzed.

### 34.5.6 HYDROPHILICITY OF MEMBRANES

Experiments were performed to measure the hydrophilicity of the membranes. For this purpose, the two membranes, Nafion 117 and Ionac MC 3470, were dipped in the WTR solution for over 48 h. Samples were viewed under a goniometer (an instrument used to measure contact angles of droplets placed on a substrate surface to indicate surface energies/wetting capabilities), to measure the contact angle of water with the membrane surface. For this purpose, a small sheet of the membrane surface was kept under observation, a drop of water added by a syringe on the surface, and the drop allowed to settle for a few minutes. The contact angle made by the drop with the surface was measured manually. The angle was compared against that for a standard hydrophobic material. For this purpose, PTFE sheet was used. Figure 34.9 shows the different contact angles for the three surfaces. It can be observed that the contact angle for Nafion 117 surface is the lowest at 60°, for Ionac MC 3470 surface it is approximately 70°, and the PTFE surface has a contact angle of approximately 120°. This result is an indication of the hydrophilic nature of the two membranes and it suggests that the cation-exchange membranes may be resistant to membrane fouling by hydrophobic NOM during the DMP.

### 34.5.7 EXCHANGE CAPACITY (Q) OF MEMBRANES

For exchange capacity determination of Nafion membranes, a 10 × 10 cm membrane was completely converted to Na<sup>+</sup> form by allowing it to exchange with 2N NaCl solution for 48 h in two consecutive experimental runs of 24 h each. The membrane was cleaned thoroughly in deionized water, dried with filter paper, and then stripped of Na<sup>+</sup> ions in two batches by exchanging with

**FIGURE 34.9** Contact angle as a measure of hydrophilicity of (a) Nafion 117, (b) Ionac MC 3470, and (c) PTFE.

$H^+$  ions in a 2N  $H_2SO_4$  solution for 48 h, as before.  $Na^+$  concentration was measured using an atomic absorption spectrometer (Perkin Elmer Model 2380). The expansion of membrane was taken into consideration in calculating the exchange capacity of the wet membrane. For Ionac MC 3470, the exchange capacity was determined the same way, keeping in mind that the membrane was originally in the  $Na^+$  form and that it needed just one stripping step to get the  $Na^+$  ions in solution. The expansion in aqueous phase was taken into account in this case too.

### 34.5.8 ISOTHERM PLOT GENERATION

The membrane was converted to the  $H^+$  form and dipped in an  $Al^{3+}-H^+$  electrolyte solution of known strength  $C_T$  and the solution was stirred for 24 h to attain equilibrium. Aluminum ion uptake by the membrane was determined by mass balance. Several sets of such equilibrium experiments were carried out using different masses/areas of both Nafion 117 and Ionac MC 3470. From these experiments, it was possible to determine  $y_{Al}$ . Four values of  $x_{Al}$  were selected and the experiment was run for different  $C_T$  values such as 50, 1000, and 2000 meq/L (or eq/m<sup>3</sup>) in case of Nafion 117. For Ionac MC 3470, the same was carried out with the  $C_T$  value of 50 meq/L.

### 34.5.9 SEM-XRF ANALYSIS AND ANALYTICAL TECHNIQUE

A  $\frac{1}{2}$ " by  $\frac{1}{2}$ " square piece of the two membranes was taken and converted to the  $Na^+$  form. Since the Sybron membranes are available in the  $Na^+$  form, they were treated "as received". For Nafion 117, the membrane was converted to the  $Na^+$  form. For this purpose, the membrane was dipped in 2% NaOH solution (for 30 min, stir) followed by DI water wash (or soak), and then rinsed. The process was repeated three times with "fresh" NaOH. For each treatment step 200 ml of 2% NaOH was used. Once the membrane was converted to the  $Na^+$  form, it was dried, a cross-section of the sample taken, and mounted for scanning electron microscopy (SEM). A dot-map of  $Na^+$  was performed using x-ray fluorescence (XRF). The sample was taken from the sample's center to eliminate edge effect. The Sybron membrane was also soaked in DI water, and after hydration the membrane was air dried before preparing a cross-section sample for analysis. Aluminum ion was analyzed using UV-VIS spectrometer as before. For pH measurement, Fisher Scientific Accumet pH meter 900 was used. All experiments were conducted at ambient temperature and no significant difference in temperature was noticed between the feed and sweep samples. SEM-XRF analysis was carried out with ThermoNORAN Quest, which is a combination of SEM and XRF.

## 34.6 RESULTS AND DISCUSSION

### 34.6.1 ALUM RECOVERY FROM WTR

In the Donnan membrane cell, the feed side of the membrane contained 6.0 L of the decanted and slightly acidified WTR collected from the AWTP while the recovery side contained 1.5 L of 10% H<sub>2</sub>SO<sub>4</sub> solution. Figure 34.10 shows the results of the process for a period of 24 h; the percentage of aluminum recovery and the concentration of aluminum in the two chambers were plotted against time. It can be seen that over 70% recovery (72%) was attained in 24 h. The noteworthy observation is that the recovered aluminum concentration was 6650 mg/L as Al, and it was significantly greater than the total aluminum concentration (2400 mg/l) present in the parent sludge, as it was recovered in a volume which was four times smaller. Figure 34.11 provides a detailed composition of the recovered alum from the DMP. Besides Al(III) and Fe(III), other contaminants are present only in trace concentrations. It is noteworthy that the recovered alum did not contain any suspended solids while NOM expressed as DOC was consistently less than 5 mg/L. The ratio of individual contaminants to aluminum in the recovered alum was comparable and in some cases lower than in the commercial alum currently being used in AWTP.

### 34.6.2 DONNAN EXCLUSION AND FOULING

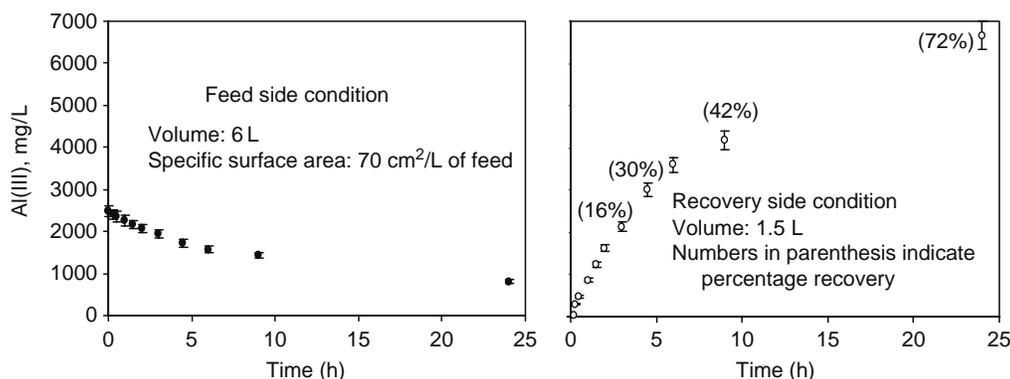

One of the primary attributes of the DMP is its ability to exclude anions, NOM, and particulate matter while recovering aluminum from the WTR without being fouled. Figure 34.12a and 34.12b shows the DOC and sulfate (SO<sub>4</sub><sup>2-</sup>) concentrations in the feed side and recovery side of Donnan membrane cell for a run that lasted 72 h. DOC is a measure of NOM in the aqueous phase, and these figures show that both DOC and sulfate remained nearly constant on both sides. DOC concentration in the recovered alum was consistently less than 5 mg/L while the same in the feed side was over 150 mg/L. Likewise, sulfate concentration was close to 2000 meq/L on the recovered solution side and about 200 meq/L on the feed side during the course of the experiment, which implied that the cation-exchange membrane disallowed permeation of NOM and sulfate from one side to the other, validating the premise of the Donnan co-ion exclusion.

Specific experiments were carried out to confirm possible fouling of membranes caused by NOM and particulate matter. During the course of this study, the same Nafion membrane was used repeatedly. The color of the membrane surface turned dark but no noticeable impairment of aluminum flux was observed even after prolonged usage. Figure 34.13 shows the results of two successive runs with a membrane already used in the laboratory for nearly three months. The same feed obtained from AWTP was used for both the runs. Figure 34.13 demonstrates that the rate of increase in aluminum concentration with time in the recovery side was slightly lower during the second run but the overall alum recovery essentially remained the same after 9 h of operation.

To investigate the effect of turbidity independently, two parallel Donnan recovery runs were carried out. During the first run, the synthetic alum feed solution was free of any turbidity while for the second run, 6000 mg/L turbidity was introduced into the feed compartment as fine glass powders with sizes in the vicinity of 1 μm. All other conditions were exactly the same for the two runs. High turbidity in the feed side did not impair the rate of alum recovery, as evidenced from the experimental results in Figure 34.14.

### 34.6.3 FE(III) RECOVERY

Ferric salts (chloride or sulfate) are also used as coagulants in water treatment plants [50], and the resulting ferric hydroxide precipitates constitute a major portion of the clarifier sludge or WTR. In principle, the DMP is capable of selectively recovering

**FIGURE 34.10** Aluminum recovery from the AWTP residuals during the DMP: decrease in Al concentration in feed, percentage recovery, and increase in Al concentration in recovery solution.

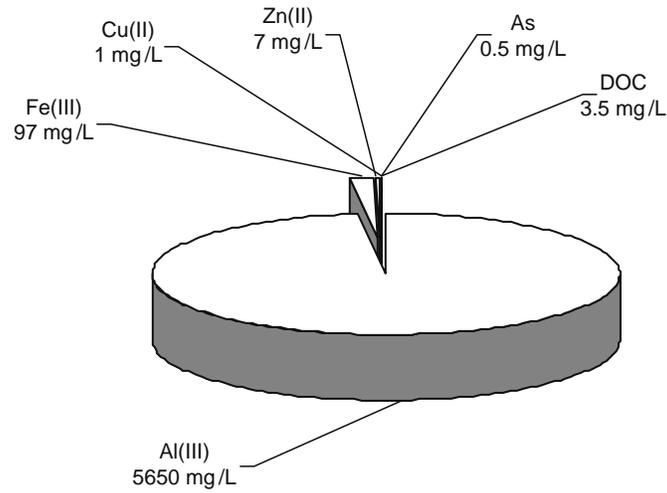

FIGURE 34.11 Composition of alum recovered from the AWTP using the DMP.

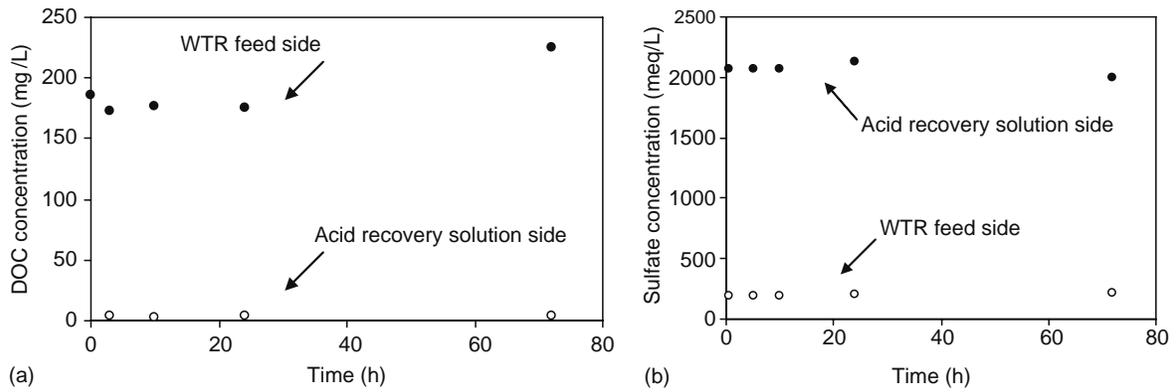

FIGURE 34.12 (a) DOC concentration in feed and recovery solution during an experimental run using the AWTP residuals and (b) sulfate concentration in feed and recovery solution during the same run.

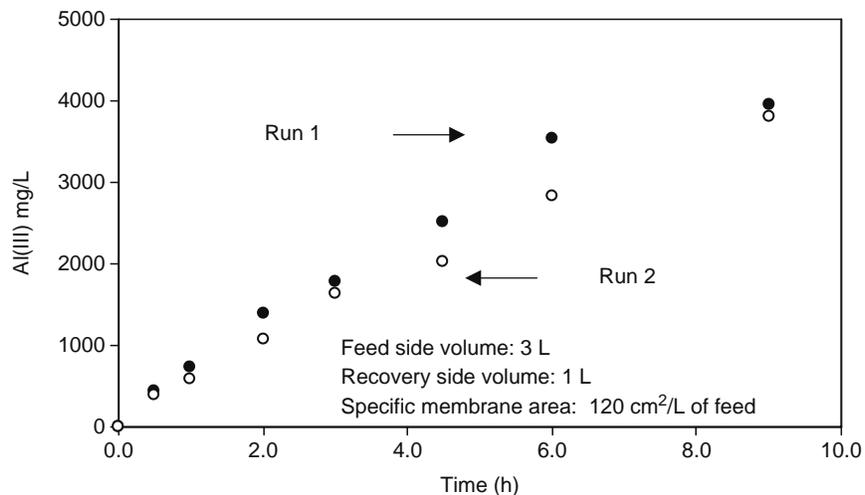

FIGURE 34.13 Aluminum recovery in two consecutive runs with WTR obtained from the AWTP.

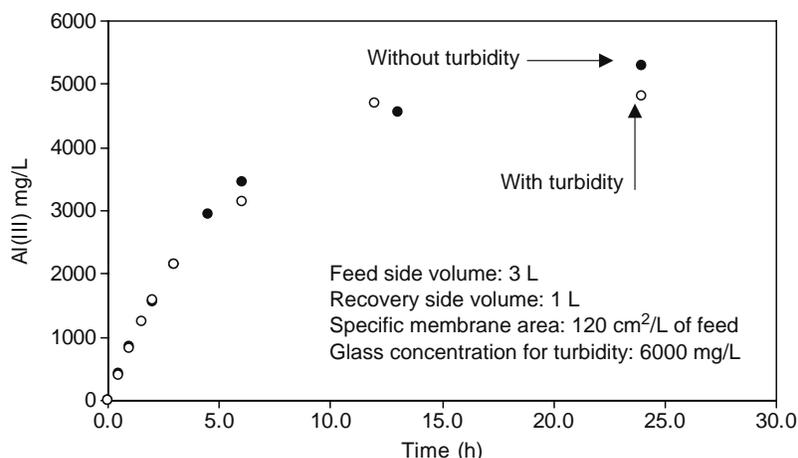

FIGURE 34.14 Influence of turbidity on removal efficiency.

Fe(III) coagulants from these WTR as well. To validate the same, the WTR from the Baxter plant (Philadelphia, Pennsylvania), which utilized FeCl<sub>3</sub> as coagulant, was used in several test runs. Figure 34.15 shows percentage Fe(III) recovery and the concentration of Fe(III) in the feed and recovery side with time. Nearly 75% recovery is attained in 24 h. The resulting Fe(III) is essentially free of NOM, particulate matter, and other impurities.

Figure 34.16a and 34.16b shows the visual comparison of recovered coagulants, both alum and ferric sulfate, between traditional acid digestion process and the DMP. Higher transparency of the coagulants from AWTP and the Baxter Plant, recovered by DMP, is readily noticeable due to the absence of turbidity and NOM. Two separate runs were carried out using synthetic solutions of aluminum sulfate and ferric chloride under otherwise identical conditions. Figure 34.17 shows that the percentage or fractional recovery of Fe(III) or Al(III) remains essentially the same i.e., the process is equally effective for concentrating any trivalent cation.

### 34.6.4 RELATIVE CARRYOVER

Besides Al(III) and Fe(III), undesirable solutes and NOM also get carried over to the recovered solution. Relative carryover ( $\eta_R$ ) of substance *i* with respect to Al is defined as the following dimensionless variable:

$$\eta_R = \left( \frac{C_R^i}{C_R^{Al}} \right) \left( \frac{C_F^{Al}}{C_F^i} \right) 100 \tag{34.31}$$

where

*C* represents concentrations

subscripts R and F denote the recovered solution and the WTR feed, respectively

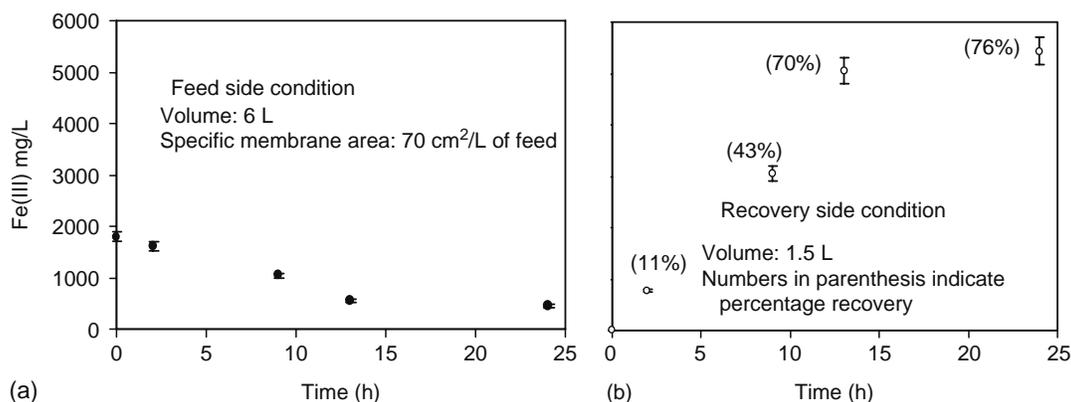

FIGURE 34.15 Ferric(III) recovery from ferric chloride-based WTR from Baxter Water Treatment Plant during DMP. (a) Decrease in Fe concentration in feed and (b) percentage recovery and increase in Fe concentration in recovery solution.

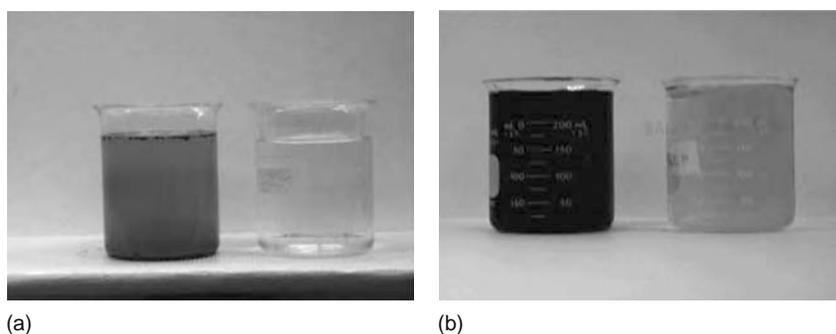

FIGURE 34.16 Visual comparison of recovered alum coagulant from the AWTP residuals by acid digestion process (a) and DMP (b).

Figure 34.18 shows the percentage relative carryover i.e.,  $\eta_R$  values of DOC, Cu(II), Zn(II), and Mg(II). It is noted that  $\eta_R$  values are nearly zero for DOC and significantly less than aluminum for all divalent cations. For conventional acid digestion process, no selective separation is achieved i.e., percentage  $\eta_R$  values of all the contaminants are essentially the same as that of Al(III).

### 34.6.5 RECOVERED ALUM AS A COAGULANT

Jar tests were conducted to evaluate the coagulation efficiency of the recovered alum. For the purpose of comparison, commercial liquid alum that is currently in use at the AWTP and mixed alum (50% recovered alum and 50% commercial alum) were employed as coagulants in the jar tests. Water from the Little Lehigh River, which is the primary raw water source of the AWTP, was used for the test. A conventional jar-test apparatus was employed in the study. Figure 34.19 is a plot of residual turbidity versus alum dosage. For dosages up to 40 mg/L alum, the mixed alum offered higher turbidity removal than commercial alum, all other conditions remaining identical. It is noteworthy that DOC, Zn, As, and Cu were nondetectable in the treated water.

### 34.6.6 EQUILIBRIUM ISOTHERM PLOT

The exchange capacity of Nafion 117 on a wet basis was calculated as 1372 eq/m<sup>3</sup>. The Nafion 117 isotherm plot for Al<sup>3+</sup>-H<sup>+</sup> equilibrium is shown in Figure 34.20a. The experimental data were generated for  $C_T$  values of 50, 1000, and 2000 meq/L. Using these plots and on the basis of selectivity coefficients calculated from Equation 34.14b, a theoretical plot for  $C_T = 222$  meq/L and  $C_T = 2000$  meq/L is obtained. These two  $C_T$  values represent the electrolyte concentration in the experiments performed. These plots were used in the model to predict theoretical concentrations in the feed and sweep solutions. It can be seen from Figure 34.20a that for a low  $C_T$  value of 50 meq/L, the isotherm is close to a rectangular plot. For higher  $C_T$  values of 1000 and 2000 meq/L, the plot approaches linearity. The drop in selectivity with increasing values of  $C_T$  is on predictable lines,

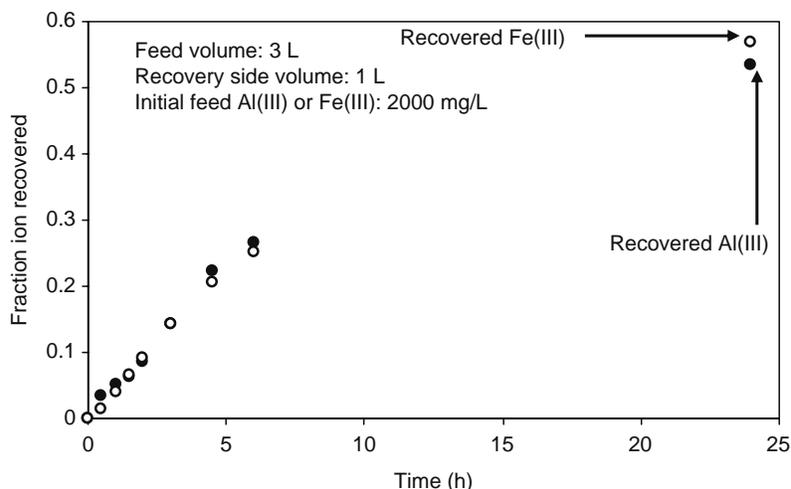

FIGURE 34.17 Fractional recovery of ferric and aluminum ions from synthetic solutions.

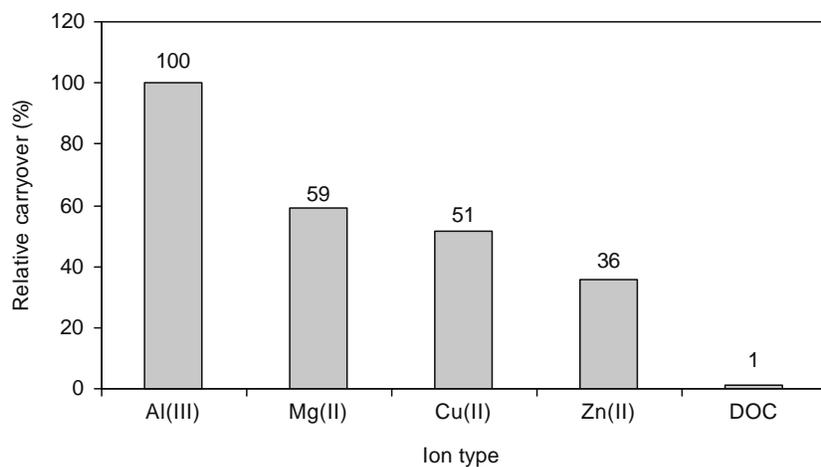

FIGURE 34.18 Relative carryover of undesirable solutes and NOM.

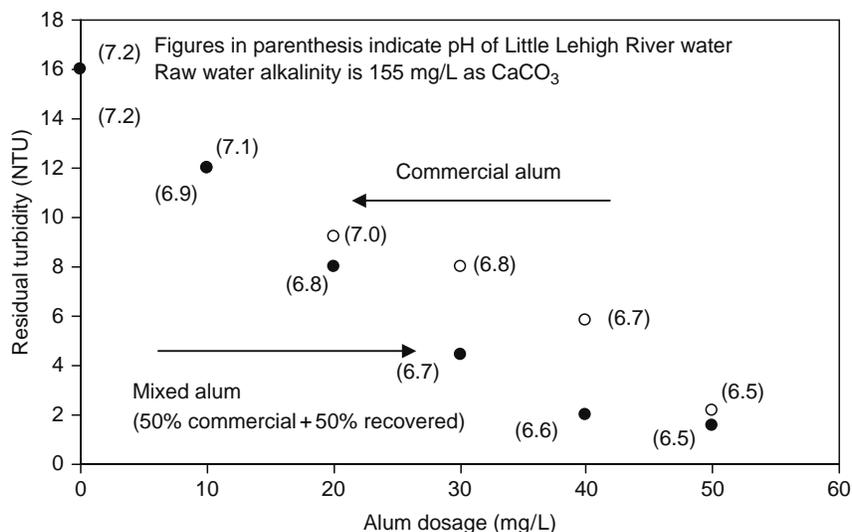

FIGURE 34.19 Residual turbidity versus alum dosage in jar tests using commercial alum and mixed alum.

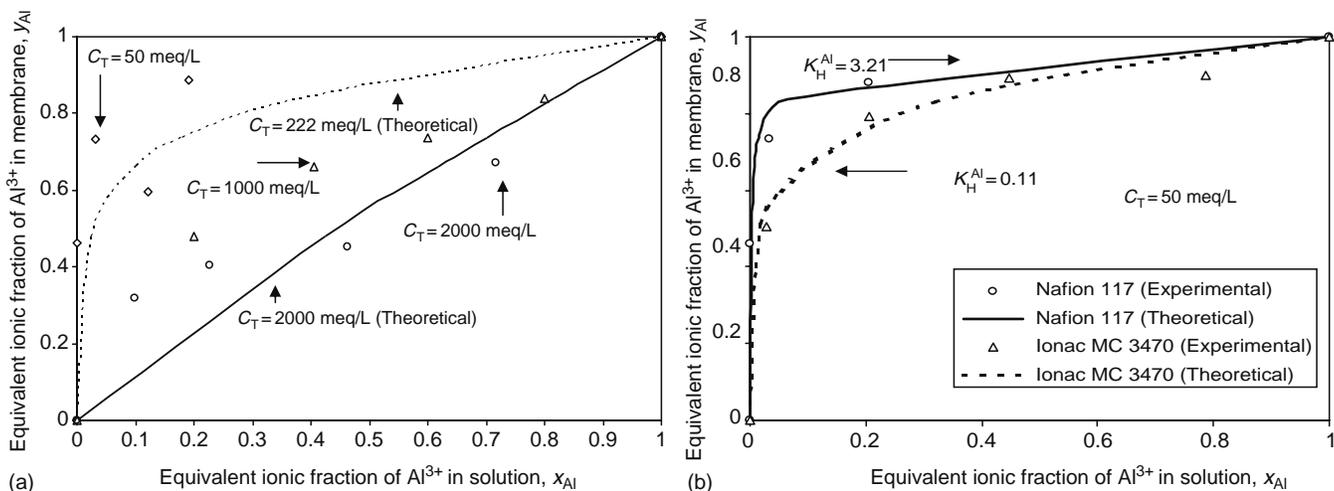

FIGURE 34.20 Al<sup>3+</sup>-H<sup>+</sup> Isotherm plot (a) for Nafion 117 and (b) comparison between Nafion 117 and Ionac MC 3470.

as for a given ionic fraction in solution, the membrane fraction is inversely proportional to the square of  $C_T$ , as observed in Equation 34.23. This implies that with increasing  $C_T$ , the isotherm plot approaches linearity and at a later stage, changes from “convex-up” configuration to “convex-down.”

A study was done to compare the isotherm plots of Nafion 117 and Ionac MC 3470. The comparison in Figure 34.20b shows that Nafion 117 has a more rectangular isotherm than Ionac MC 3470, indicating that the homogeneous membrane has a higher selectivity for  $\text{Al}^{3+}$  ions. In fact, the average selectivity coefficient  $K_H^{\text{Al}}$  was determined to be 3.21 for Nafion 117 and 0.11 (over 30 times lower) for Ionac MC 3470.

### 34.6.7 KINETIC TREATMENT OF ALUM RECOVERY IN NAFION 117

As discussed in Step 1 in the model, the exchange capacity for the membrane and the  $\text{Al}^{3+}\text{-H}^+$  equilibrium isotherm data were generated, as shown in Figure 34.20. Step 2 involved determining the aluminum ion recovery profile using a synthetic solution. The recovery profile for an experiment labeled Run 1 is plotted in Figure 34.21. For this experiment, a feed solution of 6 L ( $C_T = 222$  meq/L) and a sweep solution of 1.5 L ( $C_T = 2000$  meq/L) were used. In the same figure, aluminum flux, calculated from Equation 34.24, is also shown. For a given feed and sweep aluminum ion fraction  $x_{\text{Al}}$  determined from this experimental run, the corresponding fraction  $y_{\text{Al}}$  in the membrane surface exposed to the solution and its concentration was determined using Figure 34.20a. With the aluminum ion transfer, flux data available, and the membrane thickness provided, it was possible to determine the experimental interdiffusion coefficient value  $\bar{D}_{\text{Al,H}}$  with the aid of Fick's law in Equation 34.20a. This plot is shown in Figure 34.22a. It must be noted that this value is only an approximate value of interdiffusion coefficient, as actual values vary across the cross-section of the membrane with varying charge distribution. Using this approximate value of interdiffusion coefficient, the linearization technique described in Step 4 in the modeling section was implemented. The values of  $1/\bar{D}_{\text{Al,H}}$  from Run 1 were plotted against  $\frac{1}{1+\frac{1-y_{\text{Al}}}{y_{\text{Al}}}}$  in Figure 34.22b for surface conditions on feed surface. This plot was

used to determine the initial self-diffusion coefficient values  $\bar{D}_{\text{Al}}$  and  $\bar{D}_{\text{H}}$ . This approach can only be applied as a first approximation, as overall interdiffusion coefficient has been used to represent the interdiffusion coefficient value on feed surface. The ratio  $\bar{D}_{\text{Al}}/\bar{D}_{\text{H}}$  was determined to be 35.0 and was fed into a modeling program. The process was iterated for Run 1 to determine the theoretical recovery. But the recovery was modified to take into account the osmosis effect in solutions. The dilution effect was then imposed on the theoretical recovery plot to determine the sweep side concentration with osmosis. The initial self-diffusion coefficient values,  $\bar{D}_{\text{Al}}$  and  $\bar{D}_{\text{H}}$ , determined from Figure 34.22b underpredicted the experimental findings. So the process was iterated using  $\bar{D}_{\text{Al}}$  as the operating parameter. When the results matched well with the experimental plot for Run 1, the self-diffusion coefficient values obtained were

$$\bar{D}_{\text{Al}}: 6.5 \times 10^{-12} \text{ m}^2/\text{s} \quad \text{and} \quad \bar{D}_{\text{H}}: 2.28 \times 10^{-10} \text{ m}^2/\text{s}$$

Further to this, another experiment was carried out (Run 2). In this experiment, the feed volume was changed to 3 L (from 6 L in Run 1), sweep volume to 1 L (from 1.5 L), and the membrane area to  $370 \text{ cm}^2$  (from  $415 \text{ cm}^2$ ). It was observed that the sweep side concentration profile for these self-diffusion coefficient values matched reasonably well with the experimental findings [51]. The results are shown in Figure 34.22c. The self-diffusion coefficient of  $\text{H}^+$  ions has been investigated earlier

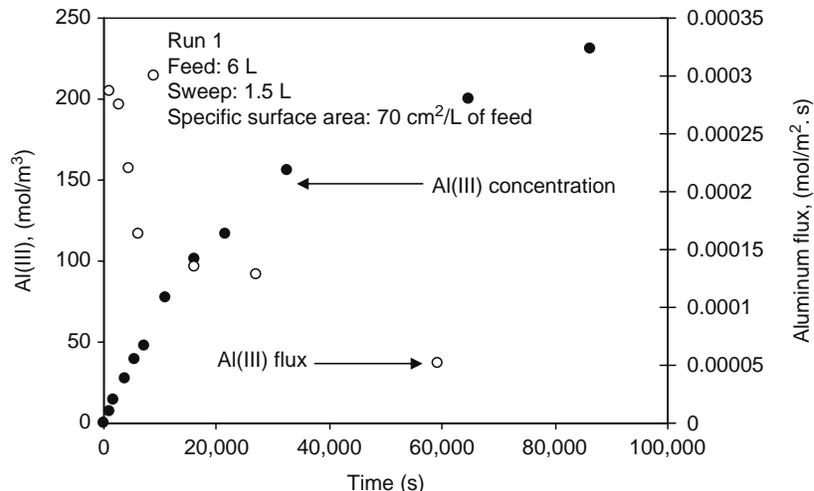

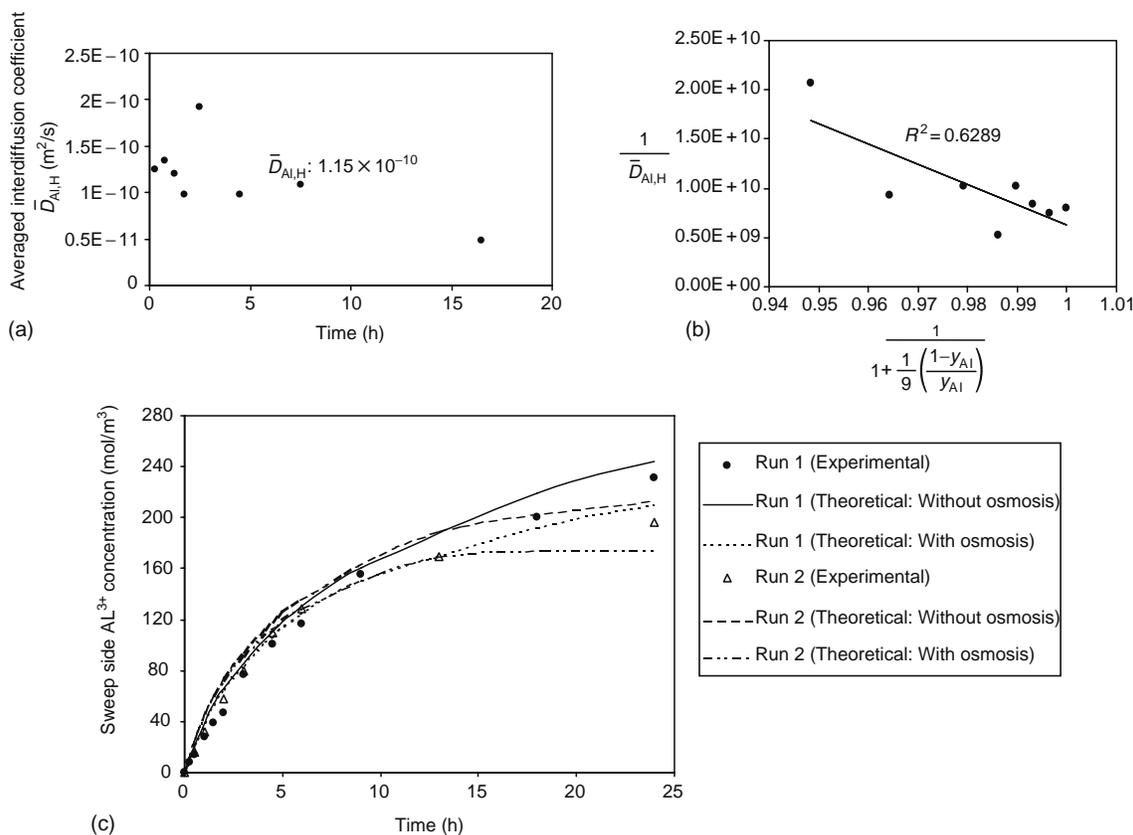

FIGURE 34.21 Sweep side  $\text{Al}^{3+}$  concentration for Run 1 and corresponding aluminum ion flux for Nafion 117 membrane.

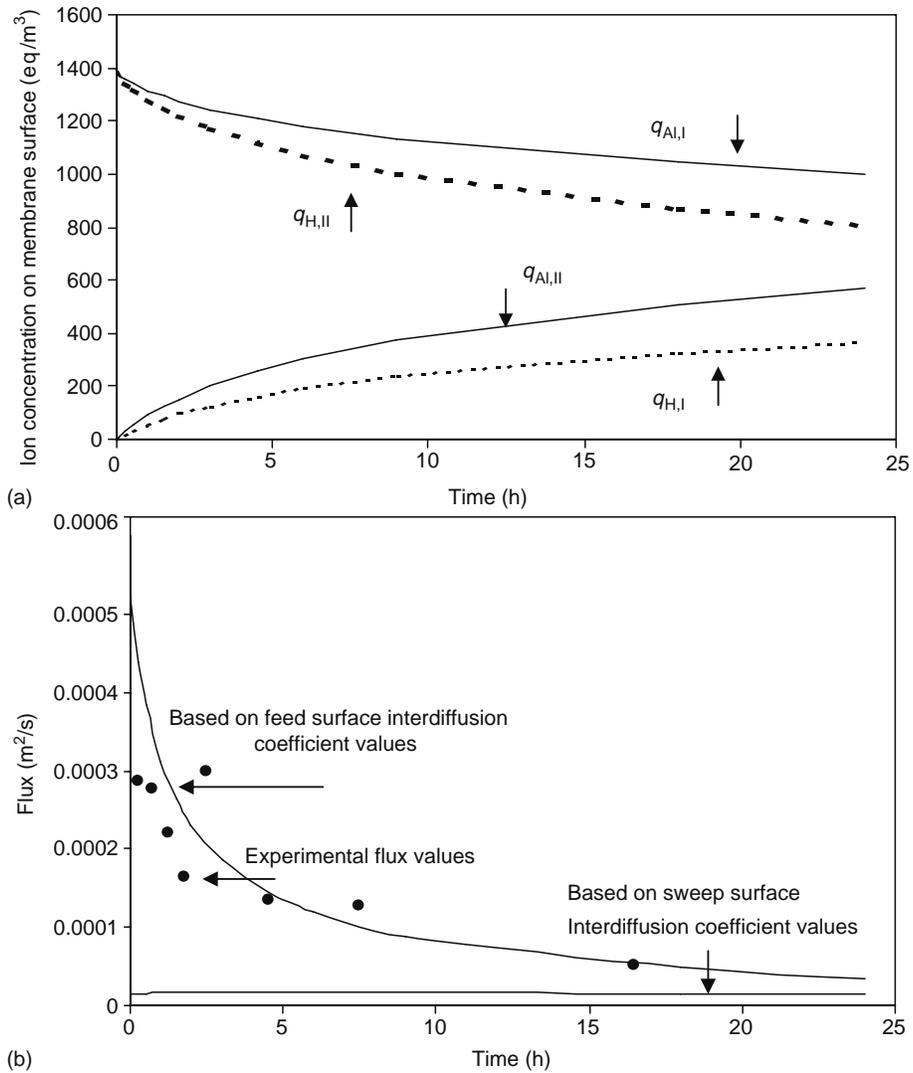

**FIGURE 34.22** (a) Average interdiffusion coefficient values based on Run 1, (b) self-diffusion coefficient determination for  $Al^{3+}-H^+$  pair using separation of variables, and (c) recovery profile for  $Al^{3+}$  (theoretical/experimental values) for Run 1 and Run 2: Nafion 117.

[37,52] and the current value is close to the values reported for the case of Neosepta C66-5T membrane by Miyoshi ( $1.33 \times 10^{-10}$  m<sup>2</sup>/s) and Sudoh et al. ( $1.86 \times 10^{-10}$  m<sup>2</sup>/s). When self-diffusion coefficient values for  $H^+$  and  $Al^{3+}$  ions in Nafion 117 were compared with the values in the aqueous phase at infinite dilution [53], the ratio of  $\bar{D}_{Nafion\ 117}/D_{infinite\ dilution}$  was found to be 1/41 and 1/93 for  $H^+$  and  $Al^{3+}$  ions, respectively. Miyoshi [32] had earlier found in their work with  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Cu^{2+}$ , and  $Mg^{2+}$  ions during DMP that the drop in self-diffusion coefficient value in the membrane phase was higher for the bivalent ions than for the monovalent ions. This point can be understood from the fact that in their movement across the membrane, trivalent ions have to link themselves with three negative sites, to maintain electroneutrality, while monovalent ions need to link with only one negative site. Therefore, the efficiency with which a multivalent ion hops within an exchange membrane is significantly reduced in comparison with monovalent ions.

### 34.6.8 INTERDIFFUSION COEFFICIENT VARIATION ON MEMBRANE SURFACES

As mentioned earlier, the interdiffusion coefficient is a variable across the membrane and is dependent on  $Al^{3+}$  and  $H^+$  distribution across the membrane. Using the model,  $q_H$  and  $q_{Al}$  distribution on the two surfaces was determined for Run 1, shown in Figure 34.23a. Data obtained from this finding were further used to calculate the flux variation with time. The results were compared against the flux obtained from the experimental findings. It could be seen, as shown in Figure 34.23b, that the flux values based on the interdiffusion coefficient  $\bar{D}_{Al,H,I}$  for feed surface were very well correlated with the experimental flux in comparison with the results obtained for sweep surface. This finding can be used to conclude that the ion transport for the present case could be well represented by the  $Al^{3+}-H^+$  distribution on feed surface, and that the charge distribution on this surface along with the interdiffusion coefficient values on this surface determined the ion transport.

Another important point that can be noted is that the interdiffusion coefficient values are closer to the self-diffusion coefficient value of  $H^+$  ions and much higher than the values obtained for  $Al^{3+}$  ions, calculations showing that  $\bar{D}_{Al,H,I}/\bar{D}_{Al}$  ranged from 35 (time  $t=0$  h) to 7 (time  $t=24$  h). In fact, the  $\bar{D}_{Al,H}$  values are significantly greater than self-diffusion coefficients of divalent and trivalent cations within a cation exchanger. For instance, the diffusion coefficient values for multivalent ions in cation-exchange resins with 15% crosslinking range between  $10^{-12}$  and  $10^{-14}$  m<sup>2</sup>/s [34]. This observation

**FIGURE 34.23** (a) Surface concentration of  $Al^{3+}-H^+$  ions: Run 1 and (b) comparison of  $Al^{3+}$  flux based on experiments with flux based on interdiffusion coefficient values on feed surface I and sweep surface II.

of high interdiffusion coefficient ( $\bar{D}_{Al,H}$ ) value in Nafion 117 is counterintuitive and the following provides a scientific explanation for high  $\bar{D}_{Al,H}$  values observed.

The composition of the membrane with respect to  $Al^{3+}$  and  $H^+$  content (i.e.,  $q_{Al}$  and  $q_H$ ) varies across the membrane, influencing the  $Al^{3+}-H^+$  interdiffusion coefficient as discussed earlier in Equation 34.20c and revised as below:

$$\bar{D}_{Al,H} = \bar{D}_H \bar{D}_{Al} \left( \frac{q_H + 9q_{Al}}{q_H \bar{D}_H + 9q_{Al} \bar{D}_{Al}} \right) \tag{34.32}$$

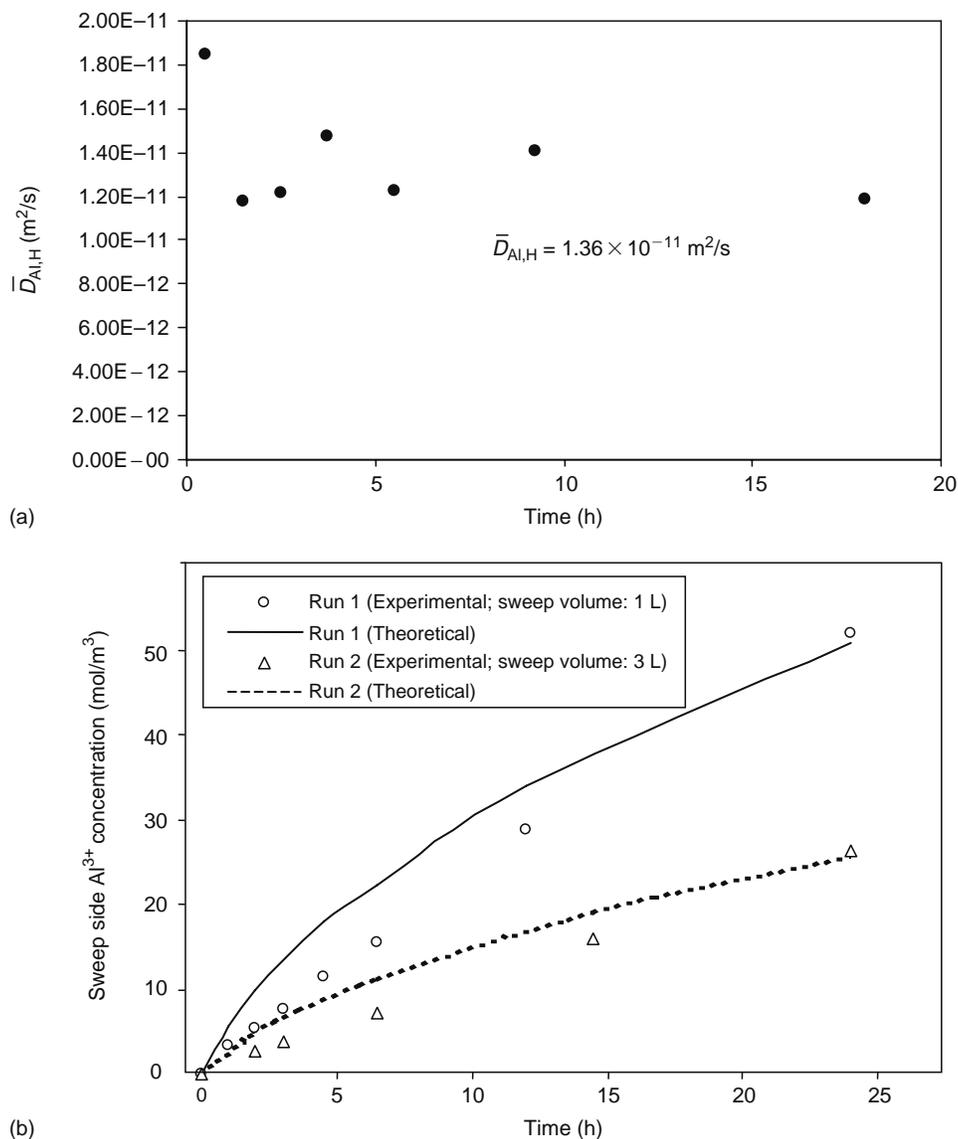

The relative distribution of  $Al^{3+}$  and  $H^+$  in the membrane governs the value of  $\bar{D}_{Al,H}$ . Nafion is a strong-acid cation-exchange membrane and exhibits significantly greater affinity for ions with higher valence. Equilibrium experiments revealed earlier that binary separation factor, which is a measure of relative affinity for two competing ions for an ion exchanger was equal to 70 for  $Al^{3+}$  over  $H^+$  for Nafion 117 at 50 meq/L solution concentration. Thus, at anytime during the process,  $q_{Al}$  is significantly greater than  $q_H$  within the ion-exchange membrane. In fact, the  $q_{Al,I}/Q$  value on feed surface was never below 0.75 during the entire period of the experiment. Considering the extreme case where hydrogen ion is essentially a trace species compared to aluminum ion, i.e.,  $q_{Al} \gg q_H$ , Equation 34.32 reduces to

$$\bar{D}_{Al,H} = \bar{D}_H \tag{34.33}$$

For the alum recovery process, the  $H^+$  ion is a minor species within the membrane. Consequently, the value of interdiffusion coefficient  $\bar{D}_{Al,H}$  approaches that of the faster-diffusing hydrogen ion,  $\bar{D}_H$ . The composition of the membrane changes with the progress of the process, thus altering the  $\bar{D}_{Al,H}$  values, but they always remain significantly greater than the self-diffusion coefficient of aluminum ions. From an application viewpoint, this phenomenon leads to a high mass transfer or alum recovery rate.

### 34.6.9 SELF-DIFFUSION COEFFICIENT COMPARISON IN NAFION 117 AND IONAC MC 3470

Experiments were carried out with Ionac MC 3470 to determine the self-diffusion coefficient values for  $H^+$  and  $Al^{3+}$  in the coupled transport. Data points were used from the experiment involving 2N acid sweep solution in Figure 34.24b, presented later. These values formed the basis for aluminum transport rate or flux ( $J_{Al}$ ) calculation at different time intervals. The equilibrium data generated in Figure 34.20b were used in conjunction with Equation 34.25 to determine the interdiffusion coefficient values. Local equilibrium was assumed at the membrane–water interface. Figure 34.24a shows computed  $\bar{D}_{Al,H}$  values for this membrane. When compared with  $\bar{D}_{Al,H}$  values for Nafion 117, it was noticed that the drop in interdiffusion coefficient values was not so steep, indicative of slow kinetics. The model discussed earlier was applied to determine the self-diffusion coefficient values of aluminum and hydrogen ions in Ionac MC 3470 membrane. A notable point was that the osmosis effect was not taken into account in this case, as no significant osmosis was observed in a separate experiment.

**FIGURE 34.24** (a) Interdiffusion coefficient values for aluminum ion transfer in Ionac MC 3470 and (b) recovery profile for  $Al^{3+}$  (theoretical/experimental values) for Run 1 and Run 2: Ionac MC 3470.

**TABLE 34.3**  
**Diffusion Coefficient Value Comparison in Nafion 117 and Ionac MC 3470**

	$\bar{D}_H$ (m <sup>2</sup> /s)	$\bar{D}_{Al}$ (m <sup>2</sup> /s)	$\bar{D}_{Al,H}$ (m <sup>2</sup> /s)
Nafion 117	$2.28 \times 10^{-10}$ (6.1)	$6.5 \times 10^{-12}$ (13.0)	$1.15 \times 10^{-10}$ (8.45)
Ionac MC 3470	$3.75 \times 10^{-11}$	$5 \times 10^{-13}$	$1.36 \times 10^{-11}$

*Note:* Numbers in brackets indicate ratio of diffusion coefficient in Nafion 117 over Ionac MC 3470.

Two experiments were carried out. Run 1 is the standard run and is the basis for generation of Figure 34.24a. In Run 2, a 2 L sweep solution was used instead of 1 L to verify the findings from Run 1. The findings from the model are presented in Figure 34.24b. The self-diffusion coefficient values were determined to be

$$\begin{aligned}\bar{D}_{Al}: & 5.00 \times 10^{-13} \text{ m}^2/\text{s} \\ \bar{D}_H: & 3.75 \times 10^{-11} \text{ m}^2/\text{s}\end{aligned}$$

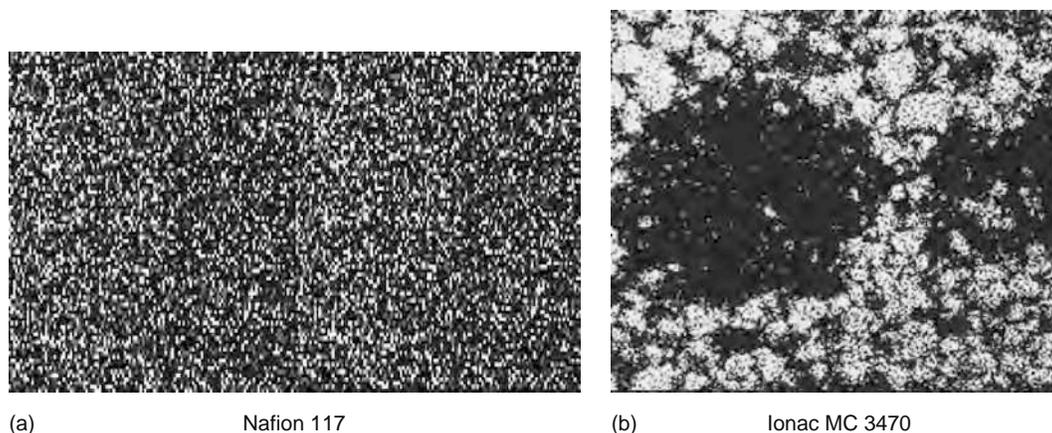

Even for Ionac MC 3470, it was the H<sup>+</sup> ion that was the trace species. A comparison of the diffusion coefficient values for the two membranes is presented in Table 34.3. From this table, it can be observed that the self-diffusion coefficient values for aluminum and hydrogen ions are similarly lowered as the experimental interdiffusion coefficient value. This lowering is about one order for both the cases. Explanation for low  $\bar{D}_{Al,H}$  values in the heterogeneous membrane is desired, as it explains the slow transport kinetics in heterogeneous membrane.

#### 34.6.10 INFLUENCE OF HETEROGENEITY ON TRANSPORT PROPERTIES OF NAFION 117 AND IONAC MC 3470

A SEM–XRF analysis was done to verify the hypothesis of conducting and nonconducting sites discussed earlier and by identifying the distribution of charged sites within Nafion 117 and Ionac MC 3470 [54]. A dot-map of Na<sup>+</sup> in Figure 34.25a and 34.25b showed that sodium ions were uniformly distributed in the homogeneous Nafion 117 membrane while they were unevenly distributed in clusters in the Ionac MC 3470. It suggests that there are regions of nonfunctional reinforcement in Ionac MC 3470, which are absent in the unsupported Nafion 117 membrane. This reinforced region is characterized by the absence of ionogenic groups.

#### 34.6.11 AL<sup>3+</sup> RECOVERY PROFILE

To develop an insightful understanding of the effect of the H<sub>2</sub>SO<sub>4</sub> (sweep solution) concentration on aluminum transport, experiments were conducted at two different initial H<sub>2</sub>SO<sub>4</sub> concentrations (C<sub>0</sub>), namely, 1 M and 2 M. Identical synthesized feed solutions of aluminum sulfate (~2000 mg/L as Al) were used in all four experiments that lasted for 24 h. Figure 34.26a and

**FIGURE 34.25** SEM–XRF dot-map of Na<sup>+</sup> in a cross-section of (a) Nafion 117 and (b) Ionac MC 3470. It may be noted that the charged sites are more uniformly distributed in the homogeneous membrane Nafion 117, while the heterogeneous membrane Ionac MC 3470 has nonconducting pockets shown by dark space.

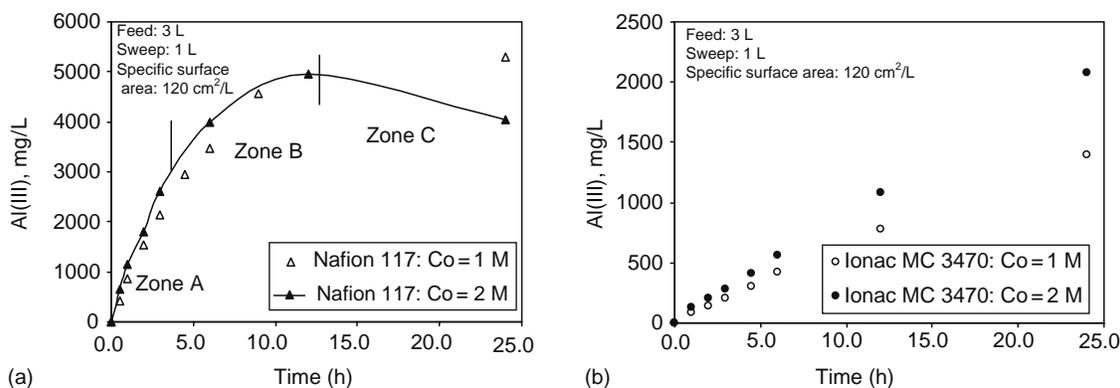

FIGURE 34.26  $\text{Al}^{3+}$  recovery profile for (a) Nafion 117 and (b) Ionac 3470.

34.26b provides plots of aluminum recovery versus time for both Nafion 117 and Ionac 3470. The following observations are noteworthy:

- For Nafion 117, the aluminum recovery profile approached saturation after 12 h but the same was linear after 24 h for Ionac 3470.
- Increasing the initial  $\text{H}_2\text{SO}_4$  concentration,  $C_0$ , from 1 M to 2 M increased aluminum recovery uptake for both membranes but there was a drop in aluminum concentration at the end for Nafion 117. This observation of drop in aluminum concentration beyond saturation is counterintuitive and was reconfirmed through a replicate experiment.

Characteristically, the aluminum recovery plot for Nafion 117 could be identified as a combination of three zones: Zone A (where the plot is linear), Zone B (where the plot reaches a plateau), and Zone C (where it tapers downward). The following provides a scientific explanation leading to the existence of the three zones.

In the beginning of the run, the driving force was characterized by a high electrochemical potential gradient in the membrane phase. The driving force remained nearly constant for the first 5 h, and consequently alum recovery rate was almost linear as shown in Zone A of the recovery plot. Zone A can therefore be termed as “kinetically driven linear zone.” As time progressed, the condition of Donnan equilibrium characterized was approached. Sufficient electrochemical potential gradient was no longer available, thus lowering the aluminum transfer flux. The aluminum recovery rate was thus governed by equilibrium conditions during this period and Zone B can be termed the “equilibrium-driven saturation zone.” In membranes such as Nafion 117, the transfer kinetics is fast enough to exhibit the two zones clearly during a 24 h experiment, as demonstrated in Figure 34.26a. Unlike this, Ionac 3470 is kinetically slower and offers higher resistance to aluminum transport. Therefore, the conditions of equilibrium were delayed and only the linear profile of Zone A was observed with Ionac 3470 during the entire period of experimentation, as shown in Figure 34.26b.

In Figure 34.27a, an interesting and counterintuitive observation was the drop in aluminum concentration with time, when a 2 M acid sweep solution concentration was used. Note that the osmosis of water is an ongoing phenomenon in Nafion 117

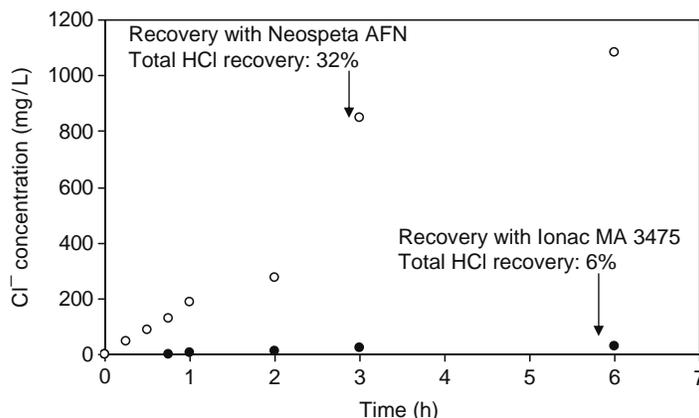

FIGURE 34.27 Influence of membrane type on diffusion dialysis of HCl.

during the DMP. It is noteworthy that osmosis took place independent of the aluminum transfer process. Thus when the aluminum recovery rate became negligible, the water transport due to osmosis still continued leading to a lowering or dilution of aluminum concentration in the recovery side. This situation was identified in Zone C, which is termed “osmosis-driven dilution zone.” Such a tapering was not observed in the experiment involving 1 M sweep solution because the osmosis effect was weaker during the period of experimentation.

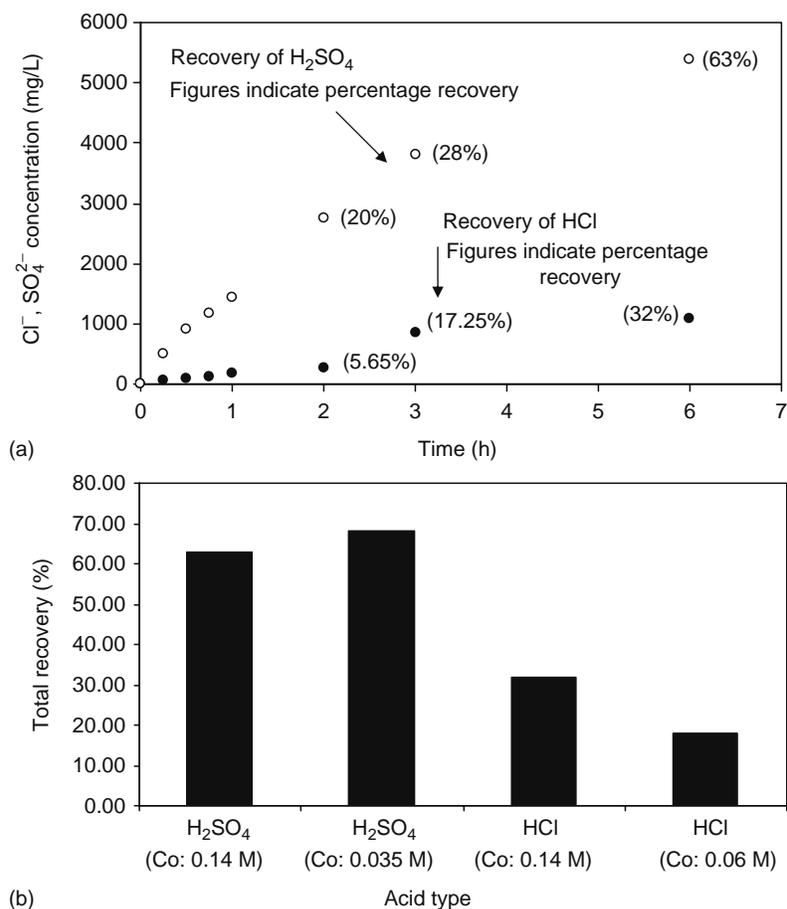

Only Zone A was observed in Ionac 3470, primarily due to low aluminum transport flux and partly due to higher resistance offered to solvent osmosis in comparison to Nafion 117. Increasing the sweep side concentration to 2 M led to greater recovery, as shown in Figure 34.26b, because a higher driving force was available in the sweep solution.

### 34.6.12 FINDINGS FROM DIFFUSION DIALYSIS EXPERIMENTS

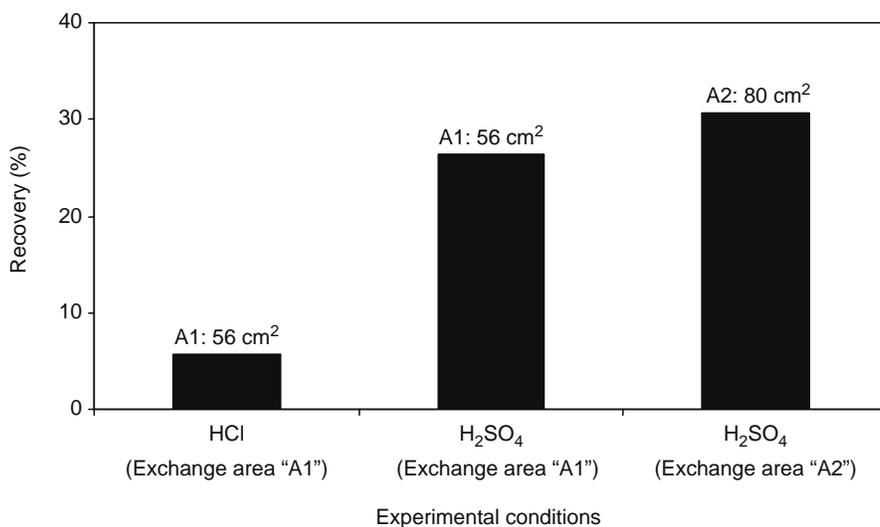

Diffusion dialysis experiments were not carried out in great detail, but some of the findings of the experiments are worth reporting. They have been discussed in the following paragraphs.

### 34.6.13 INFLUENCE OF MEMBRANE TYPE ON ACID RECOVERY

Two different membranes were used in acid recovery. These are Ionac MA 3475 and Neosepta AFN. Characteristic features of these anion-exchange membranes were discussed earlier. The experimental findings are presented in Figure 34.27. From an initial feed concentration of 5000 mg/L of  $\text{Cl}^-$  ions, only 7% was recovered with Ionac MA 3475, whereas over 30% recovery was made with Neosepta AFN. Clearly, Neosepta AFN was a better membrane for use. The high diffusional resistance to mass transfer in Ionac MA 3475 could be attributed to its membrane thickness, which was over two times more than in Neosepta

**FIGURE 34.28** (a) Influence of acid type on diffusion dialysis with Neosepta AFN and (b) influence of initial concentration on acid recovery during diffusion dialysis.

**FIGURE 34.29** Influence of diffusion dialysis on aluminum dissolution.

AFN. There could be other factors too, related to the morphology of the membranes. But these were not investigated in this study.

#### 34.6.14 INFLUENCE OF ACID TYPE AND CONCENTRATION ON DIFFUSION DIALYSIS RECOVERY

For Neosepta AFN, experiments were carried out to find out the diffusion dialysis of HCl and H<sub>2</sub>SO<sub>4</sub>. It could be seen that for a period of 6 h, the total recovery was about 63% for H<sub>2</sub>SO<sub>4</sub>, and for HCl it was around 32%. This finding is represented in Figure 34.28a. In a separate experiment, the initial concentration was changed from 0.14 to 0.06 M for HCl and 0.035 M for H<sub>2</sub>SO<sub>4</sub>. Recovery percentage did not change for H<sub>2</sub>SO<sub>4</sub> but was reduced by half to about 17% with HCl. This result is shown in Figure 34.28b. Two significant inferences drawn from these results were that the Neosepta AFN membrane was better suited for acid recovery from final WTR feed, and H<sub>2</sub>SO<sub>4</sub> could be more readily recovered through the diffusion dialysis process.

#### 34.6.15 ALUMINUM DISSOLUTION USING DIFFUSION DIALYSIS

In this experiment, the sweep side DI water was replaced by a DI water solution containing synthetic samples of aluminum hydroxide. The feed side contained 0.15 M acid solution of HCl or H<sub>2</sub>SO<sub>4</sub>. At the end of 6 h of experimentation, the aluminum concentration in the aqueous phase was higher for the case of H<sub>2</sub>SO<sub>4</sub>. When the area of exchange was increased from 56 to 80 cm<sup>2</sup>, the aluminum concentration went up marginally. Higher area allowed more acid molecules to diffuse through, and thus resulted in more dissolution of aluminum ions. These findings have been summarized in Figure 34.29.

#### 34.6.16 WTR DISSOLUTION AND pH CHANGE

In another experiment, residual WTR after DMP treatment was used as feed, and fresh WTR used as sweep solution for the diffusion dialysis experiment. The total aluminum recovered with time was noted on both the feed and sweep side. The results are shown in Figure 34.30. It can be observed that the pH dropped to a significant value on the sweep side from 6.9 to 3.5. Simultaneously, about 40% of total aluminum was dissolved in the process.

#### 34.6.17 FOULING OF ANION-EXCHANGE MEMBRANE

Two consecutive experiments, Run 1 and Run 2, were performed with the same stock of feed and sweep solutions and the pH changes in both the solutions recorded for each run. The graphs shown in Figure 34.31 show that pH variation with time closely matched for both runs, suggesting that there was no fouling of membranes because of NOM present in solution. But given that anion-exchange membranes are positively charged, their fouling after frequent usage cannot be ruled out. In fact, according to the manufacturer's specifications, fouling of Neosepta AFN may happen if the DOC concentration is greater than 100 mg/L.

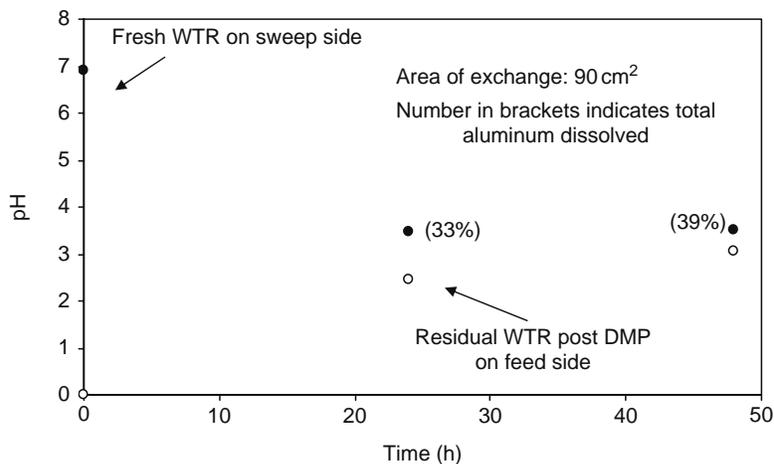

FIGURE 34.30 pH change and aluminum dissolution in fresh WTR feed/residual WTR during diffusion dialysis.

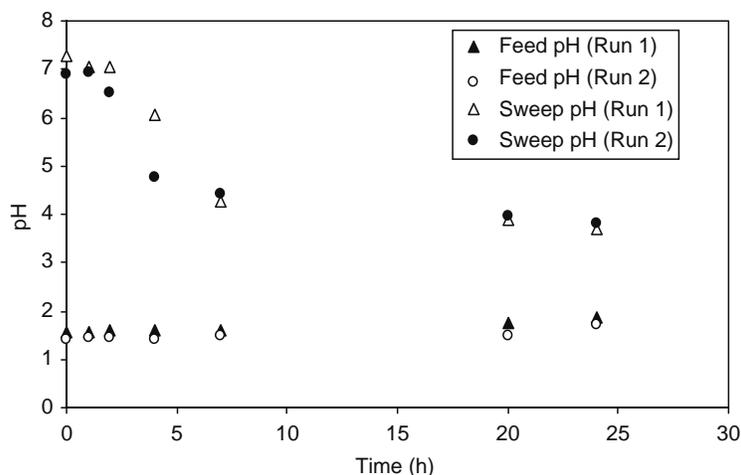

FIGURE 34.31 Study of fouling issues during diffusion dialysis.

### 34.6.18 DIFFUSION DIALYSIS CONSTANT FOR ACIDS

From the findings of the experiment, it was clear that  $\text{H}_2\text{SO}_4$  diffused faster than  $\text{HCl}$  through Neosepta AFN. On the basis of a 2 h experiment, the diffusion dialysis coefficient  $U$  was found as follows:

$$U_{\text{H}_2\text{SO}_4} = 58.6$$

$$U_{\text{HCl}} = 4.6$$

The selectivity of the membrane for one acid ( $\text{H}_2\text{SO}_4$ ) over another ( $\text{HCl}$ ) was found to be 12.7.

## 34.7 CONCLUSIONS

It was hypothesized that as opposed to pressure-driven membrane process applications, namely reverse osmosis (RO), nanofiltration (NF), and ultrafiltration (UF), Donnan membrane process (DMP) or Donnan dialysis was not susceptible to fouling by fine particulates and large organic molecules. It was driven by an electrochemical potential gradient across a semipermeable ion-exchange membrane. In open literature, no work has been reported on the application of DMP to treat slurry or sludge with relatively high concentration of suspended solids or large organic molecules. The current research is therefore novel work in the area of residuals management and it also led to a novel membrane separation application. The key conclusions drawn from this research are

- DMP was successful in recovering alum from WTR based on alum,  $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$ , and ferric chloride ( $\text{FeCl}_3$ ) coagulants. A series of laboratory tests confirmed that over 70%  $\text{Al}^{3+}/\text{Fe}^{3+}$  was easily recoverable.
- Alum recovered was essentially free of particulate matter, NOM, and other trace metals. The exclusion of negatively charged DOC was due to the presence of the negatively charged membrane surface through the process of Donnan exclusion.
- Since the DMP is driven by the electrochemical potential gradient, the presence of high turbidity and NOM in the sludge did not influence alum recovery and no noticeable membrane fouling was observed even after multiple runs for long hours of operation.
- DMP process was also selective in preferring trivalent cations over bivalent heavy metal ions.
- Nafion 117 from DuPont Chemical Co. was found to be the most effective membrane in terms of kinetics of ion transfer. The equilibrium isotherm showed that the membrane had a high selectivity for trivalent aluminum ions. This resulted in a rectangular isotherm for the Nafion 117 membrane.
- It was seen that in the experiments performed hydrogen ion was the trace species. Therefore, for coupled  $\text{Al}^{3+}-\text{H}^+$  transport, the interdiffusion coefficient approached the self-diffusion coefficient of the faster-diffusing  $\text{H}^+$  ions. This conclusion appears counterintuitive, but explains the good kinetics of the process.
- It was found that the interdiffusion coefficient values based on membrane surface I (facing the feed solution) concentration represented the actual transport process. The interdiffusion coefficient values were found to be in the range of  $10^{-10} \text{ m}^2/\text{s}$  for the Nafion 117 membrane.
- Another important observation was the osmosis of water from the feed to sweep solution, which resulted in dilution of the sweep solution during the later part of experimentation with Nafion 117. The osmosis effect was not noted for Ionac MC 3470.
- While both the interdiffusion coefficient and concentration gradient are responsible for aluminum ion flux, it was found that the former played a slightly more significant role in aluminum ion flux determination.
- It was also observed that the drop in the self-diffusion coefficient of higher valent ions in the membrane phase in comparison to their self-diffusion coefficient values at infinite dilution in aqueous phase was higher for ions with higher charge. This was attributed to greater difficulty in binding to adjacent sites for a higher valent cation.
- Comparison of a homogeneous membrane (Nafion 117) and a heterogeneous membrane (Ionac MC 3470) with respect to alum recovery showed that the recovered  $\text{Al}^{3+}$  could be concentrated to a high value of over 4500 mg/L (80% recovery) with Nafion 117, but the recovery was relatively low (25% recovery) with Ionac MC 3470. In a comparative study, the interdiffusion coefficient  $\bar{D}_{\text{Al,H}}$  was found to be  $\sim 7.23 \times 10^{-11} \text{ m}^2/\text{s}$  for homogeneous Nafion 117, while it was  $\sim 1.36 \times 10^{-11} \text{ m}^2/\text{s}$  for heterogeneous Ionac 3470.
- Scanning electron microphotograph and x-ray fluorescence showed clusters of nonconducting inert phases within the heterogeneous membrane containing no ionogenic groups. The lower interdiffusion coefficient for Ionac 3470 was attributed to its larger fraction of a nonconducting phase compared to Nafion 117.
- $\text{Al}^{3+}$  recovery profile led to identification of three zones of mass transport, namely a kinetically driven linear zone, an equilibrium-driven saturation zone, and an osmosis-driven dilution zone. All three zones were observed in Nafion 117 during a 24 h experimental run. For Ionac MC 3470, only the linear zone was observed during the period of experimentation.
- Application of diffusion dialysis had a desired effect in transfer of acid molecules from the residual WTR feed to fresh WTR sweep solution. It helped in raising the pH of residual feed from 1–1.5 to approximately 3.0. The simultaneous reduction of pH on the fresh WTR sweep solution helped in dissolving aluminum ions from the solid phase into the aqueous phase up to 40%.
- $\text{H}_2\text{SO}_4$  was found to diffuse faster than HCl. Neosepta AFN membranes were found suited for the current application and responded better than Ionac MA 3475 membranes.

### 34.8 FUTURE RESEARCH

The current research also led to identification of a number of nascent research applications. Further work can be carried out in the following areas [55]:

- Recovered alum can be compared with commercial alum in terms of its application as a coagulant. The possibility of alternative use of recovered alum such as in manufacture of polyaluminum salts and their acceptability as a commercial product must be studied.
- In the current research, a major focus was on alum recovery. A study can be carried out for ferric ion recovery and detailed modeling can be carried out for Fe(III) recovery from ferric chloride-based WTR.
- In the current kinetic modeling, it was assumed that the DMP involved coupling of two ions. A more detailed study can be carried out to study multicomponent systems undergoing DMP. Therefore, the influence of contaminant ions on alum recovery can be better characterized. In this regard, the distribution of aluminum ions in the membrane in presence of other cations may also be evaluated.

- Osmosis of water in charged membranes can be studied as a research subject.
- Diffusion dialysis process was very briefly studied in the current research. A detailed study of acid recovery from water treatment plant residuals can be a subject of research.
- More rigorous treatment of comparison of homogeneous and heterogeneous membranes involving conductivity measurements at different electrolyte strengths can help in characterizing the transport properties of these membranes.

## ACKNOWLEDGMENTS

## 35.1 INTRODUCTION TO MEMBRANE PROCESSES IN THE PULP AND PAPER INDUSTRY

Membranes are used in the pulp and paper industry in a variety of applications; in particular: for the purification and recovery of water, and for the recovery of raw materials or energy. The pulp and paper manufacturing process requires enormous amount of water; to transport the raw materials, to dissolve impurities, to seal various process equipment, to cool and heat, to wash and clean process equipment, and to generate necessary environment for the formation of the hydrogen bonding network between fibers and fillers, which is the basic mechanism of paper formation. Thus, water and its quality are essential issues in the production of pulp and paper.

A reduction in the volume of water needed at the paper machine is almost impossible because paper formation will be disturbed if the consistency of the pulp suspension becomes too high. Currently, the stock suspension (i.e., pulp and additives) in the head box of a paper machine contains 97%–99.9% water. The constraint of maintaining pulp suspension consistency means a reduction in water intake has to be realized by reusing the process water. Due to the different purposes and applications in which water is used, the water quality demands vary considerably. Membrane processes can be chosen to produce a specific water quality and are attractive alternatives to facilitate the reuse of water, either alone or combined with biological processes or other chemical and physical processes. In addition, membrane processes are an efficient way to recover raw materials, e.g., coating pigments, from effluents.

Membranes have been evaluated for use in the pulp and paper industry since the late 1960s. Initial experiments involved white water (circulation water) from a paper machine, which was purified for reuse, and bleach plant effluents, which were treated for the removal of color. The first reported commercial application of membrane processes was as early as 1972 when Green Bay Packaging (Green Bay, Wisconsin) installed a reverse osmosis (RO) system for the treatment of paper mill circulation water (white water) [1]. At that time, the typical membrane material was cellulose acetate (CA) that had a limited temperature and pH resistance. Generally, the fluxes of the CA membranes were also rather low. Extensive developments in membrane materials as well as in module construction and configurations have occurred since the 1970s. Today, RO and NF (nanofiltration) membranes are mainly thin film composite membranes made mostly from polyamide (PA) or its derivatives. In ultrafiltration (UF) or microfiltration (MF), in addition to materials used in RO, such as polyamide: polysulfone (PSu), polyethersulfone (PES), polyethylene (PE), regenerated cellulose (RC), and polyvinylidene-fluoride (PVDF) are also used as membrane materials in the filtration of pulp and paper industry effluents. Membrane manufacturers may also have chemically modified forms of these base membrane materials, the nature of the modification is generally not disclosed.

During the 1980s, three large-scale ultrafiltration plants started to treat caustic extraction stage effluents in Japan and Sweden to remove color, and reduce chemical oxygen demand (COD) and biological oxygen demand (BOD). In 1988, the first high-shear cross-rotational (CR) filter was started in Sweden (MoDo, Husum, belonging to M-Real since 2000). It was used to remove adsorbable organic halogens (AOX) and COD from the bleach plant effluent. This technology has now been installed in more than forty mills to reuse coating color and process waters, or to purify effluents. During the 1990s two new types of membrane processes, NF and the membrane bioreactor (MBR), were introduced in the pulp and paper industry. The number of studies on MBR increased considerably at the end of the 1990s and, today, some commercial MBRs are in operation in the pulp and paper industry.

Legislation, environmental issues, customer demands, and economic reasons have increased interest in membranes. According to the Paperbase databank, in 1990 the word ultrafiltration was mentioned in more than 100 different papers and reverse osmosis in about 70 papers. In 2005, the corresponding numbers were 500 and 220. However, the seemingly intensive research has not yet created many mill-scale installations.

The chapter will concentrate on membrane processes, in which pressure is the driving force and both the permeate and the concentrate are water solutions. Electrodialysis (ED) will also be reviewed briefly. The idea is to focus on installations and studies of the last 10 years. Readers who are interested in older studies or installations are referred to several review publications [1–3].

## 35.2 SPECIAL ISSUES CONCERNING MEMBRANES IN THE PULP AND PAPER INDUSTRY

In general, the effluent volumes in the pulp and paper industry are huge, even cubic meters per second, and if all the mixed effluent has to be treated by membranes, high fluxes and large membrane areas are needed. By keeping some water streams unmixed the membrane processes could be focussed on the most relevant streams and then only smaller volumes would need to be treated. Obviously, the membrane purification needed differs depending on the demands of the treated waters in the reuse application.

The effluents and process streams in the pulp and paper industry are very complex and comprise heterogeneous combinations of different wood-based compounds and their degradation products, as well as the chemicals used in the processing of the raw materials or additives used in the production of the end products. Thousands of different chemical compounds can be identified from these process streams. Some of them are known to be strongly fouling, limiting the feasibility of membrane processes. Many streams contain fibers or debris, and they can easily plug the flow channels when modules with high packing density (i.e., spiral wound modules) are used. Because the same paper machines are commonly used to manufacture different paper products (i.e., paper grades), which all need tailored process conditions and special raw materials, the concentration and composition of the feed process streams to be filtered vary considerably.

Generally, in the pulp and paper industry the temperature of the process water can vary from 10°C to 90°C, or sometimes even higher. The concentrations vary from less than 100 mg/L dry solids up to 40%–60% (e.g., coating pigments and chemicals) and the pH from <2 to 14 (e.g., in bleaching stages). Generally, in the actual papermaking process the pH is either 5 or 7.

### 35.3 PARAMETERS AFFECTING THE PERFORMANCE OF MEMBRANE SEPARATION IN THE PULP AND PAPER INDUSTRY

The most widely used or tested membrane processes in pulp and paper mill applications are based on pressure-driven membrane processes; MF, UF, NF, and RO. In the following sections, the characteristic properties of the membranes are discussed and their effect on filtration efficiency is summarized. In addition, some common influence of effluent properties and filtration conditions on membrane processes are discussed.

#### 35.3.1 CHARACTERISTICS OF MEMBRANES

Membrane properties have been characterized and their effects on flux, retention, and fouling have been studied extensively by several authors. Some common facts can be concluded from these studies.

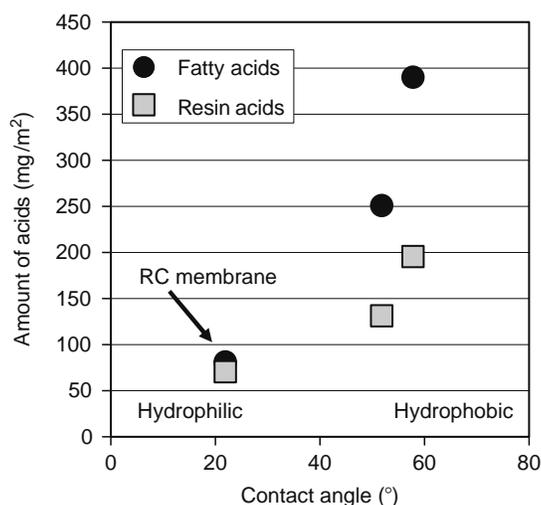

Pore size is obviously one of the most important factors affecting flux and retention. However, it has frequently been seen that the membrane with the most open pores does not usually give the highest permeate flux when process waters are filtered. Fouling of the membrane material, particularly pore plugging, can be considerably stronger with microfiltration membranes than with UF or NF membranes [4–7]. Retention is obviously affected by the pore size due to the sieving effect, especially when using microfiltration and ultrafiltration membranes. With tighter (NF and RO) membranes retention will be governed more and more by the electrostatic forces as well as by other interactions between membranes and solutes.

Another factor that has been shown to significantly affect flux and fouling is the hydrophilic character of the membranes [4,8–12]. Water spreads over the surface of a hydrophilic membrane but not on a hydrophobic membrane. The membrane material determines its hydrophilicity, which is typically evaluated by measuring the contact angle at a membrane–water–air interface. Cellulose and hemicelluloses, which form the main part of wood and paper, are extremely hydrophilic. Wood extractives such as fatty and resin acids, on the other hand, have hydrophobic characteristics and, therefore, they are found more on fouled and used hydrophobic membranes than on hydrophilic ones (Figure 35.1) [9,13].

Fatty acids foul membranes more intensive under acidic conditions. When the pH is increased above 5–6, the fatty acids form their corresponding salts, the solubilities of which are up to 100 times higher than that of the neutral acid, and therefore their fouling at high pH due to adsorption is negligible [14]. This is one reason why alkaline filtrates from bleaching or various neutral process waters are usually easier to filter than acidic waters.

Maartens et al. [15] characterized adsorbed foulants calorimetrically and concluded that foulants in pulp and paper mill effluents are phenolic and hydrophobic in nature, a result corroborated by Puro et al. [9]. Maartens et al. also modified their membranes to make them more hydrophilic and achieved less fouling and better cleaning efficiency. Thus, pretreatment or modification of a membrane can improve its fouling resistance, its flux or retention, and can enhance its usability in pulp and paper industry applications [16].

A smooth membrane usually fouls less than a rough membrane, especially, when colloidal solutions, such as waters from the pulp and paper industry, are filtered [17]. Process streams might contain fibers or even some solid particles, which can wear

**FIGURE 35.1** The amount of fatty acids and resin acids found in ultrafiltration membranes of varying hydrophilicity after a 30 day test run in an integrated pulp and paper mill at pH 5.3 (the solvent in extraction was an acetone–water solution [9:1]). (Based on data from Puro, L., Tanninen, J., and Nyström, M., *Desalination*, 143, 1, 2002; Huuhilo, T., Väisänen, P., Nuortila-Jokinen, J., and Nyström, M., *Desalination* 141, 245, 2001.)

the membrane surface, particularly under high-shear conditions. A rough membrane contains more mountains (peaks on the membrane surface) where erosion happens easily. In addition, the permeate side support spacer should be smooth, as it could otherwise cause macroscopic roughness on the membrane surface (opposite side) when under pressure. This mechanical erosion of the membrane surface has to be taken into account, when filtering concentrated solutions or solutions containing solids. Fibers have been reported to enhance the flux because of the scouring effect they cause or because of the adsorbed foulants that they carry away [18–20].

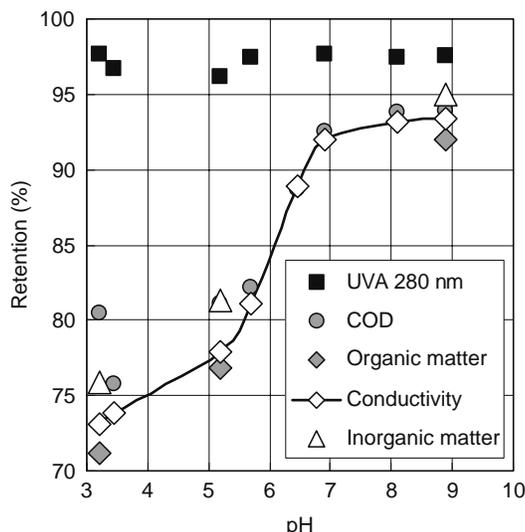

Membrane charge [3,8,21] affects membrane efficiency, particularly when low cutoff membranes are used at low salt concentration. Many polymeric membranes are amphoteric, having both negatively and positively charged functional groups in the polymer matrix. Therefore, the membrane might be positively charged at low pH and negatively charged above the isoelectric point (pH where net charge is zero). The isoelectric point of polymeric membranes is often at pH 4–6. When a membrane is charged, it is also more hydrophilic than when uncharged. An increase in the flux of a relatively dense membrane at a high pH may result from an increase in membrane hydrophilicity due to the dissociation of the functional groups in the membrane structure [22,23].

### 35.3.2 SOLUTION PROPERTIES AND FILTRATION CONDITIONS

Pulp and paper industry waters contain thousands of compounds and many of them can be dissociated and charged at the prevailing conditions. When particles are dispersed in water, they usually acquire a certain fixed charge. An increase in pH generally improves the solubility of many dissolved and colloidal substances, and often gives them a negative charge. For instance, carboxylic groups existing in, for example, fatty and resin acids (wood extractives) dissociate (become charged) when a pH of 4–6 is exceeded. Phenolic groups such as those in extractives or lignin are charged above pH 9 when the phenol is dissociated. When the membranes and the compounds have similar charges, they repel each other. The charge effect on retention is very clear as shown in Figure 35.2 [24]. All other measured parameters besides the UV absorption at 280 nm (UVA 280 nm) were retained better at high pH. The compounds absorbing UV light were mostly retained by the sieving effect in nanofiltration and not by charge. Therefore, they were equally well retained in the whole pH range. Unfortunately, the buffering capacity and the volume of the streams in the pulp and paper industry require large amounts of chemicals, making pH adjustment an uneconomical mean when improving filtration performance.

Flux is often less affected by pH than retention, but the common trend is that both are better when electrostatic forces are present. Furthermore, the electrostatic repulsion between dissociated compounds and the membrane prevents them from coming in contact and, therefore, diminishes fouling. However, if some cationic compounds (e.g., retention agents from papermaking) are present in the water stream, because of electrostatic attraction, a negatively charged membrane will most often be fouled more than a membrane, which is more or less uncharged. Regenerated cellulose is a very hydrophilic, fairly uncharged material, thus it is successfully used in the filtration of paper mill process waters.

Pulp and paper industry streams are mostly colloidal, i.e., they contain macromolecules and small particles in the range of 1 nm to 1  $\mu\text{m}$ . Salt and pH affect colloidal stability, rate of precipitation, and colloidal fouling. The higher the surface charge

**FIGURE 35.2** Size and charge effects on the retention of various lump parameters when paper mill total effluent was nanofiltered (Desal-5 DK membrane) at different pH. (Adapted from Mänttari, M., Nuortila-Jokinen, J., and Nyström, M., *J. Membr. Sci.*, 137, 187, 1997.)

of the colloidal compounds in the solution, the greater the colloidal stability and the lower the colloidal fouling. Colloidal stability can be improved by softening the water (i.e., removing multivalent ions, e.g., calcium ions, or replacing them with monovalent ions) and by adjusting pH [25,26].

One special property of the process waters discussed is the broad heterogeneity in concentration of the dissolved and dispersed molecules. This is due to different products manufactured using the same machine and also due to shut down and start-up periods. Several authors have shown that the concentrations of organic and inorganic compounds vary even tenfold in process waters [18,27,28]. This means that when using membrane technology the membranes should be resistant to big fluctuations in the feed stream.

A trend in the pulp and paper industry has been toward elevated temperatures. The temperature range of the water circuit in many mills is 50–70°C where higher temperatures yield increased productivity and reduced energy consumption [29]. Occasionally, streams from pulp mills are filtered even at 90°C. Temperature decreases the viscosity of the water stream and, therefore, increases flux. The cleaning efficiency is also usually improved at high temperature. Unfortunately, a high temperature can have a detrimental effect on membrane material properties and filtration efficiency [30]. Too high a temperature may completely destroy the membrane or change its retention properties and flux. Traditional cellulose acetate membranes withstand only 35°C but some PVDF, polysulfone, or polyamide-based membranes can function at temperatures up to 90°C. The synergy of high temperature and high pressure results in compaction of the membrane structure. The compaction irreversibly tightens the membrane structure and as a result the permeability decreases detrimentally. This effect has not been studied thoroughly, but some indications have been reported. Kallioinen et al. showed that a slight compaction of regenerated cellulose ultrafiltration membranes (cutoff 30 kg/mol) occurred already at a pressure of 3 bar [31].

Several researchers have reported significant improvements in flux at high cross-flow velocity or by using other methods to increase shear forces on the membrane surface. Flux is often a trade-off with the energy used to create the shear forces. The effect of the high cross-flow velocity vanishes when the pressure (flux) is decreased. Therefore, it may be advantageous to use a high-turbulence system under medium to high pressure to benefit fully from the high mass transfer coefficient or to use inexpensive low-turbulence filter systems at relatively low-operating pressure, even operating below the critical flux (at subcritical flux) [32–36]. The permeate flux (pressure) has a significant influence on retention especially with tighter membranes (RO, NF, tight UF) [37]. However, too high pressures and fluxes cause polarization of the retained compounds on the membrane surface (concentration polarization) resulting in flux decrease, change of retention, and compact fouling. The critical flux is the highest flux that is obtained without fouling at the applied conditions. Therefore, by controlling the flux, fouling can often be managed [38–40]. In Section 35.5, sophisticated module constructions operating at high shear are presented.

When comparing high-shear and low-shear modules in the filtration of effluents from the pulp and paper industry huge differences have been seen in retention. The colloidal material acts as a secondary layer in the filtration with a low-shear module and increases retention of substances as well as concentration polarization. Approximately a double flux (100–150 L/(m<sup>2</sup> h)) was obtained in a high-shear module compared to a low-shear module, but the retention of conductivity was 10%–15% units lower [41]. The fouling layer was reported also by Woerner et al. to determine retention [42]. Thus, the trade-off between flux and retention depends on both the tightness of the membrane and the flow velocity. Electrical field [34], ultrasonic field [43], and back pulsing with permeate or air and air scouring in hollow fiber modules have also been studied as possible methods to improve flux.

## 35.4 PRESSURE-DRIVEN MEMBRANE PROCESSES IN THE PULP AND PAPER INDUSTRY

### 35.4.1 MICROFILTRATION

Microfiltration membranes can be used as pretreatment for other membrane technologies and to remove microbes and total suspended solids (TSS) including fibers and particles. Retention of salts and dissolved organics is negligible, if they are not bound to the suspended solids. MF can be used for the recovery of coating color pigments. MBRs generally use UF or MF membranes. The materials used in microfiltration are polyvinylidene fluoride (PVDF), polypropylene, polyethylene, polysulfone, polyether sulfone, Teflon, and ceramic materials.

Microfiltration membranes are commonly used in MBRs to separate solids from water. The fluxes are very low, often below critical flux, and at low pressures when hollow fibers are used, backflushing is added to prevent or reduce flux decrease. MBRs are discussed in detail in Section 35.6.3.2, tubular modules with MF membranes have also been tested in the pulp and paper industry.

Pore sizes in MF are typically 0.05–10 μm. Generally, MF membranes suffer from pore plugging because the pulp and paper mill effluents often contain particles of similar sizes as the pores in the membranes. That is why, in many cases, fluxes in ultrafiltration are significantly better than fluxes obtained with microfiltration. Silva et al. [44] studied submerged hollow-fiber microfiltration (a) for the removal of flexographic ink from a deinking plant effluent, (b) for the concentration and recycling of the coating effluent before evaporation in a chemi-thermomechanical pulping plant, and (c) as a separation barrier in MBR for

treating old corrugated cardboard recycled mill effluent. In industrial-scale applications MF is used before other treatment processes, for example, before RO in the zero effluent McKinley mill in Prewitt, New Mexico [45,46].

### 35.4.2 ULTRAFILTRATION

Ultrafiltration is the most widely used membrane process in the pulp and paper industry. UF membranes have been used to remove or reduce suspended solids, color, extractives, turbidity, COD, and AOX from various process streams and effluents, for the recovery of raw materials. The permeate after UF is often good enough to be discharged and can often be reused in many places in the mill. UF of bleaching effluents has been extensively investigated and became established on an industrial scale using tubular (Taio Paper Iyomishima, Japan) and flat sheet (Sanyo-Kokusaku Paper Iwakuni, Japan) membranes in the early 1980s [1]. UF is also used to recover lignosulfonates from spent sulfite liquor. A commonly employed membrane filter in the pulp and paper industry, the CR filter, uses UF membranes. UF of the clear filtrate stream (effluent from the paper machine) is industrially realized in many mills using low pressure and high cross-flow velocities or high-shear rates (Section 35.6.2). Ultrafiltration membranes, in flat sheet, tubular or hollow fiber form, are often the separation barriers in MBRs. In addition, coating color recovery is commonly carried out using UF membranes.

In UF, the separation is mainly based on the difference in the molecular size of the solute compared to the pore size of the membranes. Commercial ultrafiltration membranes are available with cutoff values ranging between 1 and 500 kg/mol. Typically, the membranes used to treat alkaline effluents from pulp bleaching have a cutoff value of 4–8 kg/mol. Membranes used to treat streams from pulp mills are often made of polysulfone, or even ceramic materials such as aluminium oxide and zirconium dioxide. Other materials commonly used in UF membranes are polyamide, polysulfone, and polyethersulfone. Circulation waters of paper machines are purified using polymeric UF membranes having a cutoff around 30–150 kg/mol. Some of the best membranes for process water treatment are manufactured from regenerated cellulose (e.g., C30F from Microdyn/Nadir, cutoff 30 kg/mol). Their extremely high hydrophilicity generates a high flux at low pressure and low fouling (Figure 35.1). Coating colors are recovered using slightly more open membranes (cutoff 30–500 kg/mol). Most industrial-scale pulp and paper mill UF installations are for the recovery of coating colors; however, in process water treatment there are fewer installations but these have larger installed membrane area.

### 35.4.3 NANOFILTRATION AND REVERSE OSMOSIS

Nanofiltration or reverse osmosis treated water is needed in the most demanding places of the mill such as for the high-pressure showers in a paper machine. Surface water used in the mill as intake freshwater may also need NF or RO treatment. Permeation of monovalent ions, in particular chloride ions, is both an advantage and a disadvantage of NF compared to RO. Monovalent salts cause significant osmotic pressure when retained in RO. In NF their permeation keeps the osmotic pressure lower and thus the transmembrane pressure needed to overcome the osmotic pressure is lower. The permeation of chloride ions in NF may restrict the reuse of the permeate because of concerns regarding corrosion caused by chloride. On the other hand, the concentrate then contains less chloride and its reuse or incineration is safer.

Nanofiltration retains 40%–95% of organic compounds and multivalent ions and from –300% (negative retention by the Donnan effect) to +50% chloride ions depending on the concentration of multivalent ions. Retention is greatly affected by electrostatic forces, as discussed in Section 35.3.2, and sulfate ions, in particular, significantly affect the retention of chloride ions [24].

Typical membranes in NF are thin film composite membranes and their surface layers are mostly proprietary and not very easily identified by the user. Some industrial use of sulfonated polyethersulfone membranes has also been seen (see Section 35.6.2. Linpac recycle paper mill in Cowpens, South Carolina). Tubular and spiral wound modules are the dominating module type in NF and RO. Both membrane processes are used in industrial-scale applications in the pulp and paper industry (Table 35.1). When the membranes are installed in spiral wound modules, water pretreatment is often important to prevent plugging of the modules and fouling of the membranes.

## 35.5 SUITABILITY OF MODULES AND FILTERS

The large volumes of effluents or process streams to be treated in the pulp and paper industry require a large membrane surface area. The development of membrane modules has generally been directed to developing equipment with high packing densities, such as hollow fiber and spiral wound modules. Unfortunately, due to their small flow channels these modules tend to plug easily demanding feed streams free of particulate contaminants (e.g., fibers and suspended solids). To reduce the plugging tendency of spiral elements, more open flow channels and special spacer constructions have been developed. A further difficulty with maintaining high-flow rates in a spiral wound module is the fact that the flow rate also increases the pressure loss over the module and this will, when exceeding the upper allowed limit of the modules (typically 0.5–1.5 bar), devastate the module structure. Thus, with these types of modules the boundary layer, i.e., the concentration polarization layer, restricts the

flux and as a result the flux is often significantly lower than when high-shear modules are utilized. Despite these not so favorable properties of spiral wound modules, their packing density (membrane area/volume) is significantly higher than in tubular or in shear enhanced modules. Spiral wound modules are standardized so that different modules from various manufacturers can be used in the same pressure vessels. Therefore, spiral wound modules are available in a wide variety of membrane materials and the spiral configuration has been the least expensive per unit area of membrane. NF and RO membranes are typically used in spiral wound form and to operate successfully a sophisticated pretreatment is usually needed.

Hollow fibers have the highest packing density of the existing modules but fluxes are low. They are mostly used in MBR in the “outside-in” mode (MF and UF membranes) in the pulp and paper industry at close to subcritical fluxes to avoid fouling. In addition, their cleaning is improved by backflushing techniques. Aeration is used to minimize particle adhesion and concentration polarization.

Tubular modules are not easily plugged and can be used at high cross-flow velocity to minimize the concentration of retained substances on the membrane surface. Cross-flow velocity strongly influences the power consumption because under turbulent conditions the power will vary with the velocity raised to a power of 2.75 [47]. Unfortunately, flux is usually a function of the flow velocity and optimization needs to be done between power consumption (flow velocity  $\rightarrow$  flux) and the installed surface area of the membrane. Tubular modules are relatively easy to clean (even physical cleaning using foam balls is possible) and they can withstand some fibers in the feed water without becoming plugged. The inside diameters of tubular membranes vary from 12 mm (e.g., PCI tubular membranes, see Section 35.6.1.1) to 1.5 mm (e.g., capillary membranes from Norit membrane technology, see Section 35.6.3.1). Ceramic membranes are produced in tubular form such as single tubes or multichannel monoliths.

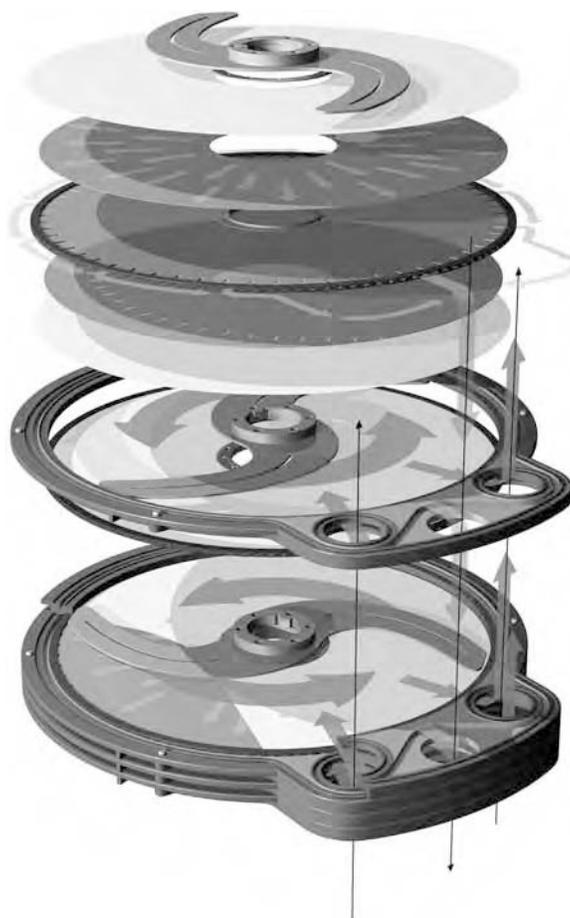

Because high fluxes and the ability to process streams containing suspended solids and fibers are often wanted in the pulp and paper industry, high-shear modules have been developed. Currently existing high-shear modules, excluding tubular modules, are modified plate and frame constructions. Both a cross-rotational module from Metso Paper and a vibration enhanced module (VSEP) from New Logic Inc. have been industrially used or tested in pulp and paper industry applications [48–51].

In cross-rotational ultrafiltration, the shear rate is generated by a rotating blade near the membrane surface, which forces the feed fluid to move with a high flow velocity across the membrane. The peripheral velocity of the blade can reach 13 m/s. Generally, only a coarse screening of the feed water is needed before the CR filter. Cross-rotational filters are available having membrane areas from 15 to 140 m<sup>2</sup>. The membranes are changed by opening the membrane stack and by simultaneously fitting new membranes to every plate or plates having damaged membranes. The industrial-scale CR filters were designed for ultrafiltration membranes. Some piloting tests have also been made with a modified module and nanofiltration membranes [18]. The principle of a CR filter is presented in Figure 35.3. As Table 35.1 shows, the CR filter is a commonly used membrane filter in the pulp and paper industry.

Another type of high-shear module, known as the vibrating shear enhanced processing (VSEP) filter, was introduced in 1991 by New Logic Inc. The VSEP is a vertical plate and frame-type construction, where membrane leaves are stacked on top of each other. One VSEP module has a membrane area of 14–140 m<sup>2</sup> in a horizontal footprint of only 1.2  $\times$  1.2 m. The CR filters and the VSEP have similar footprints. The maximum operating pressure is 38 bar. In this system, the membrane is moved and not the fluid. The VSEP employs torsional vibration of the membrane stack to generate shear forces at the membrane surface, an order of magnitude higher than those achievable in typical cross-flow modules. This reduces concentration polarization and colloidal fouling significantly and makes filtration possible with minimally pretreated streams. Another advantage of the VSEP filter is naturally a higher flux compared to low-shear filters. The energy consumption is claimed to be as low as 0.073 kW/m<sup>3</sup> of filtrate (tubular modules from 1.5 to 3.9 kW/m<sup>3</sup> [52]). The membranes are not changed individually, but the whole stack is changed when needed [50].

## 35.6 INDUSTRIAL APPLICATIONS AND CASE STUDIES

Industrial-scale applications using membranes in the pulp and paper industry go back to the 1970s and they were mainly concerned with bleach plant effluent treatment and spent sulfite liquor concentration for the recovery of lignosulfonates or energy [1]. In the late 1980s, the high-shear cross-rotational filter entered the market. This heralded probably the most efficient way to use membranes in the paper industry. The recovery of coating pigments using CR ultrafiltration is an economically extremely attractive process. In many cases the payback time of such a membrane plant is <1 year depending on the price of the recovered coating pigments. Either tubular modules or CR filters are mostly used for this application. More than 40 CR filters are recovering coating colors worldwide (Section 35.6.6). In the mid-1990s, two spiral-wound nanofiltration plants were installed for the treatment of total effluent from a paper mill (Section 35.6.3.1). By the end of the 1990s, MBRs were introduced in the pulp and paper industry (Section 35.6.3.2). The first industrial-scale MBR plant was installed in France, in 1999. Table 35.1 summarizes existing membrane filtration plants in the pulp and paper industry. The following sections focus on some recent examples of mill-scale installations as well as on relevant pilot- or laboratory-scale studies. The aim is also to review different types of applications.

### 35.6.1 PULP MILL APPLICATIONS

The idea in all pulping processes is to separate the fibers from the wood and to make the fibers suitable for further use, mostly for papermaking. The fibers can be separated from each other if the lignin, and, to a large extent, also the hemicellulose, is either dissolved and removed as in chemical pulping, or more or less softened as in mechanical pulping. There are, in principle, two ways to make chemical pulp, the sulfite and the sulfate (kraft) processes. These processes dissolve the lignin “glue” from the space between the fibers, and also degrade and dissolve some of the polysaccharides. Thus, the rather concentrated spent liquors from the pulping processes contain a large variety of wood-based compounds, their degradation products and also cooking chemicals. These streams represent a considerable pollution problem in the pulp and paper industry.

Bleaching of the pulp removes a large part of the residual lignin improving the color of the pulp. Bleaching chemicals such as chlorine, chlorine dioxide, hypochlorite, peroxide, ozone, and peracetic acid break down the lignin to different degrees and then the lignin is usually extracted in an alkaline stage. The strong color in the alkaline extraction stage effluent is due to the high molar mass lignin molecules. This high molar mass also makes their biodegradation difficult. In addition, the COD and the BOD load of the first alkaline extraction stage (E1) effluent is high. Low-molar mass chlorinated organic compounds (measured as AOX) are formed when chlorine chemicals are used in bleaching. They have mutagenic properties and they bioaccumulate, causing serious problems in the aquatic ecosystem. The E1 effluent represents only approximately 5%–10% of the total effluent load of the mill, but it contains about half of the color discharge of the mill. The bigger sizes of the molecules and their high charge densities due to high pH make the alkaline bleach plant effluent easier to filter than the previous chlorination stage (C-stage) effluents containing smaller molar mass compounds [32]. Therefore, many researchers have filtered the alkaline extraction stage effluents to remove color, to decrease the COD or the BOD load, to decrease the amount of chlorinated organic compounds in the effluents, and to purify the process waters or effluents for reuse [3,37,68–76]. The extraction stage effluents are typically concentrated by UF and the concentrate is burnt in the recovery furnace, where the cooking chemicals are recovered. The resulting filtrate is suitable for washing purposes.

Changes in the pulping and bleaching processes over the last 20 years from elemental chlorine to oxygen delignification and chlorine dioxide bleaching have caused corresponding changes in the composition of the spent liquors and process waters. The use of an increased amount of chlorine dioxide in the bleaching sequence has resulted in a lower discharge of organochlorinated compounds and their molar mass is lower. As a result, the biodegradability of the effluent has increased [77]. However, the introduction of oxygen-based bleaching agents does not seem to have removed the acute toxicity of the process discharges. Toxic compounds such as degradation products of extractives, such as resin acids, do not decompose easily and, therefore, pass into the effluent. To remove these compounds nanofiltration membranes have also been tested with bleaching effluents [3,35,37,68–70,78,80]. Filtration of acidic wastewaters from the chlorine dioxide, ozone, or chelation stages has also been studied but not as intensively as alkaline stage wastewaters [33].

### 35.6.1.1 Sulfite Pulp Mill Effluents

As early as in the 1970s, DDS reverse osmosis plants were installed in the Toten sulfite pulp mill in Norway and the Reed Lignosol mill in Canada. RO membranes were used to concentrate spent sulfite liquor to help the overloaded evaporation systems of the mill [1].

*Borregaard Industries, Sulfite Pulp Mill, Sarpsborg, Norway:* A UF plant with tubular membranes has been in use since 1981 in Norway (Borregaard Industries, Sarpsborg calcium bisulfite pulp mill, Table 35.1) for the fractionation of a lignosulfonate stream (spent sulfite liquor) into two streams, which are further processed into by-products. The composition of the spent sulfite liquor is affected by the type of wood pulped and the digestion process. The liquor typically contains approximately 60% lignin (lignosulfonates), 30% reducing sugars, and 10% inorganic material. The UF concentrate stream contains purified and concentrated lignosulfonates, and it is used for the production of vanillin. Other uses of purified lignosulfonates are, for example, industrial detergents, dispersants, precipitates, binders, and adhesives. By combining ultrafiltration with diafiltration, a purity of over 95% for lignosulfonates can be obtained [67,81].

The lifetime of the tubular membranes in the Borregaard industries' plant (1120 m<sup>2</sup>, PCI) has been about 1 year, when cleaning is made daily with an alkaline detergent. The tubular membranes need only a minimum of pretreatment and can even handle fibers. The 20 kg/mol cutoff polysulfone membrane has mostly been used at high temperature operation (70°C). In addition, a spiral wound RO (polyamide membrane from Osmonics) is used to concentrate the UF permeate from 7% of total solids to 14% before evaporation [47,67].

Generally, most of the sugars and the inorganic matter is found in the UF permeate, especially when diafiltration is used to treat the spent sulfite liquor. The sugars in the permeate stream can be fermented to alcohol (anaerobic process). Using spent liquor, a yeast (torula yeast) can live and multiply synthesizing protein (pekilo) that can be used as animal feed [81]. The sugars in the UF permeate stream or the original spent liquor can also be purified by chromatographic methods or by using nanofiltration. Hardwood hemicellulose, in particular, consists mostly of *O*-acetyl-(4-*O*-methylglucurono)-xylooligosaccharides in acid sulfite pulping to monosaccharides. Therefore, the spent acid sulfite liquor contains 240 kg xylose/t pulp when silver birch (*Betula Pendula*) is used as the raw material in pulping. Nanofiltration can recover the xylose in the permeate to a purity as high as 70% of dry solids [82]. The above-mentioned possibilities to use membranes for the utilization of sugars from spent liquors may become attractive to industries in the near future (e.g., for biofuels).

*Domsjö Fabriker AB, Sulfite Pulp Mill, Örnsköldsvik, Sweden:* The sulfite pulp mill of Domsjö Fabriker produces dissolving and papergrade pulps from spruce. Three CR1000/60-filters (3 × 84 m<sup>2</sup>) were installed in the year 2000 to treat process water after the brown pulp wash (Table 35.1). The filters operate in three stages at a recovery of 80%–90%. The ultrafiltration membranes separate lignin residues and resins and the concentrate is sent to resin recovery. The permeate is re-used in the cooking process and as sealing water. The permeate fluxes decrease with increasing concentration and range from 400 to 200 L/(m<sup>2</sup> h) [56].

*StoraEnso, Sulfite Pulp Mill, Nymölla, Sweden:* A reduction of the COD of the pulp mill effluent was the main goal when StoraEnso Nymölla in Sweden (Table 35.1) started to use tubular UF membranes to purify their oxygen bleach stage effluents [52]. Two production lines in the mill produce pulp from hardwood and softwood using the magnesium bisulfite process and oxygen bleaching (Table 35.2). The mill needed to reduce their COD emissions by 50% to get to an environmentally acceptable level to obtain the “Swan” mark. In addition, the mill wanted the removed COD (50% of the original COD) to be concentrated to 2% of the original liquid volume (a 50 time volumetric concentration) so that it could be incinerated. The dry substance in the concentrate is about 18%. The permeate is discharged to an activated-sludge plant [52].

Even though the ES404 membrane worked reasonably well with the softwood effluent (pH above 11), it fouled significantly with the hardwood effluent even when using a high cross-flow velocity. This forced the manufacturer (PCI) to develop a new more hydrophilic membrane, the EM006 membrane, for the hardwood effluent [52].

The cleaning interval ranges from once a day to twice a week depending on the stages and effluents. The guaranteed membrane lifetime is 15 months. The plant processes >300 m<sup>3</sup>/h of bleach effluents producing a concentrate stream of 6 m<sup>3</sup>/h [52]. The high UF operation temperature (>70°) eliminates the need for rapid cooling before the membrane plant and prevents precipitation of extractives on the membranes. Wallberg et al. [83] found that the presumptive fouling originated mainly from

<sup>a</sup> Higher cross-flow velocity with the hardwood line effluent.

organic compounds, but inorganics, mostly silicon, iron, and magnesium, also caused fouling. They also found that many of the membrane tubes were clogged with a clay-like precipitate consisting of fibers, organic material, and precipitated magnesium hydroxide.

### 35.6.1.2 Sulfate Pulp Mill Effluents

#### 35.6.1.2.1 Black Liquor from Sulfate Pulping

Black liquors from kraft pulping are complex mixtures of inorganic and organic compounds. The organic compounds originate mostly from carbohydrates and lignin degradation reactions. Minor amounts of extractives and cooking chemicals also exist in black liquors. The most common way to treat the black liquor is to burn it in a recovery boiler after it has been concentrated. In that way, the cooking chemicals are recovered and a significant amount of energy is produced.

Fractionation of black liquor using membrane technology has been studied in different groups since the late 1970s, but mill-scale systems have not been introduced. Both polymeric [84–88] and recently ceramic [89–92] membranes have been used to separate lignin from inorganic cooking chemicals. The black liquors are very alkaline, concentrated, and hot solutions and thus their treatment using membranes is challenging.

An increase in pulp production can lead to capacity problems in the recovery boiler. Keyoumu et al. [91] studied filtration of black liquor using ceramic ZrO<sub>2</sub>-coated membranes to lower the load on the recovery boiler in kraft pulping, and simultaneously they generated valuable side-products from the black liquor. The lignin degradation compounds isolated from the permeate of a 1000 g/mol cutoff membrane were highly phenolic in nature and could be polymerized to higher molar mass material from which, by further processing, new products could be made (special polymers).

Wallberg et al. [92] tested tubular ceramic UF membranes (Orelis, Al<sub>2</sub>O<sub>3</sub>-TiO<sub>2</sub>, cutoff 15 kg/mol) to concentrate lignin from kraft black liquor. The overall goal was to decrease the energy surplus of a modern pulp mill by removing lignin and converting it to a usable biofuel. During the UF concentration of very alkaline (pH 13–14) black liquor to a volume reduction of 10, the lignin content increased from 55 to 158 g/L (dry solids increased from 16 to 22 wt%) and at the same time the amount of cooking chemicals in the concentrate was significantly reduced. In addition, more than 50% of multivalent wood-borne elements (magnesium, manganese, and iron) were retained. The average permeate flux at 1 bar was 90 L/(m<sup>2</sup> h) at 90°C during the concentration to a volume reduction of 90% (at the end: 20 L/(m<sup>2</sup> h)).

Cortiñas et al. [89] eliminated colloidal suspended material (pitch) from kraft black liquors and partly recycled the liquor to the digester to reduce the consumption of chemicals. The colloidal pitch is formed by wood extractives. In particular, compounds such as waxes, sterols, and sterol esters that do not form soluble salts or dissolve during cooking form colloidal particles. The concentrated liquors (14%–15% solids) were filtered at high temperature using a 0.2 μm alumina membrane (USF Shumacher, Crailsheim, Germany). The pitch was almost completely retained (>99.9%), but the flux was sensitive to the black liquor composition and sometimes decreased to less than 100 L/(m<sup>2</sup> h).

### 35.6.1.2.2 Bleaching Effluents

Fälth et al. [93] ultrafiltered seven alkaline filtrates from kraft pulp mills. They observed that elemental chlorine free (ECF) and total chlorine free (TCF) filtrates from modern mills contain large fractions of low molar mass substances, which are not as well retained as the first alkaline stage effluent from a traditional mill. The membranes used were tubular polyethersulfone membranes (ES404, cutoff 4 kg/mol and EM006, cutoff 6 kg/mol) from PCI. The flux was mostly observed to depend on the concentration of the feed and slightly on the differences in feed composition. The fluxes varied from 100 to 400 L/(m<sup>2</sup> h) at 7 bar, 65°C and a cross-flow velocity of 4.1 m/s. The COD reduction was approximately 40% (traditional ECF mill 60%). The compounds causing the BOD were retained less than the compounds causing the COD. UF could thus be used before the existing biological treatment to decrease the amount of nonbiodegradable compounds in the effluent before biological treatment. Therefore, the load on the biological treatment plant decreased and the average biodegradability of the remaining substances increased [75,77,93,95].

Several authors have recently reported studies on metal removal from pulp mill wastewaters [95–97]. Tavares et al. [96] treated TCF bleaching wastewater by ultrafiltration and complexation using polymeric ligands (PVA, 60 kg/mol and PEI, 50 kg/mol) with ultrafiltration. The complexation improved the removal of COD and metals significantly, e.g., iron removal increased from 23% to 79%. Lastra et al. [97] used nanofiltration to remove complexed metal from a chelate stage effluent in a totally chlorine-free bleaching plant. The filtrations were made at 80°C using both composite aromatic polyamide membranes (PCI and X-FLOW membranes) and a ceramic membrane (titanium oxide supported on zirconium oxide from Rhodia Orelis). All membranes suffered from a significant flux decrease (cross-flow velocity 3 m/s) at flux values above 170 L/(m<sup>2</sup> h), which indicates that the critical flux was exceeded. The polyamide membranes gave almost complete rejection of the chelates of both iron and manganese ions. These ions are known to catalyze the degradation of hydrogen peroxide and as a result more bleaching chemicals are needed [97].

### 35.6.1.2.3 Evaporation Condensates of Sulfate Pulp Mills

Evaporation condensates are generated in the cooking digesters and in the black liquor evaporation units of kraft pulp mill processes. Evaporator condensates contain hundreds of volatile organic compounds and some extremely odorous compounds. For instance, methanol has been identified as a primary contaminant of concern. In addition, very odorous totally reduced sulfur (TRS) compounds such as hydrogen sulfite, methyl mercaptan, dimethyl sulfite, and dimethyl disulfite have also been identified in condensates. These compounds restrict its reuse without treatment. Foul condensates are typically treated in a biological effluent treatment system before being discharged to the environment [98].

*Irving Pulp and Paper's pulp mill in New Brunswick (Canada)* produces 280,000 t/a bleached kraft pulp without biological wastewater treatment (Table 35.1). In 1997, their discharge of BOD exceeded the regulated limit but the limited land area prohibited the implementation of conventional biological treatment. The mill identified a clean evaporator condensate stream carrying significant amounts of BOD and toxicity. An RO plant was installed in 1998 to purify the condensate. It produces 247.5 m<sup>3</sup>/h permeate that is recycled to the post-oxygen stage washer (and from there to the whole mill wastewater). The recovery, 99%, is extremely high and, thus, only 2.5 m<sup>3</sup>/h concentrate is sent to incineration to provide energy for the facility. The COD and BOD reductions are more than 90% and 80%, respectively, and the acute toxicity in the effluent discharge is virtually eliminated [60,61].

Membrane bioreactors have been tested for the treatment of foul condensates at various temperatures. The temperature of the foul condensates originating from kraft evaporators and digesters is around 50°C–70°C and an interesting option is to treat this stream using MBRs at thermophilic conditions without cooling the stream [98]. Dias et al. [99] used an MBR technique (0.03 µm hollow fiber membrane) to purify foul condensates from a Brazilian kraft mill (Eucalyptus) at different temperatures. They achieved a very high COD removal as shown in Table 35.3.

**TABLE 35.3**  
**Acclimatized Removal Efficiencies for Foul Condensate Treatment**  
**by Membrane Bioreactor (MBR)**

Parameter	MBR Treatment of Foul Condensate Foul Condensate	Removal Efficiency (%)		
		35°C	45°C	55°C

Note: TRS, totally reduced sulphuric compounds; nr, not reported.

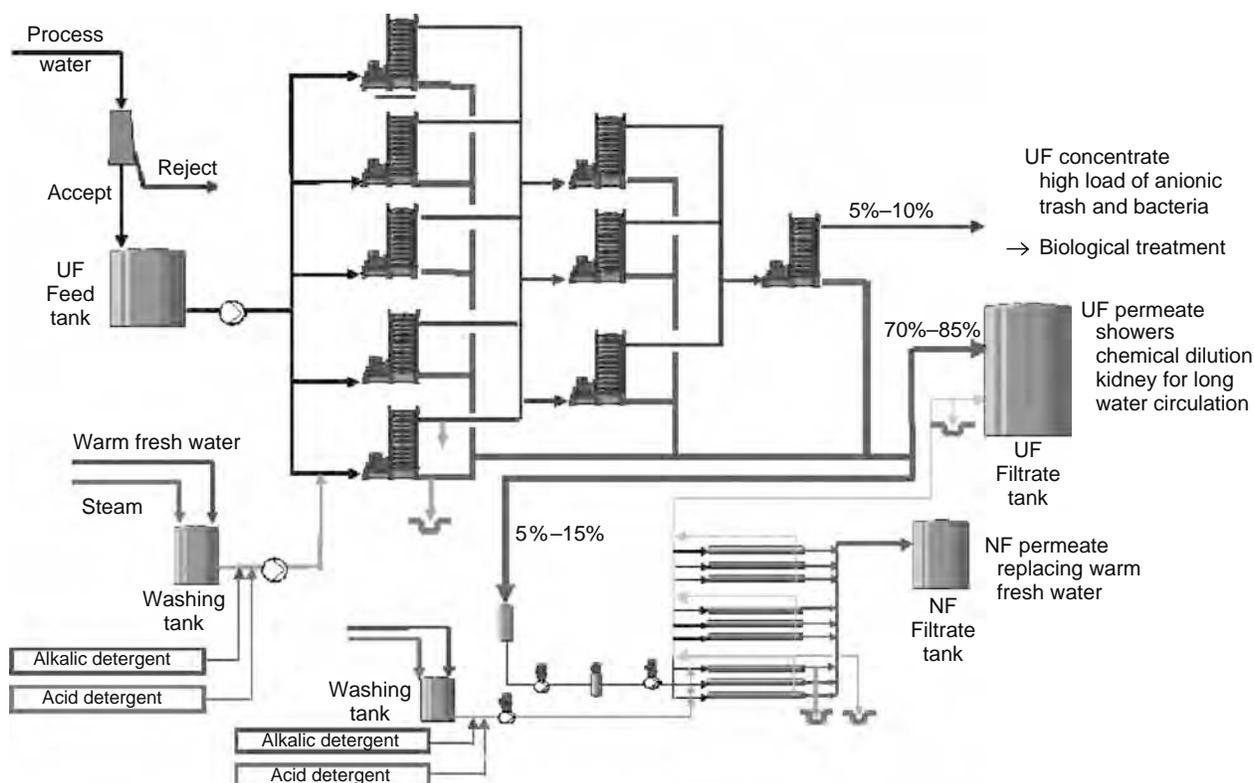

### 35.6.1.3 Mechanical Pulp Mill Effluents

*Champion International's pulp mill in Arapoti (Brazil)* tested a ZeeWeed MBR followed by reverse osmosis polishing to recycle thermomechanical pulp mill wastewater within the mill (Table 35.1). Over 4 months of tests showed that the system decreased the COD from 7800 to <20 mg/L. In addition, the total dissolved solids (TDS) content was reduced from 2000 to <300 mg/L in the RO permeate [65].

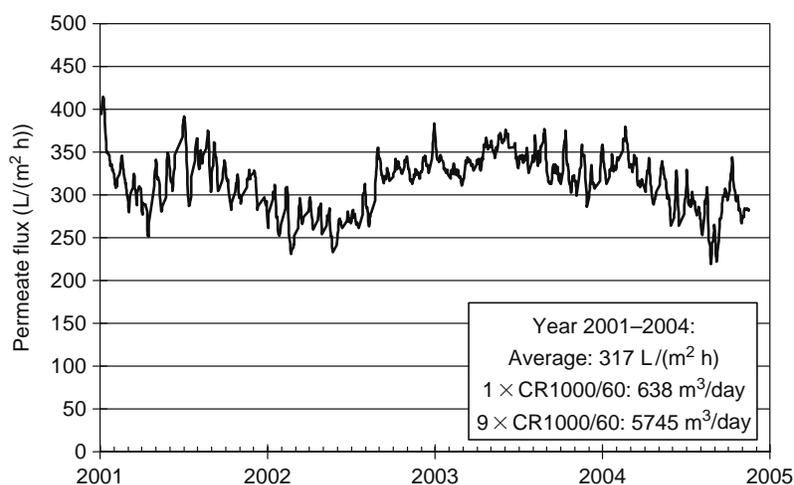

In Finland, groundwood mill circulation water was treated using an aerobic thermophilic suspended carrier biofilm process and different UF membranes [100]. The biofilm process did not increase the UF flux, which was about 400–500 L/(m<sup>2</sup> h) at 60°C–70°C with the original water using a CR filter and hydrophilic membrane. An 80% reduction in lignans and sugars was achieved in the biofilm process but the color of the water increased and was not reduced by UF. NF also efficiently removed colored compounds and its flux increased after biotreatment and when the pH of the original water (pH 5.3) was adjusted to pH 7 [101]. Nanofiltration also removes color efficiently when thermomechanical pulp (TMP) plant effluent was NF treated using an anaerobic bioreactor at thermophilic conditions as pretreatment [102]. Screw press filtrate from chemi-thermomechanical pulp (CTMP) mills has also been ultrafiltered [4,103].

### 35.6.2 PAPER MILL APPLICATIONS

*M-Real, Paper Mill, Kirkniemi, Finland:* Cross-rotational filtration technology was used in several mills for the purification of paper mill circulation waters, such as white water and clear filtrates [54,104]. M-Real Kirkniemi mill in Lohja (Finland) uses a total of 19 CR units for the treatment of white water from paper machines and for the recovery of coating color (Table 35.1). One paper machine produces 350,000 t/a coated fine paper from aspen-based mechanical and chemical pulps. When the fine paper mill was built, the authorities would not accept an increase in the effluent load. Thus, to lower the use of water, the mill decided to apply ultrafiltration technology. The first filter was installed in 1994. The permeate from the ultrafiltration system is used at the wire section showers and for chemical dilutions. A part of the UF permeate is led to nanofiltration. The permeate from the NF is led to a warm freshwater tank. The ultrafiltration is carried out in three stages (Figure 35.4). High shear on the membrane surface is the key to extremely high fluxes over long filtration periods. Figure 35.5 shows that an average flux over 300 L/(m<sup>2</sup> h) is obtained at a pressure of 0.8 bar and a rotor tip speed of 13 m/s. The UF membrane used (regenerated cellulose, cutoff 30 kg/mol) removes suspended solids, turbidity, and bacteria completely. The reduction of extractives (mainly anionic

trash) and COD is 50% and 10%, respectively. The washing frequency is every fifth day and the membrane lifetime is 15–26 months. The total operating cost for CR ultrafiltration was about 0.12€ per cubicmeter during 2001–2003. The nanofiltration unit operates at flux values of 30–40 L/(m<sup>2</sup> h) and its retention of organics (COD) is 85% and of inorganic matter (conductivity) 75% [53].

*Arctic Paper, Paper Mill, Munkedal, Sweden:* Tubular UF membranes have been used since 2002 in the Arctic Paper Munkedal mill to purify white water (Table 35.4) after sedimentation. UF removes the remaining suspended solids from the water before reuse in spraying applications in the wire section where it replaces fresh water [28]. The data in Table 35.4 are discussed further in Sections 35.6.3.1 and 35.6.3.2.

*Other Reported Studies:* Brady [105] has reported on UF systems (start-up 2000) for mill water recovery and reuse. The Koch tubular HFP-276 (PVDF) membrane used removes 50% of COD, TDS, and total organic carbon (TOC). The UF operating cost is \$1.6 per cubic meter. The plant operates continuously at a recovery rate of 98.7%. The feed stream and the mill are not reported.

Many studies have pointed out that a CR ultrafilter can operate at a flux level of 300–400 L/(m<sup>2</sup> h) when white waters are filtered. The reduction in organic compounds (COD, UV absorption at 280 nm, or sugar) using a UF membrane (cutoff 30–200 kg/mol) has been from 10% to 40% depending on the process water. The reduction of anionic trash is usually better (30%–90%) [48]. A pilot study showed that a high-shear filter (CR-nanofiltration unit) could operate without any pretreatment at a flux level of 50–120 L/(m<sup>2</sup> h) when paper mill clear filtrate was filtered. Mechanical erosion was a problem with some of the NF membranes used [18].

### 35.6.3 MEMBRANES COMBINED WITH BIOLOGICAL TREATMENT

#### 35.6.3.1 End-of-Pipe Treatment

In the mid-1990s, two spiral-wound nanofiltration plants were installed for the treatment of effluent from a paper mill. In both cases, the nanofiltration systems were installed to remove color, organic carbon, and dissolved solids from effluents for reuse or for further processing. Both plants had a very efficient pretreatment before the NF spiral-wound modules to prevent plugging of the filtration elements. For instance, the pretreatment included settling at several stages with chemicals, a sand filter, a back-washable screen filter, and a bag filter (5 μm) [106]. Neither of the plant is in operation today (P. Eriksson, personal communication, 2005).

*Papierfabrik Palm, Newsprint Mill, Eltmann, Germany:* Table 35.1 shows that Eltmann newsprint mill of Papierfabrik Palm has reduced COD, AOX, and color in their effluents using spiral-wound nanofiltration since 1999. Prior to NF, the effluent is biologically treated (activated-sludge plant) and prefiltered using sand filters. The capacity of the NF plant is 190 m<sup>3</sup> permeate per hour. The flux of the Nadir NF-PES-10 membrane has been around 10–30 L/(m<sup>2</sup> h) [107]. The NF-PES-10 membrane was chosen because of its alkaline stability (pH > 12), which was needed when cleaning the membrane. The reported COD removal is 89%, AOX 61%, and color 93% [59].

Table 35.5 compares the process water, freshwater, and NF permeate values for some parameters at the Eltmann. Water hardness measures divalent cations and is well retained in NF but the retention of conductivity is less than 40%. This is due to the negative retention of chloride ions, as often measured for NF membranes, because of the Donnan effect, which is typical for NF membranes. The reuse of NF permeate decreased the need to heat freshwater to the mill process temperature. The concentrate (36 m<sup>3</sup>/h) is recirculated back to the activated-sludge plant after lime precipitation. This precipitation process removes iron nearly completely (99.7%). The removal of color, carbonate, silicate, COD, and AOX are 72%, 66%, 61%, 40%, and 39%, respectively. However, only 10% of the conductivity (28% of sulfate) is removed by lime precipitation [59].

The reviewed mill-scale examples prove NF spiral-wound modules to be useful in the treatment of pulp and paper mill effluents but at the same time it must be concluded that extensive pretreatments are needed when spiral wound modules are utilized. This has also been pointed out in many pilot-scale studies where multilayer filters [108], flotation, and tight cartridge filters have been used before spiral wound modules [109]. Despite efficient pretreatments, the flux has commonly been only 10–40 L/(m<sup>2</sup> h) when NF membranes are used in spiral-wound modules.

*Arctic Paper, Paper Mill, Munkedal, Sweden:* In 1999, a tubular ultrafiltration unit (462 m<sup>2</sup>) was installed to polish 50% of the effluent from the Arctic Paper Munkedal paper mill in Sweden (Tables 35.1 and 35.4). The mill is located next to one of the finest

salmon rivers in the country and, therefore, there are high demands for environmentally friendly paper production, for example, by closure of the water circulation. The removal of dissolved organic matter (COD and BOD) varies from 10% to 50%. The permeate is discharged to an external pond and then to the river. About 20% of this water is reused as raw water in the mill [28]. *Papierfabrik Palm, Board Mill, Wörth, Germany*: The company produces corrugating medium and test liner from 100% recovered fiber (Table 35.1). The mill was started in 2002. It has ultrafiltered and NF/RO filtered its biologically treated effluent since start-up [107]. The plant was originally a zero liquid effluent mill (freshwater consumption 1.5 m<sup>3</sup>/t containerboard produced) but has now been allowed to discharge some cubic meters of effluent per ton of paper produced and the RO plant has been shut down (H.-J. Öller, personal communication, 2005). Table 35.4 summarizes some existing membrane applications where Norit tubular membranes are used.

### 35.6.3.2 Membrane Bioreactors

In an MBR two efficient water treatment technologies, namely membranes and biotechnology, are combined into one integrated system. The influent is fed to the aerated bioreactor where the organic compounds are oxidized by microorganisms in the activated-sludge, as in a conventional activated-sludge process. Instead of a clarification tank, micro- or ultrafiltration membranes are used to separate the water from the sludge. Interest in MBR in the pulp and paper industry has increased rapidly during the 1990s and there are currently some full-scale MBR installations in operation to purify selected effluents. In an MBR, the membranes can be installed inside the bioreactor (submerged membranes) or they can be externally installed (side-stream). Generally, hollow fibers (sometimes tubular or flat-sheets) are used inside the reactor. In a reactor with an external membrane unit, all types of modules can be utilized depending on the feed water characteristics. Some of the end-of-pipe membrane systems reviewed in the previous sections could also be counted as side-stream MBR processes [110].

The liquid volume of an MBR is lower than that of a conventional activated-sludge process. Biological processes (i.e., oxidation, nitrification, and denitrification) are exothermic reactions and thus the temperature in the MBR is higher than that in a conventional activated-sludge process. The high temperature and relatively low food to microorganism ratio makes the MBR generate less sludge. Most paper mills operate in a temperature of 50°C–70°C due to the positive effect of high temperature on productivity and energy consumption. Because biological water treatment can be done at the same temperature as the main process, energy is saved since cooling and heating steps are avoided. However, when the temperature increases, the sludge settling properties deteriorate [111–113] and COD removal often decreases in conventional activated-sludge plants. However, the settling problems are avoided in an MBR and some improvement in the COD removal can be achieved. In addition, the effluent from an MBR is free from suspended solids, bacteria, and, often, also from viruses [29].

An MBR operates at a high biomass concentration (up to 30 g/L) making a high volumetric load possible. It is also possible to obtain a long solids retention time or to maintain specifically active organisms to achieve the removal of poorly degradable compounds. This was pointed out when the performance of an MBR and an activated-sludge system for the treatment of a pulping process wastewater were compared. Furthermore, the MBR also adapts well to changes in feed characteristics [40,44,114–116].

*Papeterie du Rhin, Paper Roll Mill, France*: In 1999, Veolia Water STI installed an MBR with Zeeweed ultrafiltration membranes (pore size 0.04 μm) in Papeterie du Rhin's paper roll mill in France (Table 35.1). Recycled (not deinked) paper is used as the raw material. The bioreactor (1500 m<sup>3</sup>) is operated at a mixed liquor suspended solids (MLSS) content of 12–16 g/L. Brockmann and Praderie [58] report an average flux of 15 L/(m<sup>2</sup> h) at a pressure of 0.15 bar over a 1 year filtration period. The wastewater from the mill is first prescreened with drum screens, then sent to an equalization basin, from which it is pumped directly into the bioreactor. Table 35.6 summarizes the performance of the MBR process. The pressure used to draw the water through the membrane is 7–55 kPa. The filtrate is partly recycled as process water [27,57,58].

*Veiligheidspapierfabriek (VHP), Security Paper Mill, Ugchelen, the Netherlands*: Probably the second mill-scale MBR installation in the pulp and paper industry started in November 2000 in the Netherlands. Veiligheidspapierfabriek (VHP) Security Paper mill Ugchelen (Table 35.1) reuses the effluent from the bleaching process, cleaning it by dissolved air flotation (DAF) and an MBR. The installation reduces spring water intake, the costs of heating the spring water and the discharge costs for wastewater. The MBR operates at thermophilic conditions to save heating the water (temperature around 55°C). The membrane unit (82.5 m<sup>2</sup>) is installed outside the bioreactor (volume 250 m<sup>3</sup>) [27,28,57,117].

The mill bleaches raw cotton using sodium hydroxide and hydrogen peroxide. The effluent from the bleaching process has a high temperature (65°C–100°C), high pH (11.5), high oxygen consumption (average COD 3500 mg/L), and fibers. The DAF process is used for the removal of fibers. Instead of air, the DAF process operates with CO<sub>2</sub>-rich waste gas. In that way, the dissolved CO<sub>2</sub> partially neutralizes the effluent to a pH level of 8.2, (feasible for microorganisms) and simultaneously gas bubbles bind and lift the fibers to the surface of the flotation cell [27].

Before mill-scale installation, pilot MBR trials were carried out with pressurized Stork tubular UF membranes (Stork merged with Norit Membrane Technology in 2000) and submerged types of Mitsubishi capillary MF membranes. By increasing the temperature, the COD values of the effluent increased (Dias et al. [99] reported a similar trend, see Table 35.3). The effluent COD was around 1200 mg/L at 68°C and when the temperature was decreased to 50°C the COD in the effluent stabilized to 600 mg/L corresponding to more than 85% removal for COD. The amount of biomass generated was around 0.14 kg TSS per kg of COD. Hydrophilized polysulfone and polyvinylidene fluoride membranes were tested at different transmembrane pressures and flow velocities. Fluxes above 100 L/(m<sup>2</sup> h) were measured for both membranes at a cross-flow velocity of 3.5 m/s. With the submerged membranes the flux was only 15 L/(m<sup>2</sup> h) at a pressure of 0.1–0.3 bar, but the membrane price was lower (\$60 per m<sup>2</sup> against \$200 per m<sup>2</sup> membrane surface), and the submerged membranes did not need pressure tubes and cross-flow pumps. Thus, the total investment costs were more or less equal [27]. The MBR effluents, instead of freshwater, were tested in bleaching experiments and only an additional 10% of chemicals was needed to make the bleaching process as efficient as with ground water [117].

In the mill-scale plant above (Table 35.4), the MBR effluent COD is stabilized to about 500 mg/L (influent 3500 mg/L). By using the MBR to reuse the process water, the mill reduces the freshwater intake to bleaching by 80%, the mill wastewater discharge by 50%, and the gas consumption for heating by about 20% [28].

*Test Cases*: SCA Hygiene Products Suameer BV in the Netherlands has tested a concept where a DAF-unit is placed before a thermophilic MBR and salt is removed by electrodialysis or reverse osmosis. The mill produces tissue, in particular toweling and cleaning tissues. The hygienic paper produced demands for high-quality standards for the process water. Both organic and inorganic compounds need to be removed before reuse of the water. The COD in the feed to the MBR varies depending on the paper grade produced from 350 to 1350 mg/L and the MBR effluent COD stays below 200 mg/L (average 140 mg/L over a 200 day test period). RO and ED were tested and compared in such a way that the permeates after treatment were planned to have equal chloride concentration. The RO permeate had a lower content of COD and conductivity than the permeate from ED [117].

Papierfabrik Niederauer Mühle of Germany specializes in the production of bright white liner. They studied MBR and ED to remove organics and salt from their process water. More than 90% removal of COD and suspended solids was reported with the MBR corresponding to a COD level of 100 mg/L in the permeate [117].

Kimberly Clark's Delyn mill [114] demonstrated the suitability of MBR technology to treat and enable the reuse of water within the papermaking process. Submerged Kubota flat-sheet membrane panels were tested just using the hydrostatic pressure above the membrane pack to provide the driving force for permeate production. The pore size of the membrane was 0.4 μm but during operation the membrane became covered by a dynamic layer of protein and biological cellular material, and the effective pore size was evaluated to be <0.1 μm. Independent of the influent COD load (400–2100 mg/L) the MBR effluent COD remained around 100 mg/L. As observed in many studies, the MBR efficiently balances the variation of incoming water and produces a permeate of a relatively constant quality [58,114,118,119].

Full-scale tests using an internal circulation (IC) reactor from Paques and pilot-scale UF and RO membrane units (hollow fiber and tubular) from KOCH-GLITSCH were carried out at the VPK Oudegem paper mill in Belgium. Thermophilic anaerobic technology was combined with an aeration step and membrane filtration. The anaerobic process converts the organic compounds into methane, which can then be burned as a low cost-fuel for energy recovery. The COD was reduced by 50%–80% and sulfate ions were lowered by 30%–50%. The aeration step subsequent to the anaerobic reactor removes more than 50% of the calcium ions. Pauly and Deschilde [120] concluded that the combined thermophilic anaerobic system and the downstream aeration step were found to be at least as efficient as a mesophilic anaerobic process previously considered to be state-of-the-art in the paper industry. Biological pretreatment was found to increase the retention capability of the membranes from 5%–10% to 30%–40%. Operational stability was tested by long-term trials lasting for more than 1 year in the EU-Brite/Euram project: Paper Kidney. However, only the biological processes are currently implemented in full-scale operation.

Several effluent treatment options were evaluated at the AIPM paper mill in Herada, Israel, (Table 35.7). Stahl et al. [119] studied anaerobic treatment by an upflow anaerobic sludge blanket internal circulation bioreactor (UASB-IC, from Paques) before aerobic treatment. The effluent from the UASB-IC was then further treated by an aerobic activated-sludge-pilot (ASP,

pilot) and aerobic MBR. Significantly lower effluent concentrations of COD, BOD, and TSS were obtained when the MBR was used.

Lombardo et al. [115] and Dufresne et al. [116] have also compared an MBR and an activated-sludge system, both were efficient but the MBR was especially efficient in the removal of COD and acute toxicity.

#### 35.6.4 BOARD, RECYCLING PAPER, AND DEINKING APPLICATIONS

Generally, in board mills lower quality water is needed when higher quality papers, e.g., fine papers, are produced. For that reason many board mills have closed their water circulation systems. However, the more the system is closed, the more the circulated water has to be purified.

*McKinley Paper Company, Board Mill, New Mexico:* Table 35.1 shows that the McKinley Paper Company in New Mexico produces test liner from old corrugated containers (OCC). There is no water recipient near the mill to discharge even a minimal amount of effluent, and raw water availability is restricted because the mill is located in the desert of northwestern New Mexico. Thus, they have minimized their raw water consumption to only 1.5 m<sup>3</sup>/t board product. A waste stream of 3.3 m<sup>3</sup>/t board produced is cleaned and finally concentrated using MF and RO membranes. First, flotation is used to separate fibers, fines, and stickers from the water and then a sequenced batch reactor (SBR) type of activated-sludge treatment is carried out before membrane filtration. The effluent is aerated and clarified in the same basin, in sequence. The COD and the TSS content after biological treatment are 450–500 mg/L (retention 85%–90%) and 40–50 mg/L (retention about 80%), respectively. The efficient pretreatment enables the use of hollow fiber microfiltration (CMF, USF Memcor Ltd.) to remove suspended solids from the effluent to <1 mg/L. In addition, the permeate silt density index (SDI) is <3 and, therefore, the MF permeate is suitable for reverse osmosis treatment. A typical feed pressure in MF is 2.5 bar. During normal operation of the hollow fiber unit, the feed passes the fiber wall from the outside to the inside and an air backpulse is used from the inside to the outside for cleaning of the hollow fibers. The 0.2 μm membrane removes colloidal particles, bacteria, and also to some extent viruses, even metal particles and their hydroxides, algae blooms, yeast cell, etc. are removed [45,46].

The RO treatment removes salts and the concentrate is crystallized by a tube type of falling film evaporator and its condensate is recirculated back to the process. For example, when a stream at McKinley of approximately 660 m<sup>3</sup>/day is RO treated it results in a permeate of about 490 m<sup>3</sup>/day (1–1.3 m<sup>3</sup>/t product). The salt removal is needed because the high conductivity levels disturb the usability of the wet end chemicals [45,46].

*Linpac, Recycle Paper Mill, Cowpens, South Carolina:* The first full-scale commercial pressurized ozone membrane filtration system was tested and installed in the Linpac recycle paper mill in Cowpens, South Carolina (Table 35.1) for TDS removal [50]. The mill produces linerboard and medium for the production of corrugated boxes from an OCC and mixed office waste (MOW) furnish. The mill has no liquid discharge stream.

The principal idea of the pressurized ozone membrane filtration system is to convert total dissolved solids (TDS) to suspended solids, which are then more easily removed by membranes. The installed system consists of two processes. First, the

ozone is injected under pressure to react with the total dissolved solids of the process water, allowing the TDS to coagulate and agglomerate/precipitate as TSS. Second, ultrafiltration/nanofiltration is used to remove the coagulated and precipitated particles [50].

The Linpac linerboard mill has a two-stage tubular ultrafiltration system and VSEP filters as a kidney. The ultrafiltration systems (Koch membrane systems) treat the overflow from DAF clarifiers. TSS removal in the DAF units is improved significantly by pressurized ozone injection before the DAF. To reduce the concentrate (reject) volume from the UF system and to improve the reused water quality, a VSEP nanofiltration system has been installed to further concentrate the two stage UF concentrate [50].

The flux of the NTR-7450 nanofiltration membranes is 33 L/(m<sup>2</sup>h) at a pressure of 17 bar and a recovery of 72% (temperature 68°C–74°C). As Table 35.8 shows, the total solids in the NF concentrate is at a really high level, over 20%. The COD in the NF permeate is 3,100 mg/L, while it is 9,800–12,900 mg/L in the UF permeates. All permeates are returned to the mill [50].

*Deinking Studies:* One particularly dirty effluent is the deinking effluent, which contains printing colors. Deinking is a laundering process where chemicals, heat, and mechanical energy are used to liberate ink particles from the waste paper fiber and disperse them in an aqueous solution and finally remove them from the pulp. No commercial membrane applications exist in the area of deinking as far as the authors know. However, membrane technology has great potential particularly when paper containing water-soluble printing inks are deinked.

Conventional flotation deinking technology, such as flotation and washing processes, is widely used for deinking secondary fiber furnish that has been printed by the letterpress or lithographic (offset) processes. However, water-based inks used in flexographic news printing are ineffectively removed by conventional flotation due to their hydrophilic nature. The ink particles form a stable colloidal suspension of small hydrophilic particles in alkaline repulping conditions and are then too small (<5 μm) and hydrophilic to be removed in flotation cells. Their hydrophilic properties improve the likelihood of them being removed during washing. Washing is an efficient method to remove flexographic pigment dispersion from pulped secondary fiber, but it produces large quantities of filtrate, which can neither be directly recycled to the deinking process without detrimental effects on deinking, operation, and brightness of the deinked pulp nor discharged to the environment. Therefore, the flexographic pigments have to be removed from the wash effluent [121].

Several researchers have investigated the possibilities of membranes for the removal of dispersed water-based ink pigments from wash effluent [121–126]. Generally, membranes, in particular ultrafiltration membranes, have been found to completely remove ink pigments from effluent streams. It has also been observed that the permeate flux and the fouling tendency depend on operational conditions and effluent composition. For instance, coagulation pretreatment [125], feed water acidification [121], and surfactant addition [123] have been found to improve the flux and decrease fouling.

### 35.6.5 FRESHWATER TREATMENT

Purification of incoming water is carried out by membranes at Bahia Sul Celulose in Mucuri, Brazil (Table 35.1). The source of make-up water for the mill is a river that contains high levels of microscopic organisms and total dissolved solids. A reverse osmosis water purification system (capacity 360 m<sup>3</sup>/h, recovery 75%) was installed in 1991 to remove both dissolved solids and microorganisms. Despite various pretreatments before reverse osmosis (chlorination, flocculation, sedimentation, sand filtration, filtration through activated carbon) the membranes have suffered from high levels of biofouling that generates a high pressure drop on the system and demands frequent cleaning. After replacing the standard BW30–365 membrane with the new more fouling resistant BW30–365FR membrane (FilmTec, nowadays DOW) and optimising the operation (maximum flux 22 L/(m<sup>2</sup>h)) and cleaning conditions the fouling has been significantly reduced and the cleaning interval has been doubled to

12 days. The standard Platina-cobalt color test is utilized as a criterion to decide when to stop the alkaline cleaning. As a result, the mill saves a significant amount of chemicals. The salt retention is 98% corresponding to a permeate conductivity less than  $6 \mu\text{S}/\text{cm}$  [66]. The Stendal pulp mill in Germany (Table 35.1) also treats their raw water using RO [55].

### 35.6.6 RECOVERY OF COATING COLOR

Probably, the most successful application for membranes in the pulp and paper industry has been the recovery of coating effluents [127]. Although the volumes of coating wastewaters are negligible compared to the overall mill waters, they cause significant color in discharge water because they are not easily treated by conventional treatments. Furthermore, they represent a significant economical loss. Today, more than 40 mill-scale CR filters are recovering coating pigments. Zero effluents from the coating plants, recycling of the concentrated coating color, and reuse of the permeate are the main advantages when coating color is treated by membranes, mostly by UF [7].

The CR technology dominates the installations but tubular modules are also used [104]. Ultrafiltration recovers the color components in the coating color kitchen effluent streams, instead of them being treated with precipitation and used as landfill. The dilute effluents are concentrated with UF membranes to an appropriate total solids content after which the retentate is used in the preparation of fresh coating color. At the same time water is recovered in the permeate and can be used for dilution or washing purposes in the coating color kitchen. The payback time when treating valuable coating color is typically 1–2 years [36,128,129].

*ASSI Frövifors Bruk, Board mill, Frövifors, Sweden:* In 1991, two CR filters were installed at ASSI Frövifors Bruk board mill in Frövifors (Sweden) to concentrate and recover the waste latex coating from an air-knife coater. The 50 kg/mol cutoff polysulfone membrane produces a flux of  $200 \text{ L}/(\text{m}^2 \text{ h})$ . The mill uses  $\text{TiO}_2$  pigment, which makes the recovery process extremely economical. The UF operates at a constant concentrate solids concentration of 20% continuously for 10 days between cleanings [1,130]. When concentrating a standard coating color effluent steady flux of  $120 \text{ L}/(\text{m}^2 \text{ h})$  at a coating color concentration of 10%–15% ( $50 \text{ L}/(\text{m}^2 \text{ h})$  at 40%) is achieved [36].

*M-Real, Art Paper mill, Äänekoski, Finland:* Before their UF installation M-Real Äänekoski Art Paper mill in Finland lost 5.6 t of coating color every day, corresponding to 88% of the solids in the wastewaters. They installed UF in 1997 to recover 80% of the coating colors. A pilot-scale coating test showed that in pre-coating color the portion of recovered coating color could be even 30%, without decreasing the paper quality. However, because UF also concentrates bacteria, the slime level needs to be controlled when recycling coating colors [127].

*M-Real, Fine paper mill, Kirkniemi, Finland:* Alho et al. [127] reported a flux of  $120 \text{ L}/(\text{m}^2 \text{ h})$  in the filtration of coating color at another M-Real paper mill (Kirkniemi fine paper mill). High-shear modules can recover coating color from wastewater to a higher dry solids content than traditional modules. For example, a solids content of 60% has been reached by the CR and the VSEP filters [36,51].

### 35.6.7 MEDIUM DENSITY FIBERBOARD MANUFACTURING EFFLUENT

Several mill-scale RO plants have been installed for the treatment of wood plant effluents in medium density fiberboard (MDF) mills. Traditionally, the effluent is treated in a biological plant, although not very successfully. A very high BOD content and formaldehyde from the glue kitchen makes the effluent difficult to treat. Esmil Process Systems Ltd. has developed a process that recovers all suspended and dissolved solids from the MDF effluent and makes a zero discharge mill possible. The wood plant effluent is first flocculated and filtered in a filter press. The filter cake can be used as a substitute feedstock for the wood fiber board plant or incinerated. After a dual media sand–anthracite filtration, the effluent is treated in a spiral wound reverse osmosis unit. The hybrid process reduces the original effluent COD from 16,000 to 24,000 mg/L to a level of 6,900 mg/L before RO and the RO permeate contains 200–300 mg/L COD. Finally, the permeate is polished with a carbon filter. Water recovery for recycling as general process water, chip-washing, or boiler feed water is 90%–95%. The RO permeate is reused in the factory and the RO concentrate (COD around 200,000 mg/L) is simply sprayed on the fibers before pressing in the manufacturing process. In that way there is no effluent to treat and the sprayed concentrate actually improves the board quality and saves a little glue since the sugars polymerize during heating and form a glue-like material [63,64,67]. Finnemore and Hackley [64] reported the existence of three plants using RO in the year 2000 located in Kronospan's Chirk factory in North Wales (Table 35.1), in Sanem (Luxemburg), and in Poland. In addition, four plants were at that time under construction. The hybrid process used is according to the reports significantly cheaper (£1–£1.5 per cubic meter ultimate disposal) than a biological process (£5 per cubic meter), sewer treatment (£10 per cubic meter) or evaporation (£15 per cubic meter) [64].

## 35.7 ELECTRODIALYSIS AS POST-TREATMENT

Electrodialysis (ED) is a membrane separation process, which exploits an electrical field as the driving force instead of pressure. Charged compounds are separated by ion-exchange membranes. In the pulp and paper industry, ED is being studied for the

removal of chloride ions in the chemical recovery cycle of sulfate pulp mills [37,131]. Nanofiltration typically removes practically all multivalent ions but passes chloride ions even to such an extent that the concentration of chloride ions is higher in the permeate than in the feed (Donnan exclusion). Therefore, polishing of the permeate, e.g., using ED, may be needed. Fouling management of ED membranes is crucially important to avoid an increase in energy consumption. Fouling may also cause a loss in selectivity of the process. Especially, the anion-selective membrane was found to be markedly fouled when an alkaline bleach plant filtrate was processed [132]. Nanofiltration before ED could reduce the fouling in ED. Nanofiltration alone removes about 95% of the color and 90% of the organic compounds from the alkaline extraction stage effluents (E1 stage) and is thus an efficient pretreatment for ED [69]. ED has also been studied for removal of salt from MBR effluents (Section 35.6.3.2).

Geraldes and de Pinho [37] modeled NF permeate using a prepared salt solution to evaluate the feasibility of ED for the removal of chloride ions. The modeled permeates contained chloride ions from 1650 to 2250 mg/L depending on the water recovery. In that study, the quality requirements for the washing waters for pulp bleaching were 350 mg/L of NaCl and 30 PtCo units of color. The NF followed by ED met these requirements and the evaluated costs were \$0.65 per m<sup>3</sup> at 80% water recovery. Rapp et al. [131] reported the electrical power consumption of ED to be 0.97 kW h/kg chloride removed.

### 35.8 DEMANDS ON MEMBRANES TODAY AND IN THE FUTURE

The legislative restrictions (in 2006) are such that most pulp and paper mill wastewaters can be discharged after activated-sludge treatment. Furthermore, there are no restrictions in many countries on the intake of process water. In the future, there will most probably be limitations on the amount of intake water and the limitations for discharge loads will be tightened. The cost of freshwater will not decrease and this will force mills to increase their water reuse.

New regulations on water intake and mill effluent grades will constitute the driving forces for adopting membrane technology in pulp and paper mills. In Europe, the EU Directive on Integrated Pollution Prevention and Control (IPPC) will lead the pulp and paper industry to achieving a high level of protection of the whole environment. The IPPC includes a Best Available Technology (BAT) reference document, BREF, which refers to the pulp and paper industry. The BREF includes, among others, emission levels and flow rates for wastewaters (m<sup>3</sup>/t) and technologies regarding how to obtain these levels. This directive will come into force for existing mills from the year 2007 and will provide further opportunities for membranes in the pulp and paper industry.

One challenge is to find the right membrane and module characteristics for the different streams to be treated combined with the ability to withstand the physical and chemical nature of the streams. The combination of a temperature increase (70°C–90°C) with a high pH during filtration or cleaning makes great demands on the membranes. Furthermore, membranes can sometimes be exposed to oxidizers. High-shear conditions and rigid particles, or even fibers, can cause erosion on the membrane surface. Many applications today operate at high recovery and concentration. This sets limitations for membrane modules but high-shear modules can respond to that challenge.

A challenge will also be the further processing of concentrate or permeate streams. The recovery needs to be high so that the retentate stream can be incinerated, or other ways to treat the concentrate need to be developed. Evaporation or tighter membrane processes can be used to increase the dry solids content of the concentrate. Some mills recirculate the concentrate back to the wastewater treatment process, some sell it to the customer by binding the concentrate to the final product (MDF boards), and some use chemical precipitation to lower the impurities in the concentrate (e.g., Eltmann newsprint mill in Germany). The biodegradability of the concentrate can be enhanced by slight oxidation (e.g., ozone treatment). However, although there are several options to treat the concentrate, its destruction is often problematic.

Membranes should have high flux but at the same time also have the ability to retain small molecules for the permeate to be reused as wash water or make-up water at different places in the process. When membranes are used, fouling management is always crucially important. The development of polymeric membranes has been fast and will probably continue but in the most demanding applications ceramics might be the only solution. Their use has been restricted by the cost of the membrane material but costs will decrease with increased use and new manufacturing processes. However, polymeric membranes will also become cheaper in the future. Ultrafiltration and, in particular, nanofiltration are the membranes of the future when process streams are to be filtered. Ultrafiltration is also the right solution for coating color recovery. As the reviewed membrane installations show, membranes are needed for extremely many different purposes in the pulp and paper industry. This need will increase and more installations will undoubtedly be seen in the future.

### ACKNOWLEDGMENTS

The following persons and organizations are acknowledged for sharing their knowledge on membrane applications in the pulp and paper industry: Lasse Blom (Norske Skog), Peter Eriksson (GeOsmonics), Larry Stowell (New Logic Research, Inc.), Hans-Jürgen Öller (PTS), Peter Ohle (Zenon GmbH), Timo Sutela (Metso PaperChem Oy), Enrico Vonghia (Zenon), Margot Görzel (Microdyn-Nadir), Ryosuke Maekawa (Kubota Membrane Europe Ltd.), PCI, and NanoMemPro network.

## ABBREVIATIONS

AOX	adsorbable organic halogens
BAT	best available technology
BOD	biological oxygen demand
CA	cellulose acetate
COD	chemical oxygen demand
C-stage	chlorination stage

## 36.1 INTRODUCTION

Progressively stringent emission standards have prompted the development of innovative technologies for the treatment of both municipal and industrial wastewater. Perhaps the fastest growing technology in the wastewater treatment sector, the membrane separation bioreactor, generally designated the (MBR), was originally developed as a response to the need to achieve process intensification and the achievement of tighter emission requirements. Recently, the process has been adopted for water recycling applications [1]. Water recycling has become a reality in many countries, for example, 190 million cubicmeter of treated wastewater is reused annually in Japan [2] and the trend is increasing as the demand for water is rising.

The first commercial MBRs, in which an external microfiltration membrane module replaced sedimentation in the activated sludge (AS) process, were introduced in the 1960s by Dorr-Oliver Inc. [3]. Full-scale commercial MBRs entered service in North America in the 1970s, Japan in the 1980s, and Europe in the 1990s [4]. A reputation for excellent effluent quality

together with continuing improvements in process design and a dramatic reduction in membrane cost have seen the number of installations increase substantially in recent years. Several thousand installations now exist worldwide, typically treating effluent quantities of a few hundred cubic meters per day. Indeed, many processes are now operating at several  $1,000 \text{ m}^3 \text{ day}^{-1}$  and plans are advanced for MBR installations that will treat over  $100,000 \text{ m}^3 \text{ day}^{-1}$  [5].

The principal advantages of the MBR process over conventional wastewater technology are

1. Biomass retention is achieved by membrane separation rather than by gravity settling and therefore the process is insensitive to filamentous sludge bulking, and other floc settling and clarification problems commonly encountered in the activated sludge process. Moreover, the biomass concentration in the aeration tank is not dependent on the limitations of the secondary clarifier, thereby permitting typical mixed liquor suspended solids (MLSS) values of  $10,000\text{--}15,000 \text{ mg L}^{-1}$ , a factor four times higher than that in the conventional activated sludge (CAS) process. High volumetric reaction rates in the MBR, therefore, allow high carbonaceous conversion and nitrification rates to be achieved with short hydraulic retention times. Consequently, the size of reactor required is lower than the CAS process.
2. The long solids retention time (SRT) in the MBR is considered to be amenable to specialist slow-growing microorganisms necessary for the biodegradation of specific organic pollutants.
3. Because the membrane acts as a filter, the final effluent (permeate) is generally of a very high quality in terms of turbidity, bacteria, solids, and colloidal material. Rejection of bacteria and viruses is significant with average log reductions of up to 8 for total coliforms [6].
4. A long SRT combined with high MLSS concentrations results in a low-sludge yield. Sludge minimization is particularly an important advantage in the treatment of industrial wastewater, because such sludge is frequently classified as hazardous waste and therefore requires expensive treatment and disposal.

The engineering principles of MBR technology have developed to the extent that the process is reliable at large scale. However, the relatively poor understanding of the biological mechanisms contributing to performance, the inefficiencies associated with amelioration of membrane fouling, and poor oxygen transfer efficiencies are the three issues that need to be addressed if MBR technology is to fully mature. A significant research effort is under way to address these and other MBR performance-related issues, and it is likely that the performance of the process will continue to improve in the years ahead.

The purpose of this chapter is to review the critical factors contributing to MBR process performance and to report recent advancements in key areas. Coverage is directed toward membrane separation bioreactors, although recent developments in membrane biofilm reactors will be briefly discussed. Much of the current MBR research effort is directed toward municipal wastewater applications; however, substantial commonalities exist with respect to industrial wastewater application and where possible, reference is made to the specific aspects of the technology when applied to the treatment of industrial wastewater.

## 36.2 OVERVIEW OF MEMBRANE BIOREACTOR OPERATION

In wastewater treatment systems, the objective is to remove the maximum amount of pollutant at the minimum hydraulic residence time and with minimal production of biomass. Continuous reactors for biological wastewater treatment invariably employ cell recycle to elevate the biomass concentration and thus the productivity. The dominant wastewater treatment process in use today is the activated sludge process and its many variants. The MBR is essentially a variation of the AS process, whereby the sedimentation (secondary clarifier tank) is replaced by a membrane separation step to retain biomass and particulates in the bioreactor. Depending on the nature of the wastewater, the MBR may be configured with a single aeration tank or with separate aerated/unaerated tanks, with appropriate recycle systems. Membrane filtration occurs either within the bioreactor (submerged process) or externally through recirculation (external or sidestream process). Figure 36.1 outlines

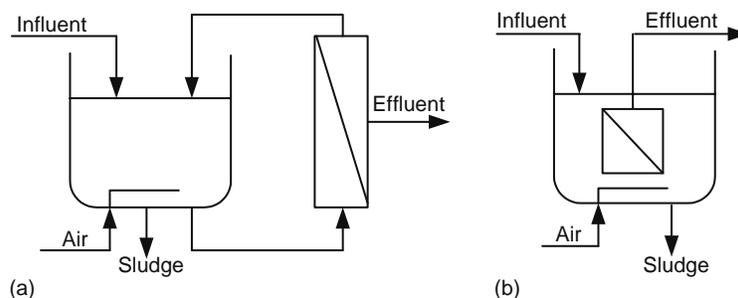

FIGURE 36.1 Schematic layout of (a) external MBR and (b) submerged membrane bioreactor.

schematically the two configurations. The membranes are generally UF or MF, which retain biomass and solids while allowing the water and nondegraded solute species to pass through the membrane. Although inorganic (ceramic) membranes have been used in some applications, capital cost considerations have favored the adoption of polymeric membranes in most MBRs to date.

In the external MBR process, an ultrafiltration or microfiltration membrane module in hollow fiber configuration is employed. In such a system, the driving force for mass transfer is the pressure created by the high cross-flow velocity (typically 2–4 m s<sup>-1</sup>). The membranes are backwashed systematically to remove solids and cleaned chemically at periodic intervals. Although the external MBR is no longer the dominant configuration, principally due to its high energy requirement, the system has some advantages compared to the submerged system, namely, higher permeate fluxes and ease of retrofit to existing biological treatment processes.

The development of the submerged MBR (sometimes known as the integrated MBR) arose out of the need to reduce the energy requirements and is now the dominant configuration in commercial use, particularly for municipal treatment applications. Membranes can be arranged in either hollow fiber (HF) or plate and frame (PF) configuration. In both cases the membranes are mounted in cassettes or modules comprising membranes, support structures, and associated flow connections. Coarse bubble aeration is used to scour the membrane, as a fouling control measure, whilst simultaneously facilitating oxygen mass transfer to the liquid. This system does not offer very high oxygen transfer efficiencies, but the rising bubbles provide a turbulent cross-flow velocity (typically 0.1–0.3 m s<sup>-1</sup>) over the surface of the membrane [7].

A direct comparison between the submerged MBR and external (sidestream) MBR has indicated that submerged MBR has an inherently lower fouling propensity as a result of the slug-flow hydrodynamic regime associated with the coarse bubble aeration [8].

A number of proprietary MBR processes are on the market, the majority of which are based on PF configurations, such as Kubota, or HF membranes, such as Zenon.

The Zenon ZeeWeed MBR process uses a submerged hollow fiber unit mounted vertically. A centrifugal pump is used to create negative pressure on the permeate side and wastewater is drawn into the lumen. For stable operation average fluxes in the region of 20 L m<sup>-2</sup> h<sup>-1</sup> would be typical under a driving transmembrane pressure of 0.2–0.5 bar [9]. Fouling control is provided by coarse bubble aeration, periodic backflushing, and occasional chemical cleaning of the membranes. Fine bubble aerators are required to supply the balance of oxygen. And MLSS concentrations of 10–15 kg m<sup>-3</sup> are typical [10].

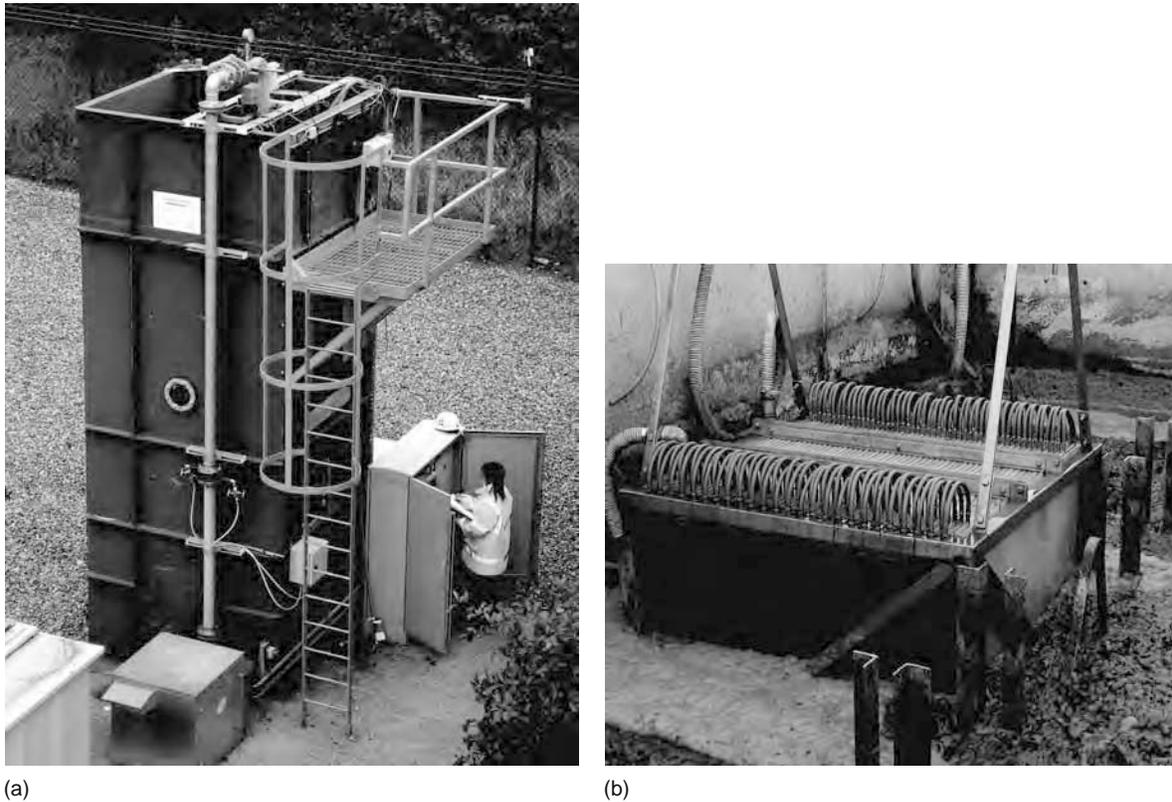

The Kubota MBR uses a flat-sheet membrane made of polyolefin with a nonwoven cloth base giving a nominal pore size of 0.4 mm. Each membrane cartridge consists of solid acrylonitrile butadiene styrene support plate with a spacer layer between it and flat-sheet membrane on both sides. Permeate is drawn through the membrane from the bulk fluid by a partial vacuum applied within the membrane plate matrix while retaining the solids in the reactor. The Kubota system operates by gravity, with a head of 1–1.5 m above the membranes sufficient to drive permeate through the membranes. Compressed air is introduced through a distribution manifold at the base of the membrane module. The MLSS is typically maintained within the range of 12–18 kg m<sup>-3</sup> [7].

In addition to the Zenon and Kubota processes, there are several other MBR products on the market from companies such as Mitsubishi Rayon, US Filter, GE Ionics, and Brightwater Engineering. Figure 36.2 shows the MEMBRIGHT process from Brightwater Engineering.

## 36.3 MEMBRANE BIOREACTOR PERFORMANCE

### 36.3.1 MUNICIPAL WASTEWATER CARBONACEOUS REMOVAL

Stephenson et al. [11] conducted a comprehensive review of MBR performance drawing on published data for installations ranging from laboratory scale to full commercial scale, and for a variety of process variants. For the treatment of municipal wastewater, volumetric loading rates ranged between 0.45–3.2 kg COD m<sup>-3</sup> day<sup>-1</sup> and 0.05–0.66 kg BOD m<sup>-3</sup> day<sup>-1</sup> with maximum reported wastewater strengths of 256 BOD<sub>5</sub> mg L<sup>-1</sup> and 900 COD mg L<sup>-1</sup>. Steady-state effluent concentrations were typically <10 BOD<sub>5</sub> mg L<sup>-1</sup> and 40 COD mg L<sup>-1</sup> corresponding to removal efficiencies of 95%–99%. Most MBRs treating municipal wastewater were operated at HRTs between 4 and 8 h. No discernable trend was evident with respect to the effect of HRT on performance. It was noted that the performance was dependent on SRT up to values of 20 days, beyond which no trend was evident. Gander et al. [6] compared the performance of MBRs treating municipal wastewater with the performance of several biological treatment processes. For a given strength of wastewater, organic loading rates in MBR processes are generally higher than that achieved in trickling filters, CAS process and the sequencing batch reactor, this can be attributed to shorter HRT utilized in the MBR. Removal efficiencies for the MBR tend to be higher than the trickling filter (65%–90%), conventional AS process (85%–95%), and sequencing batch reactors (85%–95%). However, to make such quantitative comparisons between effluent quality from the MBR and that from alternative biological treatment processes,

**FIGURE 36.2** (See color insert following page 588.) The MEMBRIGHT process from Brightwater Engineering (United Kingdom) showing (a) a typical plant and (b) the membrane module.

it is important to note that the superior effluent quality produced from MBR processes is as a result of both biological conversion of wastewater constituents combined with particulate retention by the membrane. In fact, the upper limit on permeate flux ultimately limits the loading rate of the MBR and significantly higher organic loading rates are achievable in the complete-mix AS and the BAF [6]. Objective comparisons between MBR and alternative processes are complicated by the sheer variety of reactor designs and size, membrane characteristics, operating conditions, and wastewater characteristics. Notwithstanding this difficulty, it is apparent that effluent quality and removal efficiency in MBRs, at least in terms of chemical oxygen demand and biological oxygen demand (COD/BOD), generally exceed that of all the conventional AS and trickling filter processes.

### 36.3.2 NUTRIENT REMOVAL

#### 36.3.2.1 Nitrification

Nitrification is a microbial process by which reduced nitrogen compounds (primarily ammonia) are sequentially oxidized to nitrite and nitrate. Nitrification is primarily accomplished by aerobic autotrophic bacteria that can build organic molecules using energy obtained from inorganic sources, in this case ammonia or nitrite. Various groups of heterotrophic bacteria and fungi can also carry out nitrification, although at a slower rate than autotrophic organisms. Nitrifying organisms are sensitive to a wide range of organic and inorganic compounds and at concentrations well below those concentrations that would affect aerobic heterotrophic organisms. The specific rate of nitrification in MBRs has been shown to be significantly higher than an equivalent activated sludge process, for example, Zhang et al. [12] achieved an average nitrification rate of  $2.28 \text{ g NH}_4\text{-N kg}^{-1} \text{ MLSS h}^{-1}$  compared to  $0.95 \text{ g NH}_4\text{-N kg}^{-1} \text{ MLSS h}^{-1}$  for CAS. The higher rate believed to be attributable to the enhanced retention of the slow-growing autotrophic bacteria in the MBR and also due to comparatively better mass transfer of nutrients and oxygen into the smaller MBR flocs. However, nitrification rate is sensitive to oxygen limitation and the high biomass concentrations in MBR processes present a challenge to effective and efficient oxygen transfer. Denitrification can be achieved in MBRs either by the use of an anaerobic tank separated from the aerobic tank or the use of intermittent aeration. The denitrifying organisms are predominantly facultative heterotrophs that reduce nitrate ( $\text{NO}_3^-$ ) in the absence of molecular oxygen. The organic content of the wastewater is the energy source for denitrification therefore the anoxic zone should be configured in a manner that ensures adequate carbon sources are available.

### 36.3.2.2 Denitrification

In most conventional WWTPs and MBR plants nitrogen removal is achieved by pre-denitrification [13]. In pre-denitrification systems, the anoxic denitrification tank is typically placed before the aerobic nitrification step. Nitrate is recycled from the aerobic tank to the anoxic zone. Alternative configurations exist but are less common, e.g., intermittent denitrification [13]. The advantages of pre-denitrification are that organic matter available in the anoxic zone improves denitrification rates, hence reducing the required reactor volume. Secondly, the oxidation capacity of nitrate degrades part of the organic matter, hence reducing oxygen demand and achieving savings in aeration requirement. Specific denitrification rates for MBRs are in the region of  $1 \text{ mg NO}_3\text{-N h}^{-1} \text{ g}^{-1} \text{ MLSS}$ .

In post-denitrification systems an anoxic tank is placed downstream of the aeration tank. As most organic matter is removed in the aerated zone, it is necessary to add an external carbon source to the denitrification tank. Kraume et al. [13] have discussed the particular characteristics of the MBR technology that may make post-denitrification a more attractive alternative. Low-denitrification rates in pre-denitrification MBR plants have been attributed to a combination of high-sludge age and a high-oxygen carryover to the anoxic zone from the membrane system. There is some evidence, which reported that overall nitrogen removal rates are higher with post-nitrification MBR processes than with pre-denitrification processes [13]; however, further research is required to confirm this.

### 36.3.2.3 Phosphorus Removal

Phosphorus removal processes can be achieved by two methods: chemical precipitation and biological removal. Current practice with MBR processes favors the precipitation method [14]. Biological phosphorous removal rates of over 99% were reported by Gnriss et al. [14]; however, P concentrations were below  $0.05 \text{ mg L}^{-1}$  (P-total). At higher concentrations ( $4 \text{ mg L}^{-1}$  P-total) removal efficiencies of about 75% are more typical [15]. In a six-stage MBR pilot plant [16], a combination of biological (using an initial anaerobic zone) and chemical (using alum) phosphorous removal was used to consistently achieve total phosphate concentrations of  $<0.1 \text{ mg L}^{-1}$ . The use of alum appeared to enhance the filtration characteristics of the sludge and to reduce membrane fouling. It is believed that the alum enhances the coagulation of the colloidal solids [16].

## 36.3.3 BENCHMARKING THE MBR AGAINST THE CAS PROCESS

A limited number of studies have been reported in which the MBR and AS are compared using the same wastewater. A 40 L MBR was compared to an 11 L AS process over an 80 day operating period using synthetic wastewater [17]. SRT values were 30 and 20 days for the MBR and AS, respectively, and all other conditions were identical, including the HRT which was maintained at 6 h. The MBR consisted of a ceramic tubular external membrane. Removal efficiencies for soluble components in the MBR were higher than the AS, for example, 99.0% vs. 94.5% for COD; 99.2% vs. 98.9% for ammonium; and 96.6% vs. 88.5% for total phosphorous, respectively. Interestingly, the sludge yield was lower in the CAS than the MBR the reason for which was attributed, in part, to the presence of certain types of protozoa, particularly ciliates, detected in the CAS sludge but not the MBR. Ng and Hermanowicz [18] investigated the performance and biomass characteristics of a membrane bioreactor (MBR) and a completely mixed activated sludge (CMAS) treating a synthetic wastewater. Both systems were operated at short SRT ranging from 0.25 to 5 days and hydraulic retention times of 3 and 6 h. Despite SRT values of as low as 0.25 days, the MBR removal efficiencies ranged from 97.3% to 98.4% (TCOD) in the MBR, compared to 77.5%–93.8% (TCOD) and 94.1%–97.0% (SCOD) in the CMAS. The superior performance of the MBR does not appear to be a result of higher biomass concentration. Instead, after analyzing the floc size and structure in both processes, it was speculated that improved mass transfer to the bacteria in the MBR contributed significantly to performance gain. The MBR biomass was composed of small, weak, and uniform-sized flocs with large mass of short filamentous organisms and a significant fraction of dispersed microorganisms. In contrast, the CAS sludge was composed of large flocs with filamentous organisms as a backbone. The yield coefficients for the MBR and CMAS system were  $0.42$  and  $0.35 \text{ g VSS g}^{-1} \text{ COD}$ , respectively. These were close to the theoretical maximum yield because at the relatively short SRT in this study, conditions favored biosynthesis rather than maintenance metabolism. Huang [19] compared variations in the SRT on the performances of the AS and MBR. COD removal remained constant at 90% in MBR but in the AS was 70%–80% with a slight decrease when the SRT was reduced to 5 to 10 days.

## 36.3.4 MICROPOLLUTANT REMOVAL FROM MUNICIPAL WASTEWATER

Micropollutant degrading bacteria generally have a low-specific growth rate and therefore the extended SRT in MBRs should favor the enrichment and growth of specialist bacteria with the ability to assimilate and mineralize specific pollutants. However, when making comparisons between processes, consideration must be given to the possibility that improved removal rates from the MBR may arise from the retention of such pollutants by adsorption on biomass particles rather than by improved biodegradation.

Joss et al. [20] studied the removal of estrogens in three municipal wastewater treatment processes (CAS, MBR, and fixed film). Specific-degradation rates for estrone and estradiol were higher in the MBR sludge than in the CAS sludge by a factor 2–3. It was suggested that the sludge age (30 days compared to 11 days, respectively) and floc size (10–100  $\mu\text{m}$  compared to 100–500  $\mu\text{m}$ , respectively) contributed to the difference in activity between the two processes. Recent study [21] on micropollutant removal was inconclusive on the relative merits of the MBR over CAS. Removal efficiencies ranging from complete (ibuprofen) to virtually zero (carbamazepine). Another recent study examined the potential of the MBR for water reuse applications [2], and showed high removal efficiencies for *Cryptosporidium* and coliphage. With respect to endocrine disruptors, no significant differences were observed between the MBR and the CAS processes [2]. It is evident that further research is needed on the detailed mechanisms of micropollutant removal in MBRs before firm conclusions on performance can be drawn.

### 36.3.5 CARBONACEOUS REMOVAL FROM INDUSTRIAL WASTEWATER

Table 36.1 summarizes the characteristics and performance data from selected published studies of MBRs applied to the treatment of industrial wastewater. Industrial wastewater is typically of a higher strength than municipal wastewater and this is reflected in the higher loading rates, typically in the range 2–16  $\text{kg COD m}^{-3} \text{ day}^{-1}$  for pilot and full-scale installations. COD removal efficiencies are typically greater than 90% and frequently greater than 95% for the reported studies. Corresponding HRT values were in the range of 45–240 h for pilot-scale studies and 36–54 h for the full-scale studies. HRT values are significantly longer than those of municipal applications reflecting the higher organic loading rates and the nature of the wastewater, frequently including oil and grease constituents. Sludge yield are generally quite low, perhaps as a result of the generally high MLSS values and long SRTs.

### 36.3.6 REMOVAL OF SPECIFIC ORGANIC POLLUTANTS FROM INDUSTRIAL WASTEWATER

Reemtsma et al. [27] performed a detailed analysis of the removal efficiencies of a variety of compounds from a tannery wastewater using a commercial scale MBR. The overall removal of aromatic compounds as determined by UV absorbance ( $\text{ABS}_{254}$ ) was 84%, a value significantly higher than that achieved from conventional treatment under similar conditions [28]. However, the removal efficiency of selected polar sulfur-containing aromatic pollutants of borderline biodegradability did not show significantly better results than the CAS process. Naphthalene sulfonates are used as dispersants and are commonly encountered as constituents in industrial wastewater. Reemtsma [27] reported 99% removal of naphthalene monosulfonates and 40% removal of naphthalene disulfonates. Higher removal efficiencies of these compounds have been reported for CAS and despite sufficient time for adaptation in the MBR and a sufficiently low concentration, no explanation for the poor removal of disulfonates was clear. Benzothiazoles are used as fungicides and as vulcanizing agents in rubber production. An average of 87% removal for all compounds in this category was observed in the MBR. However, the removal efficiency varied strongly among compounds in this group. These results indicated comparable, but not significantly better reports for the CAS system. Scholz et al. [23] investigated an oily wastewater-containing surfactant in a laboratory MBR with a typical retention time of 13.5 h. Overall hydrocarbon removal efficiency was >99%; however, this figure refers to the differences between influent and effluent concentrations, and does not take into account significant partitioning of oil and grease into the sludge. Analysis of the biodegradation efficiencies of selected aliphatics (C10–C24) showed that all fractions were degraded at comparable efficiency once sufficient time was allowed for bacterial adaptation. Zaloum et al. [25] reported degradation of an oily wastewater using an external UF MBR. Despite shock loads, excellent removal rates of oil and grease were obtained and total phenol removal was 96%. Morrison et al. [29] studied the removal of methyl tertiary-butyl ether (MTBE) in a 5.9 L MBR equipped with an external ceramic membrane. With a HRT of 1 h and an influent concentration of 5  $\text{mg L}^{-1}$ , removal efficiencies averaged 99.98%. Although it took 150 days to reach steady state, removal efficiencies were 76% within a few days of start-up.

The complex composition of industrial wastewater and the limited number of studies published to date do not allow a definitive conclusion to be drawn on the comparison between the MBR and conventional processes.

### 36.3.7 ENERGY CONSUMPTION

Energy costs account for a significant portion of the life-cycle costs of the MBR, whether sidestream or submerged [10]. Energy is required for pumping feed water, recycling of retentate, aeration and, in certain process variants, permeate suction. Substantial differences in energy consumption exist between submerged and external membrane configurations. External membranes require a high cross-flow velocity (2–4  $\text{m s}^{-1}$ ) and energy requirements in these processes is dominated by the energy associated with pumping. Energy consumption values in the range 0.045–140  $\text{kW h m}^{-3}$  product are reported by Gander et al. [6] for a variety of external processes. Typical values can be expected to be in the midpoint of the range. The wide range in values is a function of several variables including the membrane characteristics, packing density, and recycle flow rate. Aeration requirements contribute about 20% to the overall energy requirements of the external MBR processes. Typically fine bubble aerators are used which have standard oxygen transfer efficiency (SOTE) values of 25%–40% at 5 m depth. In the

submerged MBR systems aeration normally contributes  $>70\%$  to the overall energy cost. Coarse bubble aerators provide the dual function of scouring the membrane and providing oxygen to the microorganisms. However, coarse bubble aerators are less efficient than fine bubble aerators with SOTE values of 19%–37% at 5 m depth [6].

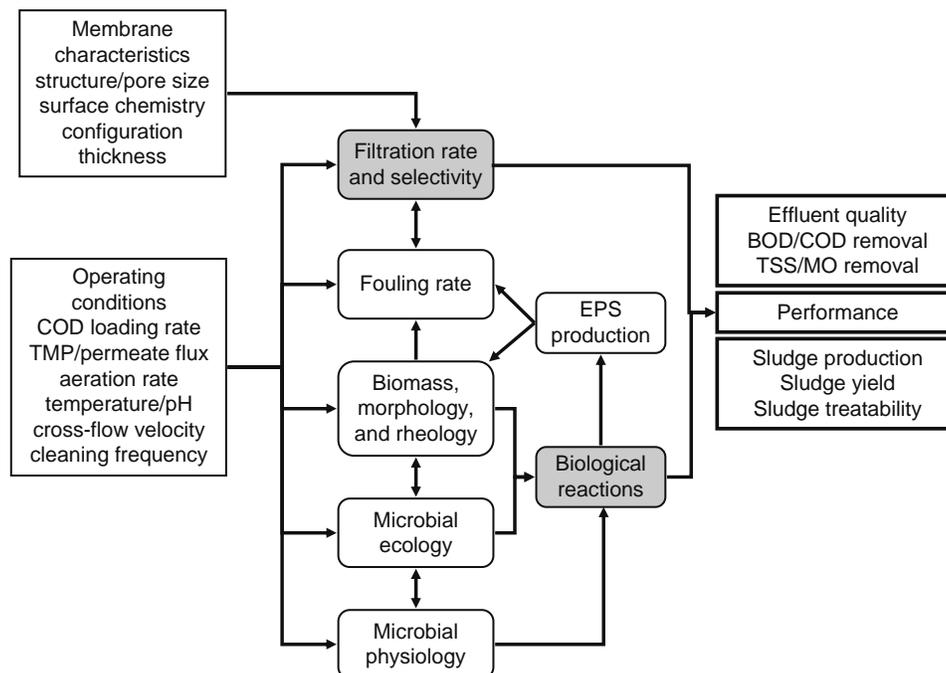

### 36.4 MECHANISMS CONTRIBUTING TO MBR PERFORMANCE

Evaluation of MBR process performance is quantified by two principal indicators: (i) effluent quality, incorporating carbonaceous and nutrient removal rate; and (ii) sludge characteristics incorporating yield and treatability. Although each indicator is ultimately determined by a combination of membrane filtration and a broad range of biological reactions, analysis of the process must be built on an integrated framework that incorporates each and every one of the interrelated factors influencing performance. Figure 36.3 schematically outlines the various interrelated factors determining process performance in MBRs. The current understanding of how these interrelated factors impact on MBR performance is discussed in the following sections.

#### 36.4.1 MEMBRANE FOULING

Perhaps the foremost problem that has limited the performance and consequent widespread adoption of the MBR process is membrane fouling. Fouling is a term that encompasses several mechanisms contributing to increased mass transfer resistance across the membrane. It is caused by the accumulation of biomass and particulate matter on the membrane surface, adhesion of macromolecules on the surface, and clogging of the membrane pores. The principal organic foulants in MBR processes are biomass solids, aggregated colloidal material, and extracellular polymeric substances (EPSs). Inorganic foulants include scalants such as calcium carbonate [7]. The relative contribution of different foulants to mass transfer resistance varies widely from study-to-study depending on the characteristics of the wastewater, biomass, and membrane and also the influence of chemical cleaning [30]. A recent study [31] used statistical analysis to investigate the contribution of several biomass characteristics, permeate flux, and the aeration velocity on the fouling rate in a pilot-scale submerged HF MBR. Only the permeate flux, the solid concentration, the carbohydrate concentration in the EPS, and the aeration velocity affected the fouling rate.

The aggregation rate of colloidal and particulate materials is dependent on the permeation rate, hydrodynamics, and surface forces between the membrane and colloid material, therefore fouling rates are system dependent. However, certain broad trends are evident with respect to fouling. Below a certain permeation rate the TMP varies linearly with flux and above this transition flux, a sharp increase in TMP is observed concomitant with a permeate flux decline. A time-dependent flux decline is also

**FIGURE 36.3** Schematic interrelationship between factors that determine process performance in MBRs. Wastewater characteristics are implicit in this outline. The term “biological reactions” includes exogenous and endogenous metabolism, extracellular enzymatic activity, and product formation (EPS).

observed. The critical flux hypothesis is that upon start-up, there exists a flux below which a time-dependent flux decline does not occur, while fouling takes place above this critical value [32]. It is known that the critical flux in MBRs depends on hydrodynamics, particle size, and membrane surface characteristics. Typically MBRs are operated below the critical flux to minimize fouling. However, the validity of the critical flux concept in MBR operation has been questioned recently since after prolonged operation irreversible fouling has been observed at subcritical fluxes [33].

The importance of biopolymer deposition on the membrane has been highlighted by Chu and Li [34] who noted that such material may accelerate bacterial attachment to the membrane in addition to its contribution to fouling resistance. The formation of a slime layer on the membrane, comprising an EPS matrix with embedded bacteria, may be analogous to a biofilm, the significance of which is the difficulty of its removal by nonchemical methods. The question of whether biofilm formation plays a significant role in MBRs is yet to be addressed. Indeed, a comprehensive model of fouling in MBRs is not yet available.

Because fouling rate is highly dependent on the flux, it is essential to optimize the TMP to achieve the best performance without exceeding the critical flux. Clearly the value of the critical flux is dependent on the system design, operating conditions, and wastewater characteristics. Gander et al. [6] report that for many submerged PF MBRs operating at TMP of <0.4 bar, the critical flux is not exceeded. In addition to flux control, several defouling strategies are employed. Coarse bubble aeration promotes the scouring of the membrane to suppress the fouling layer. In some systems (FP) the scouring action is accelerated under zero-flux conditions in an operation known as relaxation. For certain types of membrane (HF) periodic backflushing is employed whereby permeate flow is reversed for a short time, typically for 30–60 s every 15 min. High-frequency backpulsing (typically 0.1–2 Hz) is a very effective defouling approach but, at present, is only suitable for ceramic membranes [30]. Chemical cleaning is necessary in all MBRs after a certain time to remove biopolymers and colloidal residues from the membrane surface. The cleaning frequency can vary from up to 30 days for effluent treatment to every 6 months for water treatment applications [35]. The duration of chemical cleaning is typically in the region of 1–2 h [9]. The intensity or frequency by which these fouling amelioration strategies need to be applied will impact on the economic performance of the process. Inevitably the antifouling strategy will depend on the particular MBR configuration: for example, the Zenon system uses periodic backflushing and coarse bubble aeration scouring, while the Kubota process uses a combination of relaxation and coarse bubble aeration scouring.

### 36.4.2 BIOMASS MORPHOLOGY AND RHEOLOGY

The importance of biomass morphology on process performance relates to its impact on membrane fouling, volumetric reaction rate, adsorption of organic and inorganic particulate matter to flocs, and the treatability of sludge. It is generally acknowledged that biomass morphology in the MBR is markedly different to that of activated sludge in terms of floc size distribution, fraction of dispersed bacteria, and quantity and composition of EPS [36].

The floc, a heterogeneous aggregate of microorganisms and EPS, is the dominant component of the biomass in MBRs, as it is in an activated sludge. EPS is used as a general term for organic macromolecules such as polysaccharides, proteins, nucleic acids, lipids, and other polymeric compounds, which have been found to occur in microbial flocs and biofilms [37]. However, it must be stressed that a significant fraction of the total EPS present exists as soluble components in the bulk liquid. Although the mechanism of flocculation is poorly understood, it is generally accepted that EPSs are central to the aggregation of dispersed bacteria into floc particles. It is also known that hydrodynamic forces including turbulent shear stress contribute to floc size distribution, a mechanism of particular relevance to external MBRs with high cross-flow velocities [17]. Both small floc size distributions and a high fraction of dispersed microorganisms are factors generally regarded as advantageous from the perspective of soluble pollutant degradation. It is believed that mass transfer limitations in larger flocs may limit the reaction rate. This hypothesis was confirmed by Joss et al. [20] who used a mass transfer model to investigate differences between MBR and CAS processes for removal of estrogens from municipal wastewater. CAS floc sizes were in the range of 100–500  $\mu\text{m}$ , while MBR flocs were in the range of 10–100  $\mu\text{m}$ . Activity differences of a factor 3–4, favoring the MBR were found to be attributable to mass transfer limitations in the CAS flocs. It should be noted that mass transfer limitations are dependent not only on floc size but also on the specific reaction rate and on the substrate concentration in the bulk liquid. Nevertheless, high-volumetric removal rates can be expected when the biomass consists of a high fraction of dispersed bacteria and the floc size distribution is small. Indeed, several studies on MBR morphology have reported such a biomass composition. Zhang et al. [12] reported that samples from several MBRs showed the floc size distribution to be in the range of 7–40  $\mu\text{m}$  compared to 70–300  $\mu\text{m}$  from CAS. Witzig et al. [36] analyzed floc size and structures in MBR samples, over a prolonged period of operation. Samples of the sludge taken at regular intervals over the 351 day operation were analyzed and it was confirmed that the relative fraction of flocs to dispersed biomass was low compared to what would be expected in conventional AS.

A widely used parameter in the quantitative analysis of the oxygen transfer rate in wastewater treatment bioreactors is the dimensionless factor,  $\alpha$ , defined by the following equation:

$$\alpha = \frac{k_L a_{\text{sludge}}}{k_L a_{\text{water}}} \quad (36.1)$$

where  $k_1 a$  is the volumetric oxygen transfer coefficient. Several factors contribute to the value of  $\alpha$ ; MLSS concentration, loading rate, surfactant concentrations, and air flow rates, but it is primarily determined by the high apparent sludge viscosity, attributable to flocs, filamentous organisms, and EPS. In a survey of several MBRs, Drews and Kraume [38] reported that  $\alpha$  decreases from about 0.75 to 0.20 as the biomass concentration increases from 5 to 20 kg m<sup>-3</sup>.

The impact of biomass concentration on energy costs is substantial and clearly an optimum biomass concentration exists that maximizes volumetric reaction rate while minimizing the aeration costs. Most full-scale MBR plants aim to operate at a biomass concentration of between 10 and 15 g L<sup>-1</sup> [38]. The average  $\alpha$  value at typical MBR for municipal wastewater with an MLSS concentration of 12 kg m<sup>-3</sup> MLSS for municipal MBRs is about 0.6 [39]. A design value for  $\alpha$  of 0.5 has been recommended [40].

Biomass morphology also impacts on sludge treatability. Ng and Hermanowitz [41] showed that MBR sludge was more difficult to dewater than that from CAS operated under the same conditions. Values of the sludge resistance to filtration (SRF) in the MBR were, in fact, in order of magnitude higher than in the CAS (typically  $1 \times 10^{16}$  m kg<sup>-1</sup>).

### 36.4.3 MICROBIAL ECOLOGY

Microbial ecology in MBRs is an area that has received limited attention until relatively recently and yet, like morphology, substantial differences exist between MBR and AS processes. The poor understanding of microbial ecology in MBRs has limited full exploitation of the biological resource available in MBRs and indeed in biotreatment processes in general. Techniques such as fluorescence in situ hybridization (FISH) with rRNA-targeted oligonucleotide probes and PCR-DGGE have revolutionized microbial ecology research and are only recently being applied to MBRs. Klatt and LaPara [42] analyzed bacterial community dynamics in laboratory scale MBR inoculated with sludge from a conventional AS. It was observed that substantial shift in microbial activity and community structure occurred during the first few days of MBR operation and even after the MBR performance stabilized with respect to pollutant removal, the bacterial community continued to adapt its physiology possibly in a manner that optimized the performance. However, establishment of relationships between community dynamics and process performance requires significant further research. Witzig et al. [36] conducted phylogenetic analysis using FISH and revealed that the subclass  $\beta$ -proteobacteria constitute the dominant group of bacteria within the sludge community of a full-scale MBR. While this result was not unexpected when compared to conventional AS process, it is interesting to note that nitrifying activity in the MBR was not associated with *Nitrosomonas* and *Nitrosospira*, common constituent of conventional AS process. It is clear that microbial ecology differs significantly from the AS process.

### 36.4.4 MICROBIAL PHYSIOLOGY

In any wastewater treatment system, a fraction of the biomass can be categorized as (a) viable cells that assimilate substrate and are capable of division, (b) dormant cells, (c) nonviable cells that can use substrate but cannot grow, and (d) dead cells that have no activity, but still possess a cell wall [43]. Reported biomass concentrations (generally expressed as MLSS) in biotreatment processes may be misleading since they do not indicate the physiological state of the biomass. FISH with rRNA-targeted oligonucleotide probes is now being used to quantitatively investigate the population dynamics and viability of the biomass. Witzig et al. [36] used this approach to determine the overall physiological state of sludge from the MBR. The percentage of FISH detectable cells remained reasonably constant over the entire operating duration of 182–351 days. This is a significant result because it shows the stability of the sludge over long periods despite changes in environmental conditions in the MBR over this period. The percentage of cells with low rRNA molecules remained in excess of 50%. While this indicates domination of cells with low metabolic activity, it does not exclude the possibility that such cells participate in some metabolic transformation processes and contribute to the low observed yield in the MBR process. Hasar et al. [44] estimated the biomass viability in a submerged MBR to be in the region of 50%.

### 36.4.5 FACTORS CONTRIBUTING TO BIOMASS YIELD

Treatment and disposal of sludge from wastewater treatment plants has been estimated to account for about half of the total cost of wastewater treatment [45]. For this reason, the MBR has been receiving significant attention as a viable wastewater treatment technology in which the biomass yield can be expected to be significantly lower than conventional processes if operating conditions are appropriate. Indeed, several studies have demonstrated that zero net sludge production is attainable in MBRs provided the COD loading rate is sufficiently low. For example, Muller et al. [46] operated a full-scale external HF MBR for 300 days with a COD loading rate between 0.9 and 2.0 g COD L<sup>-1</sup> day<sup>-1</sup>. The observed sludge yield is approaching zero; however, this was achieved under such high biomass concentrations (MLSS of 45–50 g L<sup>-1</sup>) that oxygen transfer became limiting. Similarly, Benitez et al. [47] reported a net yield of zero in a laboratory scale external HF MBR over a prolonged period, but again the biomass concentration was relatively high (25 g L<sup>-1</sup>).

The microbial biomass yield coefficient from a carbon energy substrate mixture is defined as the dry weight of microbial biomass produced as a result of the utilization of unit weight of the carbon energy substrate mixture. Yield coefficients vary

remarkably depending on the environmental conditions imposed on the culture system and on the variability of those conditions. In practice, yield coefficient minimization is generally achieved by the exploitation of two separate mechanisms: (a) uncoupling of growth from respiration and (b) enhancement and of the death/lysis/cryptic growth cycle. The ability of the MBR to retain biomass at extended SRTs together with the achievement of relatively high biomass concentrations is advantageous as far as yield coefficient minimization is concerned.

### 36.4.5.1 Maintenance

Anabolic pathways synthesize the molecules (e.g., proteins, nucleic acids, lipids, and carbohydrates) required by the cell with the input of energy. Catabolic pathways break down large organic molecules, with the release of energy, into smaller constituents, which in turn serve as precursors for the biosynthesis via the anabolic reactions. Pirt [48] proposed that a portion of the total carbon energy source is consumed for anabolism and the remaining portion is utilized for maintenance. Maintenance is the collection of cell energetic requirements for survival or for preservation of a certain cell state, which are not directly related to or coupled with the synthesis of more cells. When an exogenous energy supply exists, a portion is diverted intracellularly to meet maintenance requirements and the remainder is used for synthesis. However, if the energy supplied equals the maintenance requirement, the cell mass does not increase, i.e., the observed yield is zero. When the energy supplied is less than the maintenance requirement, the difference will be met by utilization of internal energy supplies, i.e., endogenous metabolism. These concepts are exploited for yield coefficient minimization by operating the MBR in a manner that ensures that pollutant compounds are utilized preferentially for nongrowth cellular functions instead of biosynthesis. If all the substrate was utilized exclusively for anabolism, the net yield would be at its maximum, termed the true growth yield,  $Y_G$ . Substrate utilization for maintenance  $q_M$  is generally assumed to be constant. The relationship between the observed yield ( $Y_S$ ) and the true yield can be described by the following equation [2]:

$$\frac{1}{Y_S} = \frac{q_M}{\mu} + \frac{1}{Y_G} \quad (36.2)$$

Pirt's energy allocation model, in the form of Equation 36.2, is somewhat restricted for application in wastewater treatment. The value of  $\mu$ , the specific growth rate, is difficult to determine due to the variety of physiological states in the biomass, the variety of microbial species, each with different growth rates and substrate affinities.

Pirt's formulation can also be written in terms of the utilization rate of the substrate ( $r_S$ ), being the sum of that utilized by anabolism and that utilized by the biomass for maintenance requirements:

$$-r_S = \frac{-1}{Y_G} r_X - q_M X \quad (36.3)$$

$$r_X = Y_G(r_S - q_M X) \quad (36.4)$$

If it is assumed that  $Y_G$  and  $q_M$  are constant for a given system, it becomes apparent that the rate of biomass synthesis decreases as the biomass concentration increases. It is, therefore, possible to achieve a state in which the amount of substrate provided is diverted entirely to the maintenance demand if the biomass concentration is sufficiently high and consequently a zero sludge yield is achievable. However, high biomass concentrations may not always be desirable from an operational perspective due to difficulties in meeting oxygen demand and the impact on the membrane fouling rate.

### 36.4.5.2 Lysis-Cryptic Growth

Prolonged starvation forces a cell to deplete its endogenous energy supplies until vital functions (e.g., growth, replication, and osmosis) cease. The cell wall ultimately disintegrates with the release of internal components, a process known as lysis. It is important to note that starvation in itself does not initiate lysis [49], but the exact mechanisms for lysis are not yet clear. The products of cell lysis provide a substrate for microbial metabolism, because this autochthonous substrate cannot be distinguished from the growth on the original substrate, it is therefore termed as cryptic growth. Since a portion of the carbon is liberated by respiration, the process of lysis-cryptic growth contributes to overall yield reduction. Indeed, this has been exploited in treatment processes by the use of physical or chemical methods to promote a degree of cell lysis. For example, ozonation has been successfully employed in some processes [50,51].

### 36.4.5.3 Predation

It is becoming apparent that the exploitation of higher organisms such as protozoa, metazoa, and rotifers that predate on the bacteria and particulate organics is a potentially effective method for sludge minimization [45].

Protozoa are motile eukaryotes, the majority of which are aerobic heterotrophs. They are typically an order of magnitude larger than bacteria and often consume bacteria as an energy source. As far as MBRs are concerned it seems that protozoa and metazoa may not be as dominant as in CAS processes. Witzig et al. [36] analyzed samples from an MBR process and found that, with the exception of short periods after changes in operating conditions, protozoa and metazoa were rarely present in the sludge community.

Rotifiers are aerobic heterotrophic animal eukaryotes. They are very effective in consuming both dispersed and flocculating bacteria, and small particles of organic matter. Worms are the largest organisms observed in conventional AS and may have the potential to act as significant contributors to sludge reduction in MBRs. However, the necessary understanding of the connection between worm growth and the operational characteristics of wastewater treatment systems is still lacking [45].

### 36.4.6 EXTRACELLULAR MICROBIAL ACTIVITY

The breakdown and utilization of biopolymeric particulate matter is a common occurrence in wastewater treatment processes. Such material is defined as intact bacterial cell mass, particulate debris resulting from cell lysis and EPS. Bacteria, the major microbial component in most biotreatment processes, are not able to directly assimilate biopolymeric particulate material. The particulates must first be broken down into soluble poly- or monomeric molecules. Cicec et al. [17] conducted a comparison of extracellular enzymatic activity between AS and MBR treating wastewater with identical composition. A comprehensive enzymatic analysis of both soluble and particulate fractions of the mixed liquors in each reactor revealed several informative findings; overall activity was consistently higher in the MBR than in the AS; both systems produced enzymes specific for the degradation of the wastewater constituents only; no enzymes were detected in the MBR effluent, while considerable amounts were detected in the AS effluent; the enzyme concentration in the MBR soluble phase was higher than that in the AS. These findings suggest that the MBR is superior to the AS process in retaining both aqueous phase and particulate phase enzymes, a result that further confirms the performance potential of the MBR.

## 36.5 PROCESS ECONOMICS

Côté et al. [10] undertook a detailed economic analysis to compare the life cycle costs of the MBR to both the conventional activated sludge process and the CAS with tertiary filtration (AS-TF). A range of plant sizes were considered, treating between 3,800 and 76,000 m<sup>3</sup> day<sup>-1</sup> of sewage. The MBR consisted of a Zenon system with an average flux of 20 L m<sup>2</sup> day<sup>-1</sup>. Capital costs included the land costs in addition to the process. For the MBR, capital costs were lower than the CAS options on account of the savings associated with eliminating secondary clarifiers, reduced aeration tank volume, reduced footprint, all of which offset the additional cost of the membrane system and fine screen. Total operation and maintenance (O&M) costs were calculated to include labor, materials (including membrane replacement), energy, and chemicals (e.g., membrane cleaning). The O&M costs for the MBR were 20%–30% higher than the AS plant and slightly higher than the AS-TF process. Total life cycle costs were generated assuming 20 years of operation, 6% interest rate, 2.5% inflation rate, and an energy cost of \$0.10 kW<sup>-1</sup> h<sup>-1</sup>. The MBR had a life cycle cost of 5%–20% higher than CAS increasing with plant size, but was similar to the cost of the CAS-TF. Based on these calculations, it is evident that, at present, MBRs are best suited to small- to medium-size applications. Future developments in MBR technology will rely on methods that reduce the operating cost. Recent innovations have seen improvement in aeration efficiency by methods such as intermittent aeration or stacked membrane modules configurations.

## 36.6 NOVEL MEMBRANE BIOREACTORS: MEMBRANE ATTACHED BIOFILMS

The chapter focuses on membrane bioreactors where a UF or MF membrane is employed for biomass retention and filtration. However, membrane bioreactors where the membrane provides a support for biofilms are an alternative form of membrane bioreactor for wastewater treatment application. Two processes, in particular, the membrane-aerated biofilm reactor (MABR) and the extractive membrane bioreactor (EMB), have seen significant interest in recent years. Figure 36.4 shows these two technologies schematically. The application of biofilms reactors for wastewater treatment systems is advantageous in view of

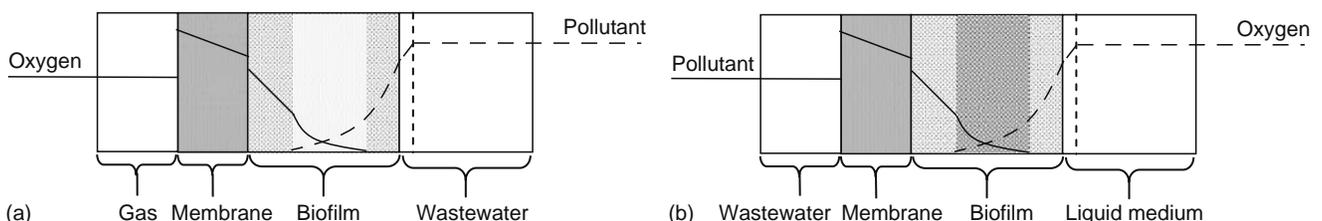

FIGURE 36.4 Schematic diagram of (a) MABR and (b) EMB.

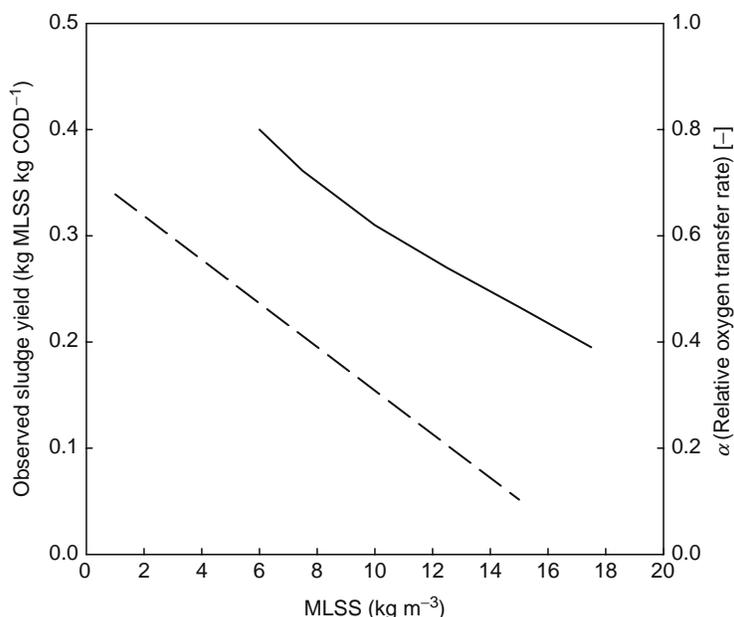

their potentially high volumetric productivity and the ability to completely uncouple SRT from HRT. These reactors are especially useful for slow-growing organisms, which would otherwise be washed out of the system, nitrifying biofilms being a case in point. Biofilm processes are simple, reliable, and stable because natural immobilization allows excellent biomass retention and accumulation without the need for separate solid-separation devices. Conventional biofilm reactors, such as the trickling filter, have traditionally been employed for applications such as nitrification.

In an MABR, first reported in 1978 [52], the biofilm is immobilized on an oxygen permeable membrane, typically in hollow fiber configuration. The membrane lumen is pressurized with oxygen, which diffuses through the membrane into the biofilm where oxidation of pollutants, supplied from the biofilm side of the membrane takes place. In the MABR, the membrane function is solely for oxygen supply as opposed to wastewater filtration. Indeed, dense membranes such as silicone are frequently employed in MABR systems. The MABR has been applied at laboratory scale for the treatment of VOCs [53], and for combined COD removal/nitrification/denitrification [54]. A recent study [55] demonstrated the potential of the concept at pilot scale; however, significant developments are needed, for example, with respect to biofilm thickness control before the commercial potential of the process can be realized [56].

Certain organic constituents in industrial effluents are present in sufficiently high concentrations to inhibit biological growth. The operating principle of the EMB is that organic constituents in the wastewater are selectively transported through a membrane into a compartment in which specialist degrading organism are present. In the EMB wastewater flows in the lumen of hollow fiber membranes and components such as phenol [57], chloronitrobenzene [58], and dichloroaniline [59] are selectively transported through the membranes into biofilms where biodegradation takes place. The EMB process is reviewed by Freitas dos Santos et al. [60].

### 36.7 CONCLUSIONS

There is now a significant body of evidence to demonstrate that the MBR can achieve excellent effluent quality and a reduced sludge yield compared with conventional aerobic biotreatment processes. The MBR has been proven at full commercial scale for both municipal and industrial wastewater applications and has developed a reputation for its high COD, BOD, nitrogen, and pathogen removal efficiencies. Nevertheless, many practitioners are hesitant to adopt MBR technology due to cost, reliability, and operating problems [61]. To address these issues, several engineering and scientific challenges remain to be addressed before the full potential of the process can be fully realized. Poor oxygen transfer efficiencies, particularly at high MLSS concentrations make the life cycle cost of the process uncompetitive against conventional processes. Figure 36.5 illustrates one of the dilemmas in MBR operation; high MLSS values are associated with reduced sludge yield, but there is a corresponding decrease in oxygen transfer efficiency (related to  $\alpha$ ) and therefore an impact on life cycle costs. Most MBRs in commercial operation are currently operated at permeate fluxes and biomass concentrations well below that theoretically possible to

**FIGURE 36.5** Trends in observed sludge yield coefficient (dashed) and dimensionless  $\alpha$ -factor (continuous) as a function of MLSS. Sludge yield calculated according to Equation 36.4, using the values of  $m_s$  and  $Y_G$  suggested by Wiesniwski et al. [62]. (Data for  $\alpha$  is from Cornel, P., Wagner, M., and Krause, S. *Water Sci. Technol.*, 47, 313, 2003.)

minimize fouling and oxygen transfer limitations, respectively. A detailed understanding of the relationship between process variables and microbial physiology, ecology, and morphology is still lacking. Insufficient data currently exists to confirm its superiority in removing micropollutants and organic compounds of borderline biodegradability.

It is likely that over the next decade, the ongoing research effort together with increasing operation experience will bring improvements in the technical and economic viability of the process that will accelerate the uptake of the MBR for both municipal and industrial wastewater treatment.

## ABBREVIATIONS

AS	activated sludge
BAF	biological aerated filter
BOD	biochemical oxygen demand
CAS	conventional activated sludge
CMAS	complete-mix activated sludge
COD	chemical oxygen demand
EMB	extractive membrane bioreactor
EPSs	extracellular polymeric substances
FISH	fluorescent in situ hybridization
HF	hollow fiber
HRT	hydraulic residence time
$k_{La}$	volumetric mass transfer coefficient
MABR	membrane-aerated biofilm reactor
MBR	membrane bioreactor
MF	microfiltration
MLSS	mixed liquor suspended solids
MO	microorganism
MTBE	methyl tertiary-butyl ether
O&M	operation and maintenance
PF	plate and frame
$q_M$	specific substrate utilization rate for maintenance
$r$	reaction rate
$S$	substrate concentration
SCOD	soluble chemical oxygen demand
SOTE	standard oxygen transfer efficiency
SRF	sludge resistance to filtration
SRT	solids retention time
TCOD	total chemical oxygen demand
TF	tertiary filtration
TMP	transmembrane pressure
TSS	total suspended solids
UF	ultrafiltration
$X$	biomass concentration
$Y_G$	true biomass yield coefficient
$Y_S$	observed biomass yield coefficient
$\alpha$	factor indicating effect of biomass on mass transfer coefficient
$\mu$	biomass specific growth rate

## 37.1 INTRODUCTION

Membrane-assisted solvent extraction processes have known an increasing number of applications in the last decades [1–4]. This technique not only overcomes the limitations of conventional liquid extraction, such as flooding, intimate mixing, limitations on phase flow rate variations, and requirement of density difference but also provides a large surface area of mass transfer per volume of contactor [5]. Excellent reviews of the technology and its applications were presented by Ho and Sirkar in 1992 [6], and by Gabelman and Hwang [7].

Not only the efficient removal of toxic heavy metals like hexavalent chromium (Cr(VI)), cadmium (Cd), zinc (Zn), nickel (Ni), etc., and other contaminants like phenol from industrial wastewaters [8–18] but also the recovery of valuable solutes from aqueous phases, for example, citric acid, carboxylic acids, amino acids, L-phenylalanine, etc. [19,20], are well-demonstrated applications of this technique.

From a practical point of view, it may be important not only to extract the solute but also to concentrate it [21]. For this reason, simultaneous extraction and stripping of the solute has been developed using two hollow-fiber (HF) modules in series, one for the extraction and the other for the back-extraction processes. The modules are connected to each other by an organic extractant in a recirculating line. This configuration guarantees that saturation of the carrier does not occur, as it is continuously regenerated and consequently the carrier concentration can be reduced maintaining the mass transfer rate, and therefore decreasing the associated operating costs of the process. Representative examples of the simultaneous membrane solvent extraction and back extraction of one solute can be found in the literature, for example, removal and concentration of valeric acid [22], sodium lactate [23], Cu [24,25], Cr(VI) [26], etc. Furthermore the technology has also been applied to the separation of the components of metallic mixtures such as the separation of a mixture of Cr(VI) and Cu(II) using LIX84 and H<sub>2</sub>SO<sub>4</sub> in the organic and back-extraction phases, respectively, for the recovery of Cu, and TOA and NaOH for Cr [27], the separation of Zn and Cu [28–30], and more recently the separation of Cd and Ni [30–32].

In addition to the conventional way that needs the use of two HF modules, different efforts have been directed to process design with minimum area requirement. A special configuration of HF modules, i.e., contained liquid membranes (CLMs), was investigated as an alternative trying to maximize the separation driving force in the membrane contactor by incorporating two different bundles of HFs; the aqueous phases flowed through the hollows of the bundles and the organic phase was contained in between them. However, since the first works [33–37], a number of experimental and theoretical analysis have been done on the two fiber membrane contactors, which do not show real advantages if the circulation rate of the organic phase is fast enough.

A somehow larger number of references have been published dealing with applications of supported liquid membranes [38–43]. When HF modules are used as contactors in this technology, the organic phase fills the pores of the HF and the aqueous phases flow along the fibers, through the inner side and through the outer side. The main drawback of the technology is the instability of the supported liquid membrane (SLM) that leads to undesirable results such as quick loss of efficiency and organic pollution of the aqueous phases [41].

More recently HF modules have been used in a different configuration that based on similar fundamentals tries to minimize the required membrane area, that is, emulsion pertraction technology. In this case, the organic and back-extraction phases are emulsified before the entrance to the HF module and they can be separated at the module outlet. Although there are only a few references to this alternative, its viability to the recovery of Cr(VI) and Cu from polluted waters [44–46] as well as to the removal of hydrocarbons [47] has been shown, but much effort is needed on the modeling of this technology before additional successful applications can be developed.

### 37.2 MODELING OF NONDISPERSIVE SOLVENT EXTRACTION OF MULTICOMPONENT METALLIC SOLUTIONS

The design of any process has to be supported by a proper understanding of the system behavior. Next, the kinetics of the simultaneous extraction and back-extraction processes of two metallic ions by membrane-assisted solvent extraction is analyzed theoretically.

Chemical reactions between metallic solutes and organic extractant in the extraction process, and between organic complex species and back-extraction agent, are assumed to take place at the inside wall of the membrane where the aqueous–organic interface is located. The mass transfer process of each solute from the initial phase to the receiving phase is considered to take place through the following steps: (1) diffusion through the feed aqueous layer, (2) interfacial chemical reaction, (3) diffusion through the HF membrane, and (4) diffusion through the organic phase layer. The order of steps is reversed during the back-extraction process.

Considering that the small diameter of the HFs forces the fluid to flow in laminar regime, two different approaches can be followed for the analysis of mass transfer in hollow-fiber modules:

1. The velocity and concentration profiles are developed along the HFs by means of the mass conservation equation and the associated boundary conditions for the solute in the inner fluid. This analysis separates the effects of the operation variables, such as hydrodynamic conditions and the geometry of the system, from the mass transfer properties of the system, described by diffusion coefficients in the aqueous and organic phases and by membrane permeability. The solution of such equations usually involves numerical methods. Different applications can be found in the literature, for example, separation and concentration of phenol, Cr(VI), etc. [48–51].
2. The mass flux of a solute can be related to a mass transfer coefficient which gathers both mass transport properties and hydrodynamic conditions of the system (fluid flow and hydrodynamic characteristics of the membrane module). The total amount transferred of a given solute from the feed to the receiving phase can be assumed to be proportional to the concentration difference between both phases and to the interfacial area, defining the proportionality ratio by a mass transfer coefficient. Several types of mass transfer coefficients can be distinguished as a function of the definition of the concentration differences involved. When local concentration differences at a particular position of the membrane module are considered the local mass transfer coefficient is obtained, in contrast to the average mass transfer coefficient [37].

Although the second approach can be considered a simplification of the first many systems have been satisfactorily described, and it is often preferred due to its mathematical simplicity. Studies on mass transfer through aqueous–organic interfaces immobilized at the pore mouths of a microporous membrane have shown that for a HF device, the overall mass transfer coefficient obtained can be related to the individual phase mass transfer coefficients and the membrane resistance using simple film theory. However, many authors considered that this separation controlling, overall mass transfer resistance was dominated by the resistance of the membrane. This is because the permeability of the membrane is low and because the membrane is thick [4,19,20,23,52,53]. On the other hand, other authors reported for different systems and conditions that the kinetic control of

the whole process could be shared between diffusion in the aqueous phase boundary layer and the kinetics of the chemical reaction [10,54–57].

Next, a mathematical model that allows description of the separation and concentration of the components of a metallic mixture will be detailed; the principal assumptions of the model are (1) convective mass transfer dominates diffusive mass transfer in the fluid flowing inside the HFs, (2) the resistance in the membrane dominates the overall mass transport resistance, therefore the overall mass transfer coefficient was set equal to the mass transfer coefficient across the membrane, and (3) chemical reactions between ionic species are sufficiently fast to ignore the contribution of the chemical reaction rates. Thus, the reacting species are present in equilibrium concentration at the interface everywhere [31,32,58,59]. For systems working under nonsteady state, it is also necessary to describe the change in the solute concentration with time both in the modules and in the reservoir tanks. The reservoir tanks will be modeled as ideal stirred tanks.

With the assumptions mentioned above two main parameters will be necessary in the description of the separation–concentration process of one solute, that is, the membrane mass transport coefficient and the equilibrium parameter of the extraction interfacial reaction.

As a representative example, the model will be applied to the separation of Ni and Cd by nondispersive solvent extraction with the mentioned assumptions; to avoid duplicate equations, the subscript “*i*” has been used, where *i* = 1 represents cadmium and *i* = 2 represents nickel.

### 37.2.1 EXTRACTION MODULE

Differential mass balances of the solutes in the feed and organic solutions in the extraction module are expressed through the following equations:

Aqueous solution extraction (EX):

$$-\frac{1}{v_A} \frac{\partial C_{A_i}}{\partial t} = \frac{\partial C_{A_i}}{\partial z} + \frac{2\pi n_f r_f}{F_A} K_m (C_{O_i} - C_{A_i}) \quad (37.1)$$

with boundary conditions

$$z = 0 \quad C_{A_i} = C_{out_i} \text{ (extraction tank)} \quad (37.2)$$

$$t = 0 \quad C_{A_i} = C_{A_i,initial}, \quad i = 1, 2 \quad (37.3)$$

where  $C_{O_i}$  is the interfacial concentration of the metal in the organic phase that is related to the aqueous metal concentration through the chemical equilibrium equation.

Extraction:

$$K_{\text{EX}} = \frac{(a_{\overline{\text{Me}_i\text{X}_n(\text{HX})_{m-n}}}) (a_{\text{H}^+})^n}{(a_{\text{Me}_i}) (a_{\overline{\text{HX}}_m})^n} \quad (37.5)$$

$$K_{\text{EX}} = \left( \frac{C_{\overline{\text{Me}_i\text{X}_n(\text{HX})_{m-n}}} C_{\text{H}^+}^n}{C_{\text{Me}_i} C_{\overline{\text{HX}}_m}^n} \right) \left( \frac{[\gamma_{\overline{\text{Me}_i\text{X}_n(\text{HX})_{m-n}}}] [\gamma_{\text{H}^+}]^n}{[\gamma_{\text{Me}_i}] [\gamma_{\overline{\text{HX}}_m}]^n} \right) \quad (37.6)$$

In a first approach, it is usually assumed that the ratio of the activity coefficients of the species in the organic phase keeps constant for a range of experimental conditions [60]. If the separation process is carried out at constant value of the pH of the aqueous phases the activity of the hydrogen ions,  $a_{[\text{H}^+]}$ , remains constant in the extraction and back-extraction processes and can be simplified, whereas the activity of the metallic solutes,  $a_{[\text{Me}_i]}$ , varies during the experiment since both the metal concentration and the activity coefficients change significantly with operation conditions. The corresponding values of the activity coefficient of the metal ions in aqueous solutions can be calculated using the Debye–Hückel equation. Also activity changes of complex species in the organic phase may be found, the modeling of the organic phase activity coefficients usually introduces empirical considerations. Therefore, Equations 37.5 and 37.6 can be expressed as follows:

$$K'_{\text{EX}} = K_{\text{EX}} \frac{[\gamma_{\overline{\text{HX}}_m}]^n}{[\gamma_{\overline{\text{Me}_i\text{X}_n(\text{HX})_{m-n}}}]^n} = \left( \frac{C_{\overline{\text{Me}_i\text{X}_n(\text{HX})_{m-n}}} C_{\text{H}^+}^n}{C_{\text{Me}_i} C_{\overline{\text{HX}}_m}^n} \right) \frac{[\gamma_{\text{H}^+}]^n}{[\gamma_{\text{Me}_i}]} \quad (37.7)$$

Organic solution:

$$\frac{1}{v_O} \frac{\partial C_{O_i}}{\partial t} = -\frac{\partial C_{O_i}}{\partial z} + \frac{2\pi n_f r_f}{F_O} K_m (C_{O_i} - C_{O_i}) \quad (37.8)$$

Boundary conditions of the organic phase:

$$Z = 0 \quad C_{O_i} = C_{out_i} \text{ (organic tank)} \quad (37.9)$$

$$t = 0 \quad C_{O_i} = C_{O_i,initial}, \quad i = 1, 2 \quad (37.10)$$

### 37.2.2 BACK-EXTRACTION MODULE

The extraction and back-extraction steps take place consecutively, connected by the concentration of the metal-extractant complex species in the organic phase. The description of the back-extraction process is carried out using similar equations to those used in the extraction process. The equilibrium of the interfacial reaction between the organic complex species and the back-extraction agent is applied in this case.

Aqueous solution back extraction (BEX):

$$\frac{1}{v_S} \frac{\partial C_{S_i}}{\partial t} = -\frac{\partial C_{S_i}}{\partial z} + \frac{2\pi n_f r_f}{F_S} K_m (C_{O_i} - C_{O_i}) \quad (37.11)$$

Boundary conditions for the stripping aqueous phase:

$$z = 0 \quad C_{S_i} = C_{out_i} \text{ (stripping tank)} \quad (37.12)$$

$$t = 0 \quad C_{S_i} = C_{S_i,initial}, \quad i = 1, 2 \quad (37.13)$$

with the equilibrium back-extraction reactions

$$k_{BEX} = \frac{(a_{[Me_i]}) (a_{[(\overline{HX})_m]})^n}{(a_{[Me_i X_n (HX)_{m-n}]} (a_{[H^+]})^n} \quad (37.15)$$

and

$$K_{BEX} = \left( \frac{C_{Me_i} C_{(\overline{HX})_m}^n}{C_{\overline{Me_i X_n (HX)_{m-n}}} C_{H^+}^n} \right) \left( \frac{[\gamma_{Me_i}] [\gamma_{(\overline{HX})_m}]^n}{[\gamma_{\overline{Me_i X_n (HX)_{m-n}}}]} [\gamma_{(H^+)}]^n \right) \quad (37.16)$$

that with similar assumptions to those made in the extraction reactions would transform into

$$K'_{BEX} = K_{BEX} \frac{[\gamma_{\overline{Me_i X_n (HX)_{m-n}}}]^n}{[\gamma_{(\overline{HX})_m}]^n} = \left( \frac{C_{Me_i} C_{(\overline{HX})_m}^n}{C_{\overline{Me_i X_n (HX)_{m-n}}} C_{H^+}^n} \right) \left( \frac{[\gamma_{Me_i}]}{[\gamma_{(H^+)}]^n} \right) \quad (37.17)$$

Organic solution back extraction (BEX):

$$-\frac{1}{v_O} \frac{\partial C_{O_i}}{\partial t} = \frac{\partial C_{O_i}}{\partial z} + \frac{2\pi n_f r_f}{F_O} K_m (C_{O_i} - C_{O_i}) \quad (37.18)$$

Boundary conditions of the organic phase:

$$z = 0 \quad C_{O_i} = C_{O_i} \text{ (outlet extraction module)} \quad (37.19)$$

$$C_{O_i} = C_{O_i,initial}, \quad i = 1, 2 \quad (37.20)$$

### 37.2.3 STIRRED TANKS

In a batch process the dynamic response of the system is determined by simultaneously solving differential Equations 37.1 through 37.20 together with the modeling equations for the three vessels considered as ideal stirred tanks. It is assumed that the solute concentrations at the reservoir and at the module inlet for both phases are identical.

$$V \frac{dC_{out_i}}{dt} = F(C_{in_i} - C_{out_i}) \quad (37.21)$$

$$t = 0 \quad C_{out_i} \text{ (organic tank)} = C_{O_i,initial} \quad (37.22)$$

$$C_{out_i} \text{ (extraction tank)} = C_{A_i,initial} \quad (37.23)$$

$$C_{out_i} \text{ (stripping tank)} = C_{S_i,initial} \quad (37.24)$$

Consequently, the most basic model can be considered to describe the separation of metallic mixtures using HF membranes. It consists of a set of coupled differential equations corresponding to the mass balances of the metallic solutes in the extraction and back-extraction modules, a set of algebraic equations corresponding to the description of the chemical equilibrium reactions, and for batch processes six total differential equations additionally describing the mass balances in the stirred tanks. The use of the mathematical model would require the knowledge of the design parameters, that is, the membrane mass transport coefficient and the parameters of the interfacial chemical equilibria. The model can be generalized and applied to the determination of the response of different systems containing more than one solute.

#### Case study 1: Separation of cadmium and nickel

The case study of multicomponent solvent extraction using HF modules is the separation of Ni and Cd from concentrated solutions that simulated those generated during the leaching step of the recycling process of Ni–Cd batteries. Feed solutions contained the metals in a high concentration range of 0.2–0.4 M, thus an organic phase where the organic extractant has a high concentration value was also needed. Among the commercial extractants available for the separation of Cd and Ni, di(2-ethylhexyl) phosphoric acid has been reported to give excellent results; the extractant was diluted in kerosene that acted as solvent and a third component had to be added to avoid the segregation of a third phase (second organic); tributyl phosphate (TBP) is one of the most common compounds used for this purpose. Finally, a sulfuric acid solution acted as back-extraction phase.

For simultaneous extraction (EX) and back extraction (BEX), two HF modules in series are needed; the organic phase flows from the EX module to the BEX module. In the first module, extraction of solutes is accomplished by the organic phase that contacts the back-extraction solution in the second module, flows to the homogenization tank of the organic phase, and enters again the extraction step (Figure 37.1). Aqueous phases flow through the inner side of the microporous HF membranes whose pores are filled with the organic extractant, and the organic extractant flows concurrently in the shell side in both HF modules.

The mathematical model for the description of the separation kinetics of Cd and Ni in HF modules under non-steady-state conditions has been explained in detail in the previous section. The competition of both components in the complexation reaction with the organic carrier is assumed to be the main difference in the permeation rates of the two components (separation process). This ratio depends on the difference of the individual equilibrium parameters rather than in the different diffusivity of

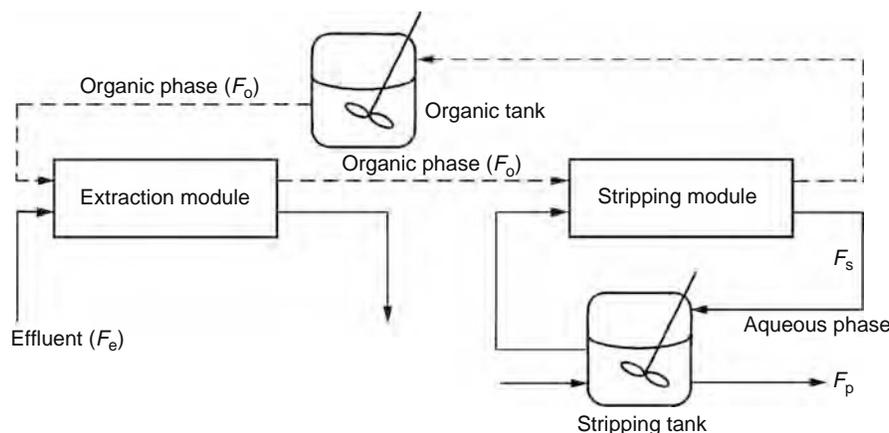

FIGURE 37.1 Flow diagram of a nondispersive solvent extraction process.

the resulting complex species in the organic phase. Thus, the value of the pH of the feed phase can be considered as an optimization variable of the process selectivity.

The determination of the membrane mass transport coefficient can be made by means of the empirical correlation

$$K_m = \frac{D\varepsilon}{\delta\tau} \quad (37.25)$$

after estimation of the corresponding diffusivity of the complex species through the organic membrane from well-known correlations. For simplicity the same value of the membrane mass transport coefficient for both metals can be assumed, equal to  $1.57 \times 10^{-7}$  m/s, the value reported previously [32].

The necessary consideration of equilibrium models of the chemical reactions in the overall mathematical model describing the separation kinetics of both metals involves considerable difficulty since there is no agreement in the literature on the stoichiometry of the ion-exchange reactions of Cd and Ni with the organic carrier D2EHPA, and on what value the equilibrium parameters take. The situation is even more complex when working with highly concentrated solutions since D2EHPA has been reported to exist as a dimer in the organic phase and may form complex species with a metal acting as a dimer. Typical metal ( $\text{Me}^{2+}$ ) complexation with  $n$  dimers,  $\overline{(\text{HX})}_2$ , of D2EHPA could be described by the following equation that represents also the back-extraction reaction:

The equilibrium model and parameters of the reaction of Cd with D2EHPA have been taken from the literature as  $n = 2$  and  $K'_{\text{EX}(\text{Cd})} = 1.82 \times 10^{-5}$  [31].

In the case of Ni, the situation is even more complex since the stoichiometric equations reported in the literature differ widely depending on the diluents used, on the aqueous phase compositions, or on the extractant concentrations employed. A discrimination procedure of the equilibrium models corresponding to the back-extraction reactions has been reported previously by taking into account the expressions given in Table 37.1 and obtaining the best results with the following equation [59]:

that considers the formation of a mixed complex species in the organic phase between the extractant and both metals and the simultaneous back extraction. After integration of the system of Equations 37.1 through 37.24 and incorporating a model that considers (1) negligible extraction of Ni, (2) the formation of a mixed complex species in the organic phase between the extractant and both metals Cd and Ni, during the initial loading of the organic phase, and (3) the existence of only one reaction responsible for the BEX process of Cd and Ni characterized by the corresponding equilibrium parameter, and simulated data are obtained making use of the set of optimum values of the parameters,  $K'_{\text{EX}(\text{Cd})} = 1.82 \times 10^{-5}$ ,  $K'_{\text{BEX}(\text{NiCd})} = 8.8 \times 10^{-5}$  m<sup>3</sup>/mol, and  $K_m = 1.57 \times 10^{-7}$  m/s. As a representative example, Figure 37.2 shows some comparative results corresponding to an experiment with the following initial concentrations, 0.2 M of nickel and of cadmium in the feed phase and pH equal to 3.5, and 0.2 M of nickel in the back-extraction phase.

From the curves in Figure 37.2 it is observed that there is a negligible extraction of nickel due to the working value of pH in the feed phase, thus making the process selective toward Cd. Concerning the back-extraction process, both metals are removed from the complex species formed with the organic extractant. Finally, a good agreement between simulated and experimental data is also observed, thus corroborating the validity of the kinetic model for process design and optimization.

### 37.3 MODELING AND OPTIMIZATION OF EMULSION PERTRACTION PROCESSES

As mentioned in the introduction section, an emerging alternative to achieve the separation of metallic pollutants from aqueous effluents and their concentration in a receiving phase is the emulsion pertraction technology using HF modules.

Figure 37.3 shows an enlarged view of the membrane with the aqueous phase in the lumen side and the continuous organic phase and dispersed droplets of the stripping solution (emulsion phase) in the shell side. The hydrophobic microporous membrane is wetted by the organic phase.

The mathematical model needed for process design follows the basis that have been reported for a system with two HF modules but needs to be adapted to describe all the mass transport processes in the same module. As a representative example, it will be applied to the recovery of Cr(VI) from polluted waters that may also contain other competitive anions such as sulfate, chloride, etc.

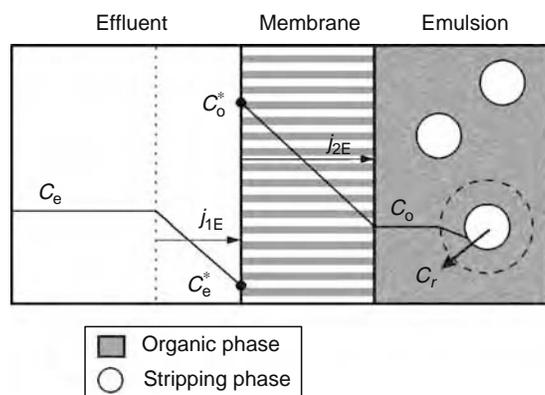

The extraction reaction of Cr(VI) from acidified solutions using tertiary amines as extractant is represented by the equation

whereas the back-extraction reaction with hydroxyl ions is represented through

In the proposed model, the mass transfer of Cr from the feed to the stripping phase takes place in four steps: (1) diffusion in the feed-phase stagnant layer to the interface with the membrane, (2) interfacial reaction of Cr(VI) with the extractant Alamine 336 to form a complex species (Equation 37.28), (3) diffusion within the supported liquid membrane, and (4) chemical reaction

**FIGURE 37.3** Enlarged view of the fiber with the feed aqueous phase in the lumen side and emulsion phase in the shell side.

at the interface of the stripping globules (Equation 37.29). Thus, the main model hypotheses are that the extraction chemical reaction (Equation 37.28) is considered fast enough to reach equilibrium instantaneously and the chromium mass transfer resistance in the stripping phase stagnant film is considered negligible [46]. The diffusion of the other species is assumed to be faster than those corresponding to the Cr compounds.

Then, the mass transfer flux through the feed-phase stagnant layer can be described according to Fick's equation

$$j_1 = k_1 (C_e - C_e^*) \quad (37.30)$$

and in the organic membrane

$$j_2 = k_m (C_o^* - C_o) \quad (37.31)$$

where

$C_e$  is the chromium bulk concentration in the aqueous phase

$C_e^*$  is the aqueous Cr concentration at the membrane interface

$C_o^*$  is the organic Cr concentration at the membrane interface in equilibrium with  $C_e^*$

$C_o$  is the Cr concentration in the organic phase, as shown in Figure 37.3

Interfacial equilibrium concentrations in the extraction side are related through the expression of the chemical equilibrium parameter

$$K_{eq} = \frac{[(R_3NH)^+ HCrO_4^-]^*}{[R_3N]^* [H^+]^* [HCrO_4^-]^*} \quad (37.32)$$

where the superscript (\*) indicates equilibrium concentrations.

Assuming pseudosteady state, then

$$j_1 = j_2 \quad (37.33)$$

For a general case where the hypothesis of chemical equilibrium at the organic–stripping interphase cannot be considered owing to fast consumption of the stripping reagents, the kinetic rates of the involved reactions should be considered [46]. By applying this situation to the back extraction of the chromium–organic complex species, the rates of formation and dissociation of  $CrO_4^{2-}$  in Equation 37.29 are given by  $R_1$  and  $R_{-1}$

$$R_1 = k_1 OH^2 C_o \quad (37.34)$$

$$R_{-1} = k_{-1} C_r \quad (37.35)$$

where  $C_r$  is the chromium concentration at the stripping phase.

Thus, the flux of chromium from the organic phase to the stripping phase through the dispersion bubbles interface is given by

$$j_3 = R_1 - R_{-1} = k_1 \left( OH^2 C_o - \frac{C_r}{K_r} \right) \quad (37.36)$$

The evolution of the  $OH^-$  concentration in the back-extraction phase with time can be considered as an empirical function of the Cr concentration in the same phase of the type

$$OH = C_o - r C_r \quad (37.37)$$

where  $C_o$  is the initial concentration of  $OH^-$  in the stripping phase and  $r$  is a coefficient that would take the value of 2 (stoichiometric coefficient of  $OH^-$  according to Equation 37.29) if there would be no competitive reactions between the extractant Alamine 336 and anions other than that of chromate.

The value of the mass transfer parameter  $k_l$  for fluids flowing through tubes in laminar flow may be calculated from the Levêque equation, neglecting the influence of the concentration changes along the HF [46]

$$\left(\frac{kld}{D_a}\right) = 1.62 \left(\frac{d^2 u_{\text{tube}}}{D_a L}\right)^{\frac{1}{3}} \quad (37.38)$$

where

$d$  is the inside diameter of the HF

$D_a$  is the diffusivity of the chromic anion in the aqueous feed solution

$u_{\text{tube}}$  is the mean velocity of the aqueous feed solution

$L$  is the module length

The membrane mass transport coefficient,  $k_m$ , may be calculated by means of Equation 37.26.

In Equation 37.28, the proton concentration can be expressed according to Cr(VI) concentration in the aqueous phase in the equilibrium

$$H_e^* = H_e - (C_e^{\text{in}} - C_e^*) \quad (37.39)$$

For a system operating at nonsteady state, it is also necessary to describe the change of the solute concentration with time. For simplicity, the concentration of Cr(VI) in the aqueous and organic phases has been described by means of macroscopic mass balances of the permeating solute developed in a certain volume of the fiber at a time interval.

*Module mass balance*

Feed solution:

$$\frac{V_e^M}{L} \frac{dC_e}{dt} = -F_e \frac{dC_e}{dz} - \frac{A}{L} j_1, \quad t = 0, C_e = 0 \quad (37.40)$$

$$z = 0, C_e = C_e^{\text{in}}$$

Organic solution:

$$\frac{V_o^M}{L} \frac{dC_o}{dt} = F_o \frac{dC_o}{dz} + \frac{A}{L} j_1 - \frac{V_r^M}{L} A_v k_l \left( \text{OH}^2 C_o - \frac{C_r}{K_r} \right), \quad t = 0, C_o = C_o^0 \quad (37.41)$$

$$z = L, C_o = C_o^T$$

Stripping solution:

$$\frac{V_r^M}{L} \frac{dC_r}{dt} = F_r \frac{dC_r}{dz} + \frac{V_r^M}{L} A_v k_l \left( \text{OH}^2 C_o - \frac{C_r}{K_r} \right), \quad t = 0, C_r = C_r^0 \quad (37.42)$$

$$z = L, C_r = C_r^T$$

The term on the left-hand side of Equations 37.40 through 37.42 corresponds to the solute accumulation. The first term on the right-hand side represents the convective transport along the tube length, the second term in Equations 37.40 and 37.41 represents the transfer of solute from the aqueous feed phase to the organic phase, and finally the last term in Equations 37.41 and 37.42 shows the flux of Cr(VI) from the organic phase to the stripping phase contained in the emulsion globules where  $A_v$  is the interfacial area of the stripping bubbles by volume of the stripping phase.

For a complete description of the separation process, it is necessary to include the mass balances in the emulsion reservoirs as well as the interfacial equilibrium expression at the feed-membrane side.

*Mass balance of the stripping solution in the stirred tank*

Stripping phase:

$$V_r^T \frac{dC_r^T}{dt} = F_r (C_{r,z=0} - C_r^T) \quad t = 0, C_r^T = C_r^0 \quad (37.43)$$

Organic phase:

$$V_o^T \frac{dC_o^T}{dt} = F_o (C_{o,z=0} - C_o^T) \quad t = 0, C_o^T = C_o^0 \quad (37.44)$$

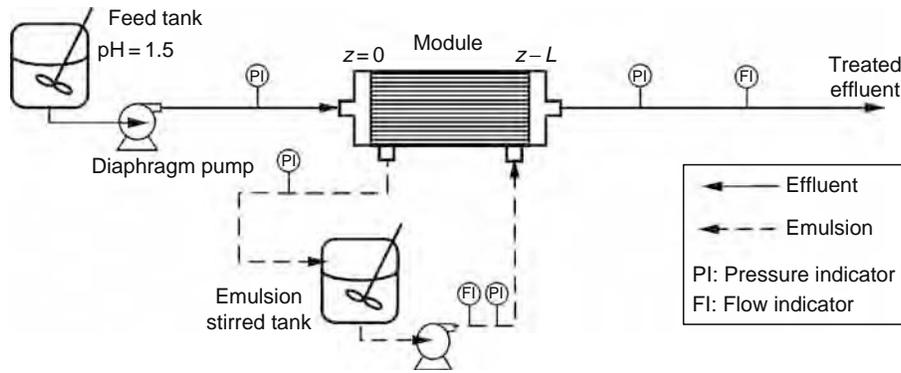

FIGURE 37.4 Flow diagram of an emulsion pertraction process.

where

$F_r$  and  $V_r^T$  are the stripping phase flow rate and stripping volume in the emulsion tank  
 $F_o$  and  $V_o^T$  are the organic phase flow rate and volume in the emulsion tank

*Case study 2: Separation and concentration of hexavalent chromium from waste waters*

The separation and concentration of chromate anions by means of quaternary ammonium salts as extractants and using 2 HF modules deserve attention in the literature [12,13,17,26]. The use of the pertraction emulsion technology allows reduction of the required equipment by achieving the separation and concentration processes in the same module. Figure 37.4 shows a flow diagram of the emulsion pertraction process. Feed phase circulates through the inner side of HFs whereas the emulsion that contains the stripping phase flows through the outer side of the fibers in a recycling mode. Figure 37.5 shows data of a representative run where Cr increases its concentration in the stripping phase whereas it is removed from the feed solution.

To analyze the behavior of the system with the mathematical model proposed in the previous section, three parameters are needed: the chemical equilibrium parameters  $K_{eq}$  and  $K_r$  of the extraction and of the stripping chemical reactions, respectively, and the product,  $A_i k_i$ , of the interfacial area of the emulsion and the kinetic constant of the forward stripping reaction. Estimation of the parameter values needs deep experimental analysis; in the literature the following set of parameter values has been reported:  $K_m = 2.25 \times 10^{-7}$  m/s;  $K_{eq} = 1.041$  mol<sup>-2</sup>/m<sup>6</sup>;  $A_i k_i = 10.62$  m<sup>6</sup> mol<sup>-2</sup> h<sup>-1</sup>; and  $k_r = 10^4$  [46]. The mathematical model and parameters can be used to obtain simulated values at different operation conditions.

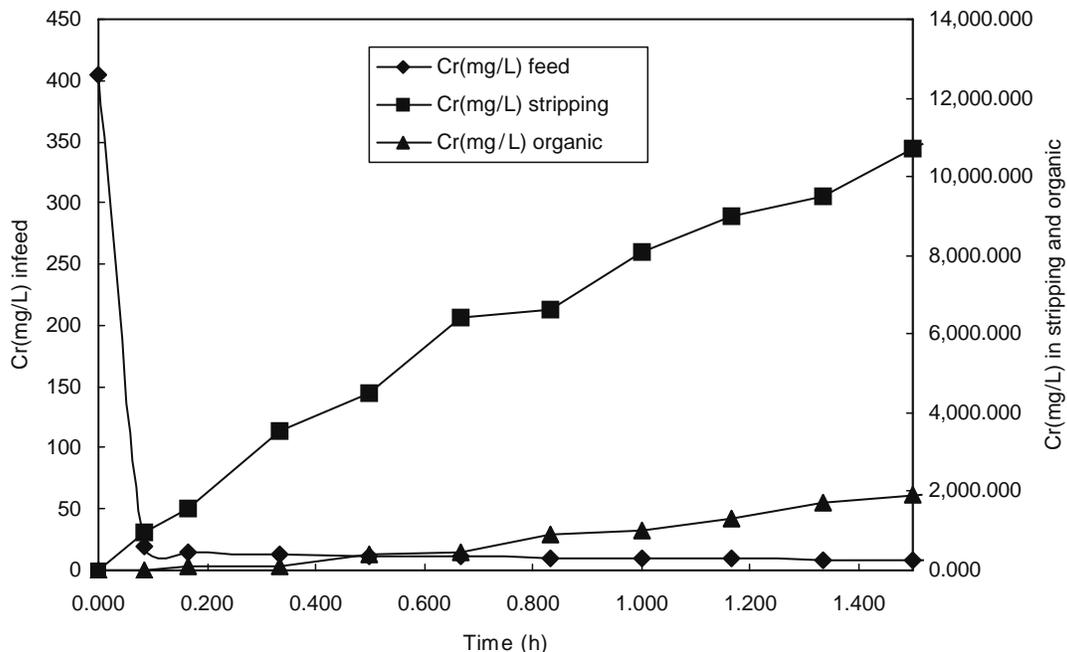

FIGURE 37.5 Experimental results of a representative emulsion pertraction run.

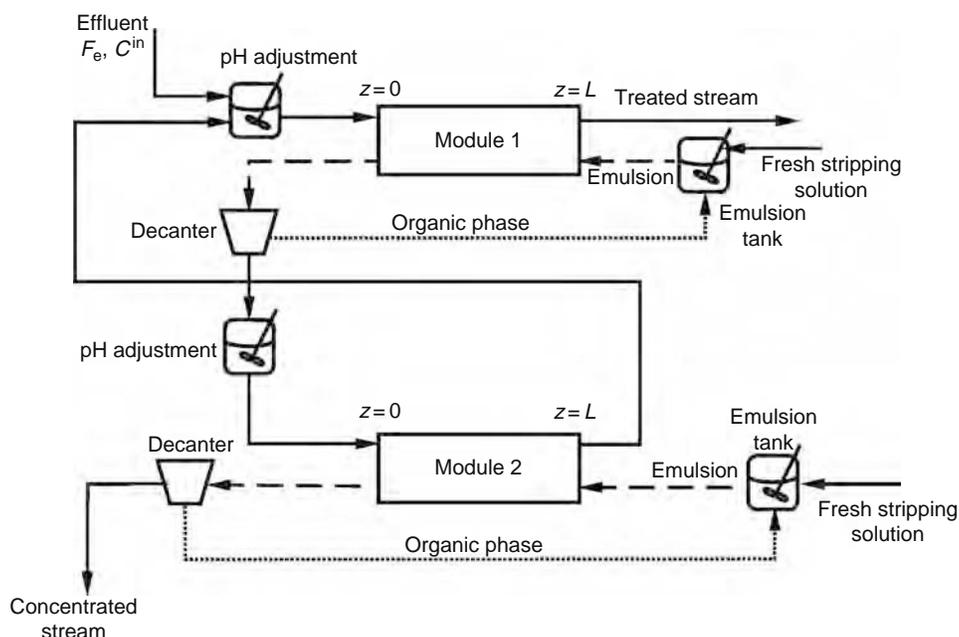

FIGURE 37.6 Proposed configuration for the pertraction plant.

### 37.3.1 OPTIMIZATION OF A PERTRACTION PLANT

In this section, the reported model and the parameters will be used to obtain the optimal operation point that maximizes the amount of Cr treated in an emulsion pertraction plant. It is considered that the plant operates continuously and the reduction target value of Cr(VI) in the effluent as well as the concentration levels are fixed values equal to  $0.00961 \text{ mol/m}^3$  ( $0.5 \text{ mg/L}$ ) and  $384.615 \text{ mol/m}^3$  ( $20,000 \text{ mg/L}$ ), respectively.

For this purpose a cascade-type plant with two membrane modules is proposed, as shown in Figure 37.6. The effluent enters the first module, and leaves it with the imposed output concentration level. In the same module, the emulsion runs in countercurrent mode, and after leaving the module the phases are separated. The organic phase is mixed with fresh back-extraction phase and returns to the first module, while the aqueous phase is acidified to pH 1.5 and then goes to the second module.

In the second module, the aqueous phase transfers the metal to a second emulsion batch, and finally it is mixed with the effluent that enters the first membrane module. The second emulsion concentrates Cr in the back-extraction aqueous phase, and after the phase separation at the output, the organic phase is mixed with fresh back-extraction solution and returned to the same module.

There are two reasons for proposing the previous configuration. The first one is related to the desired Cr levels in the output streams. It is not possible to reach both concentration constraints without a cascade-type configuration in continuous operation. The second reason concerns the undesired presence of other competitive anions such as sulfate in the concentrated stream. The importance of mass transfer of competitive anions is low at high Cr(VI) concentrations but can have a significant influence when the concentration of Cr(VI) is low [44]. Then, in the plant devised, sulfate and other anions are transferred to the stripping phase in the first module, but there is no significant mass transfer from the aqueous stream to the back extraction in the second module, as the aqueous stream has a relatively high Cr concentration.

#### 37.3.1.1 Mathematical Formulation

The model for the pertraction process has been explained in the previous section. A system of partial differential equations describes the behavior of the aqueous and emulsion phases, and ordinary differential equations describe the dynamic behavior of the tanks. There is also a set of algebraic equations for the chemical equilibrium and connections between the equipment.

As the plant to be optimized considers a process operating at steady state, then the variation of the phase concentrations with time is zero. For this reason, the mathematical model that describes the plant is a set of ordinary differential equations, as the phase concentrations depend only on the module axial position. In the tanks, the concentrations are constant. The differential-algebraic nonlinear optimization (DNLP) problem P1 to be solved includes the ordinary differential equations that represent the mass balances for the phases in the membrane module. The objective function to be maximized is the amount of metal processed  $F_e C^{\text{in}}$ , where  $F_e$  is the effluent flow rate whose Cr(VI) concentration after dilution from wastewaters is  $C^{\text{in}}$ . The problem has the following form:

$$\begin{aligned}
& \text{Max}_{\mathbf{v}} F_e C^{\text{in}} \\
& \text{s.t.: } \mathbf{h}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{w}, \mathbf{v}) = 0 \\
& \quad \mathbf{g}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{w}, \mathbf{v}) \leq 0 \\
& \quad \mathbf{I}(\mathbf{x}(0), \mathbf{x}(L)) = 0 \\
& \quad \mathbf{x}^{\text{LB}} \leq \mathbf{x} \leq \mathbf{x}^{\text{UB}} \\
& \quad \mathbf{w}^{\text{LB}} \leq \mathbf{w} \leq \mathbf{w}^{\text{UB}} \\
& \quad \mathbf{v}^{\text{LB}} \leq \mathbf{v} \leq \mathbf{v}^{\text{UB}} \\
& \quad \mathbf{x} \in R^n
\end{aligned} \tag{P1}$$

where  $\mathbf{x}$  represents the set of differential distributed variables such as the aqueous, organic, and back-extraction concentration profiles along the modules, and  $\dot{\mathbf{x}}$  is the derivative of  $\mathbf{x}$  with respect to the module axial position  $z$  (with  $z \in [0, L]$ ). The vector  $\mathbf{w}$  is the set of algebraic distributed variables, such as the interface concentration along the modules. The set of nondistributed optimization variables, such as the aqueous or emulsion flow rates in the network, is represented by  $\mathbf{v}$ . For all variables types, upper and lower bounds are imposed.

The mass balances, equilibrium, and interconnection relationships are represented by the set of differential and algebraic equalities  $\mathbf{h}$  for the membrane modules, while the restrictions on the effluent output concentrations and the recovered metal concentration are represented by the inequalities  $\mathbf{g}$ . The initial conditions for the differential equations are given by  $\mathbf{I}$ .

The aim in the optimization problem is to maximize the objective function by selecting the optimum values for the optimization variables  $\mathbf{v}$ . To solve the optimization problem P1, commercial software tools such as GAMS [61] can be used after discretization of the differential equations.

### 37.3.1.2 NLP Formulation

The following is the resulting NLP problem P2, derived from P1 after discretization of the differential equations by using the orthogonal collocation technique:

$$\begin{aligned}
& \text{Max}_{\mathbf{v}} F_e C^{\text{in}} \\
& \text{s.t.: } \mathbf{h}(\mathbf{x}, \mathbf{v}, \mathbf{w}) = 0 \\
& \quad \mathbf{g}(\mathbf{x}) \leq 0 \\
& \quad \mathbf{x}^{\text{LB}} \leq \mathbf{x} \leq \mathbf{x}^{\text{UB}} \\
& \quad \mathbf{w}^{\text{LB}} \leq \mathbf{w} \leq \mathbf{w}^{\text{UB}} \\
& \quad \mathbf{v}^{\text{LB}} \leq \mathbf{v} \leq \mathbf{v}^{\text{UB}} \\
& \quad \mathbf{x} \in R^n
\end{aligned} \tag{P2}$$

The equations included in P2 are described in the next subsections.

#### 37.3.1.2.1 Material Balances for the Membrane Modules

After removing the time derivatives and replacing the differential mass balances given by Equations 37.40 through 37.42 by a set of algebraic equations applying orthogonal collocation, the mass balances for the membrane module  $j$  are as follows:

Aqueous phase:

$$\sum_{q=0}^{N+1} C_{e,q}^j \dot{\phi}_q(z_i) = -k_L \left( C_{e,i}^j - C_{e,i}^{j,*} \right) \frac{A}{L F_e^j}, \quad i = 1, \dots, N+1, \text{ and } j = 1, 2 \tag{37.45}$$

$$C_{e,0}^j = C_e^{j,\text{in}} \tag{37.46}$$

Organic phase:

$$\sum_{q=0}^{N+1} C_{o,q}^j \dot{\phi}_q(z_i) = -k_L \left( C_{e,i}^j - C_{e,i}^{j,*} \right) \frac{A}{L F_o^j} + A_v k_l (\text{OH}_i^j)^2 C_{o,i}^j \frac{V_r^M}{L F_e^j}, \quad i = 0, \dots, N \text{ and } j = 1, 2 \tag{37.47}$$

$$C_{o,N+1}^j = C_{o,0}^j \tag{37.48}$$

Back-extraction phase:

$$\sum_{q=0}^{N+1} C_{r,q}^j \dot{\phi}_q(z_i) = -A_v k_l (\text{OH}_i^j)^2 C_{o,i}^j \frac{V_r^M}{LF_r}, \quad i = 0, \dots, N \text{ and } j = 1, 2 \quad (37.49)$$

$$C_{r,N+1}^j = 0 \quad (37.50)$$

The organic and stripping flow rate that constitutes the emulsion stream are related by

$$4F_r^j = F_o^j, \quad j = 1, 2 \quad (37.51)$$

### 37.3.1.2.2 Chemical Equilibrium and Other Relationships

Equations 37.32 and 37.33 and Equations 37.37 through 37.39 are replaced by the following set of equations:

$$K_{\text{eq}} C_{e,i}^{j*} H_{e,i}^{j*} (CT - C_{o,i}^{j*}) = C_{o,i}^{j*} \quad (37.52)$$

$$k_L (C_{e,i}^j - C_{e,i}^{j*}) = k_m (C_{o,i}^{j*} - C_{o,i}^j) \quad (37.53)$$

$$\text{OH}_i^j = 3000 - r C_{r,i}^j \quad (37.54)$$

$$H_{e,i}^{j*} = H_e^{\text{in}} - (C_e^{\text{in}} - C_{e,i}^{j*}) \quad (37.55)$$

where  $i = 0, \dots, N + 1$  refers to the collocation points along the module axial position, and  $j = 1, 2$  refers to the module number.

### 37.3.1.2.3 Material Balances for Mixers and Tanks

The mass balance for any mixer or a tank of Figure 37.6 is given by

$$F_k^{\text{out}} = \sum_n F_{k,n}^{\text{in}}, \quad k = e, o, r \quad (37.56)$$

where  $k$  represents the organic, stripping, or organic phase, whose inlet streams are represented by  $F_{k,n}^{\text{in}}$  and the output stream by  $F_k^{\text{out}}$ .

The chromium balance for the phases that constitute the emulsion is given by

$$F_k^{\text{out}} C_k^{\text{out}} = \sum_n F_{k,n}^{\text{in}} C_{k,n}^{\text{in}}, \quad k = e, o, r \quad (37.57)$$

## 37.3.2 OPTIMIZATION RESULTS

Let us consider a process that treats an effluent having Cr(VI) using two membrane modules of 19.3 m<sup>2</sup> each. After the optimization procedure that starts with discretization of the differential equations using 10 collocation points in each membrane module, formulation of the NLP problem P2, and solution with the optimization code GAMS using the NLP solver CONOPT2, the solution reported in Table 37.2 was obtained. Both the treated effluent and the concentrated Cr solution for reuse are at their upper and lower bound, respectively. 99.5% of the metal is removed from the wastewater and concentrated for reuse. The Cr concentration profiles along the membrane modules are shown in Figures 37.7 and 37.8. The stripping phase is then concentrated up to nearly 20 mol/m<sup>3</sup> in the first module and then goes to the second one, where its relatively high Cr level allows the mass transfer to the stripping phase at 384.615 mol/m<sup>3</sup>, as shown in Figure 37.8.

It can be seen in Figure 37.7 that almost all the metal is removed from the effluent in the first half of the module. As a consequence, in the second half of Module 1 the effluent concentration remains constant. However, this fact does not imply that the portion of the module is idle, but only that the mass transfer from the effluent to the organic phase is null. In all the modules there is mass transfer from the organic to the stripping phase. This is the reason why the stripping phase increases its concentration as it flows from  $z=L$  to  $z=0$ . The organic phase concentration decreases as it flows from  $z=L$  to a given point located more or less in the middle of the membrane module. This happens as the mass transfer from the effluent to the organic phase is nearly zero, while the mass transfer from the organic to the stripping phase is not null.

**TABLE 37.2**  
**Optimal Operating Conditions of an Emulsion Pertraction Plant for Chromium(VI) Recovery**

	Nonlinear Optimization (NLP) Solution	Lower Bound	Upper Bound
Objective function			
Cr(VI) treated (mol/h)	0.311	0.005	1
Optimization variables			
Effluent flow rate, $F_e$ (m <sup>3</sup> /h)	0.131	0.020	0.200
Effluent input concentration, $C_{in}$ (mol/m <sup>3</sup> )	2.37	1.92	7.77
Emulsion flow rate (Module 1) (mol/m <sup>3</sup> )	0.116	0.020	0.200
Emulsion flow rate (Module 2) (mol/m <sup>3</sup> )	0.004	0.001	0.020
Constraints			
Output stripping concentration (mol/m <sup>3</sup> )	384.615	384.615	500
Output aqueous concentration (mol/m <sup>3</sup> )	0.00961	0.001	0.00961

Mathematically, this occurs because the second term in the right-hand side of Equation 37.47 dominates the first term, which is close to zero.

As the emulsion continues flowing from the middle of the module to  $z=0$ , the mass transfer from the effluent to the organic phase increases and outnumbers the mass transfer from the organic to the stripping phase. In other words, the first term on the right-hand side of Equation 37.47 compensates the second, which has an opposite sign.

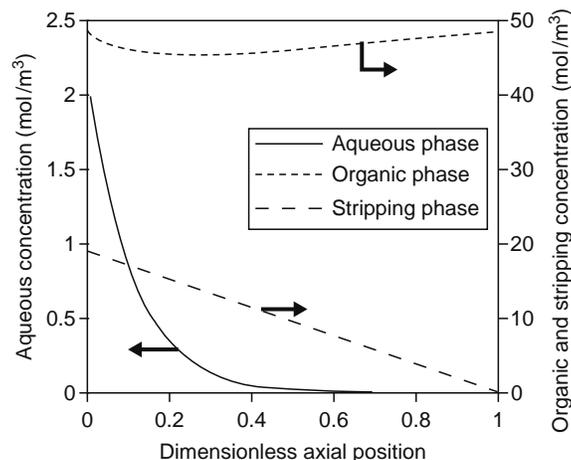

As the organic phase is reused after separated from the emulsion in a decanter, the organic concentrations at  $z=0$  and  $z=L$  are the same. The same happens in Module 2, as its organic phase is also separated from the emulsion and reused. The modeling procedure that has been applied to the Cr system allows an understanding of the main phenomena involved in the process and it is recommended to be applied to other systems of practical interest.

### 37.4 CONCLUDING REMARKS AND FUTURE DIRECTIONS

Membrane-assisted solvent extraction processes have known an increasing number of applications in the last decades. The technique not only overcomes the limitations of conventional liquid extraction, such as flooding, intimate mixing, limitations on phase flow rate variations, and requirement of density difference but also provides a large surface area of mass transfer per volume of contactor. Simultaneous extraction and stripping of the solute has been developed using two HF modules in series, one for the extraction and the other for the back-extraction processes.

An important number of references have been published dealing with many applications of supported liquid membranes. Mathematical modeling of the process has been developed and it can be generalized and applied to the determination of the response of different systems containing more than one solute. After evaluation of the parameters, process optimization can be applied using common optimization procedures, as described in the text.

According to previous explanations, the technique is prepared to be managed as more common chemical engineering processes. Previous results indicate that intensification of the processes can be reached leading to new conceptual and practical design of many industrial separations. Special effort should be devoted in the near future to the development of practical applications of the technology.

## 38.1 INTRODUCTION

The process intensification theory, devoted to the development of new systems of production able to work, with respect to conventional operations, with higher efficiency and flexibility, lower energy consumption and waste production, higher capacity/size ratio, is well satisfied by membrane engineering. Beside the well-known membrane operations such as micro/ultra/nanofiltration and reverse osmosis, also membrane contactors (MC) that are gaining particular attention during the past years, as promising alternative systems to be used for the rationalization of industrial cycles, well satisfy the process intensification approach. Membrane contactors are a relatively new class of membrane operations particularly interesting for performing mass transfer between phases. The field of application covers many unit operations such as scrubbing, stripping, extractions, and concentration processes [1]. Membrane contactors are able to efficiently treat diluted streams and this aspect makes them very interesting for the purification of streams containing traces of pollutants that sometimes are difficult to remove up to the desired levels by conventional operations. This contribution would like to point out the potentialities and the drawbacks of membrane contactors, particularly for the treatment of gaseous streams, by presenting and discussing all research efforts made in this field. The role of the membrane properties and of the module design on the membrane contactors performance is underlined.

## 38.2 WHAT IS A MEMBRANE CONTACTOR?

Membrane contactors are membrane systems usually based on microporous membranes that keep two phases in contact. The presence of the membrane and the right choice of the operating pressures avoid the mixing of the phases. This implies that the flow rates of the phases can be varied independently over a wide range without any problem of flooding, loading, channeling,

**TABLE 38.1**  
**Main Advantages and Disadvantages of MC with respect to Conventional Systems**

Advantages	Disadvantages
Higher interfacial area per volume	Operative pressures dependent on breakthrough ones
No dispersion between phases	Additional resistance to mass transfer due to the membrane
Wide range of operative flow rates	Shell side bypassing
No loading or flooding limitations	Membrane fouling
No foaming	Pretreatments to reduce fouling
No separation of phases after the operation	Limited lifetime
Low-pressure drop	
Constant interfacial area between phases	
Flexibility and compactness	
Reduced size and weight	
No moving parts	
Easy scale-up due to a modular design	

or entrainment. Depending on the particular application, membranes can be hydrophobic or hydrophilic, but in both the cases they do not present any selectivity for the species involved in the mass transport: a generic compound  $i$  is transferred through the membrane micropores by only diffusion. The driving force for the permeation is related to a difference of concentration/partial pressure between the phases. Membrane distillation is the only operation that occurs thanks to a difference of temperature across the membrane. Usually the mass-transfer coefficients achievable in these systems are not higher than those related to conventional devices; however, the extremely higher interfacial area available for the mass transport leads to a higher mass transfer. The typical interfacial area per unit of volume of membrane contactors varies between 1500 and 3000 m<sup>2</sup>/m<sup>3</sup>, whereas for conventional contactors this ratio is in the range of 100–800 m<sup>2</sup>/m<sup>3</sup> [2]. Their performance is strongly related to the membrane properties. Important parameters that influence the transport are porosity, pore size, thickness, degree of hydrophobicity, breakthrough pressure, stability, thermal, mechanical, and chemical resistance. The mass transport can be enhanced by also acting on the module design and flow configurations. An uniform and turbulent flow is, in fact, preferred for avoiding fluid bypass or stagnant zones and for reducing the mass-transport resistances. However, pressure drops have to be also carefully controlled. Species that can foul the membrane have to be removed before sending the streams to be processed to the membrane units. The main advantages and disadvantages of membrane contactors are reported in Table 38.1. The following section discusses the basic principles of membrane contactors when applied in gaseous streams treatments.

### 38.3 BASIC PRINCIPLES OF MEMBRANE CONTACTORS FOR GAS TREATMENTS

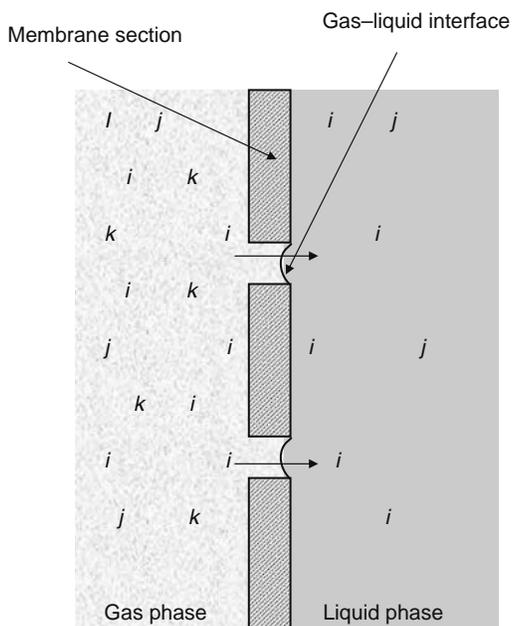

The removal of species from gaseous streams in membrane contactors is usually accomplished by means of absorbent solutions. The type of absorbent liquid and its temperature, as the concentration of species to be removed in the gas and in the liquid phase, influence the mass transport. The selectivity of separation can be determined by selecting the absorbent solution; making this choice, the eventual production of toxic by-products and the impact on the environment have to be taken into account.

When hydrophobic membranes are used (olefins are preferred because of their low cost), the aqueous absorbent cannot penetrate through the pores and the membrane is gas filled; whereas if hydrophilic membranes are employed, the membrane is liquid filled (Figures 38.1 and 38.2). Latter situation is preferred only if the reaction between the gaseous species and the absorbent solution is fast or instantaneous; if not, it is better to work with a gas-filled membrane, to reduce mass-transfer resistances. The module design and flow configuration also play an important role in defining the membrane contactors efficiency. This aspect is discussed in detail in Section 38.5.

#### 38.3.1 MASS-TRANSFER RESISTANCES

The resistances to the mass transport that a species encounters when is transferred from the gas to the liquid phase are reported in Figure 38.3. Gas and liquid phases contribute to the overall resistance because of the formation of boundary layers close to the membrane surface. This implies that the concentration of a generic species  $i$  in the bulk of the two phases is different from its concentration at the membrane surfaces. The resistance offered by the membrane with gas-filled pores will be different (generally lower) than that with liquid-filled pores, due to the different effective diffusion coefficients. The overall mass-transport coefficient is given by

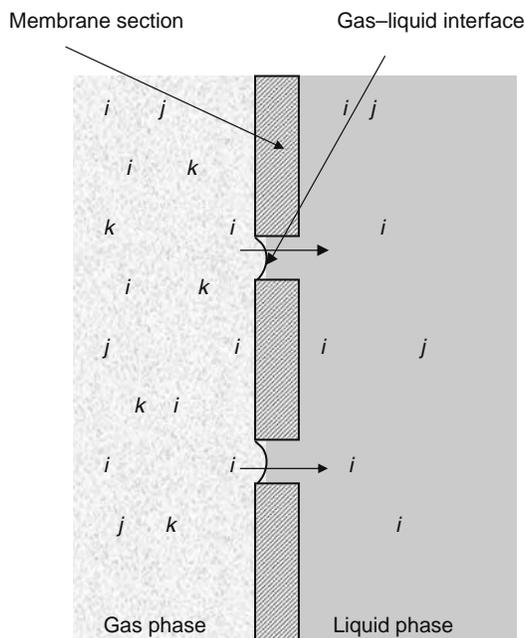

$$\frac{1}{K_L} = \frac{1}{k_1} + \frac{1}{k_m \cdot H} + \frac{1}{k_g \cdot H} \quad (38.1)$$

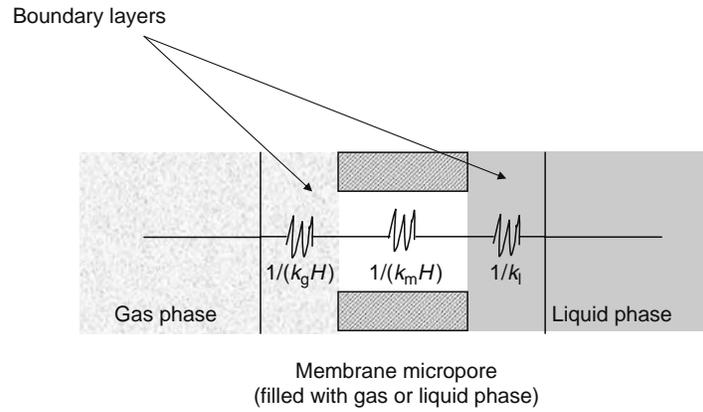

**FIGURE 38.1** Contact between gas and liquid in a hydrophobic membrane contactor. The species *i* diffuses through the membrane gas-filled micropores from the gas phase to the liquid absorbent.

where

- $K_L$  denotes overall mass-transfer coefficient (m/s)
- $k_l$  denotes liquid mass-transfer coefficient (m/s)
- $k_g$  denotes gas mass-transfer coefficient (m/s)
- $k_m$  denotes membrane mass-transfer coefficient (m/s)
- $H$  denotes Henry's constant

**FIGURE 38.2** Contact between gas and liquid in a hydrophilic membrane contactor. The species *i* diffuses through the membrane absorbent-filled micropores from the gas phase to the liquid absorbent.

**FIGURE 38.3** Resistances to the mass transport offered by the gas, membrane, and the liquid. The resistance offered by the membrane will depend on the phase presents into the micropores.

$k_g$  and  $k_l$  can be calculated by using correlations that are function of fluid properties and flow rates, such as

$$Sh = aRe^b Sc^c \quad (38.2)$$

where

$Sh$  denotes the Sherwood number

$Re$  denotes the Reynolds number

$Sc$  denotes the Schmidt number

The constants (a, b, and c) that appear in the above expression are available in literature and are specific for the particular system employed for carrying out the experiments [1,3–5].

$k_m$  is usually derived by

$$\frac{1}{k_m \cdot H} = \frac{\delta \tau}{D_{\text{eff}} \varepsilon H} \quad (38.3)$$

where

$\delta$  denotes membrane thickness (m)

$\tau$  denotes membrane tortuosity (dimensionless)

$\varepsilon$  denotes membrane porosity (dimensionless)

$D_{\text{eff}}$  denotes effective diffusion coefficient of  $i$  through the membrane ( $\text{m}^2/\text{s}$ )

For enhancing the removal, it is important to reduce those resistances as much as possible by acting on the fluid dynamic (for  $k_g$  and  $k_l$ ) and on the membrane properties (for  $k_m$ ). Increments of the liquid and gas flow rates, as a module design that promotes turbulent flow, lead to a reduction of gas and liquid boundary layers, with consequent improvements of the mass transport.

The expressions above reported for describing the mass transport are relative to inert membranes; sometimes phenomena of interfacial absorption between the species to be transferred and the membrane material could happen. In these cases, other parameters have to be considered and the equations become more complex.

### 38.3.2 MEMBRANE REQUIREMENTS

From Equation 38.3, it results that the mass-transport coefficient in the membrane increases as the porosity increases and as the thickness and tortuosity decrease. These parameters are related to each other; the tortuosity, for instance, is a function of the porosity of the membrane and the specific porosity–tortuosity relationship depends on the manufacturing method [6].

The two parameters can be correlated by the empirical expression [6]:

$$\tau = \frac{(2 - \varepsilon)^2}{\varepsilon} \quad (38.4)$$

Fractal theories of random walks developed a different expression [6]:

$$\tau = \frac{1}{\varepsilon} \quad (38.5)$$

Iversen et al. [6] found that for a polymer structure similar to the interstices between closely packed spheres (phase inversion membrane), Equation 38.4 is able to well describe the tortuosity–porosity relationship; whereas for a polymer structure similar to random spheres or clusters (stretched membrane), Equation 38.5 has to be used.

Other important properties to consider in membrane manufacturing are the degree of hydrophobicity, the pore size and the pore size distribution, the chemical, thermal, and mechanical stability. The hydrophobicity is fundamental for preventing the presence of liquid through pores. It can be determined by contact angle measurements (CAM). The technique measures the angle formed between the liquid and the membrane pore. The obtained results are dependent on the morphology of the membrane surface, such as the roughness, that strongly influences these types of measures [7]. Higher pore size leads to higher fluxes but also to lower breakthrough pressures (pressures at which liquid starts to penetrate into the pores and the membrane loses its hydrophobic character). The breakthrough pressure for gas/liquid operations is given by the Laplace's equation:

$$\Delta p = \frac{(2\sigma \cos \theta)}{r} \quad (38.6)$$

where

$\sigma$  denotes surface tension

$\theta$  denotes contact angle

$r$  denotes pore radius

The pore size distribution has to be carefully controlled to ensure the same performance along the membrane; moreover, to avoid coalescence of bubbles, a particular distance among adjacent pores is required. The chemical stability of the membrane also plays an important role when using absorbent solutions. Hydrophobic membranes in contact with absorbents can interact with them, changing their structure and morphology and losing hydrophobicity. The resistance to the mass transport increases and also the influence of operating conditions on the system can vary. Malek et al. [8], for example, found that under partially wetted conditions, by increasing the liquid flow rate, there is a maximum for the overall mass-transfer coefficient; whereas for both wetted and nonwetted conditions, the overall mass-transfer coefficient always increased with liquid velocity.

The problem of the interactions between membrane and absorbent solution interests, for instance, the removal of CO<sub>2</sub>. Reactive absorption liquids, such as amines, that are used for this type of removal, usually wet polyolefin membranes. Wettability depends on the surface tension of the liquid, membrane material, contact angle, and pore properties of the membrane. Possible solutions to this problem are to employ more resistant membrane materials, to use different absorbent liquids, and to deposit a nonporous layer on the membrane surface that prevents any passage of the liquid through pores. In order to do not increase too much the resistance to the mass transport, the layer has to be thin and highly permeable to the gaseous species. The dense skin can be useful also for avoiding any possible contamination of the feed gas by the absorbent (Figure 38.4).

Once the absorbent exits from the contactor, it can be regenerated in another membrane contactor unit both by stripping with vacuum or by sweep and by heating. Figure 38.5 reports a simplified scheme for an absorber–desorber flow sheet with the desorber operating under vacuum.

### 38.3.3 FACILITATED TRANSPORT

Beside the systems until now described, facilitated transport membranes can be also used for gas streams treatments [9,10]. Due to the presence of carriers specific for the species to be removed, these types of membrane contactors are characterized by very high selectivity. In supported liquid membranes (or immobilized liquid membranes [ILMs]), a carrier solution is impregnated in the micropores; Figure 38.6 shows the mechanism of these systems. The support properties are certainly important for the overall performance (higher porosity and lower thicknesses, for example, lead to higher fluxes; the substrate structure affects also the minimum thickness needed to maintain the ILM integrity). Membrane instability due to the loss of the carrier solution and the long-term stability of the carrier-self are the main drawbacks of these systems and different solutions have been attempted by researchers to improve their efficiency. Sirkar [11] placed the solution between two porous membranes, but the thickness was too high to guarantee high fluxes. A reduction of the diffusional resistance has been obtained by Teramoto et al. [12] by moving the solution between the two microporous membranes. However, a reduction of selectivity and a wetting of the micropores by the liquid have been registered.

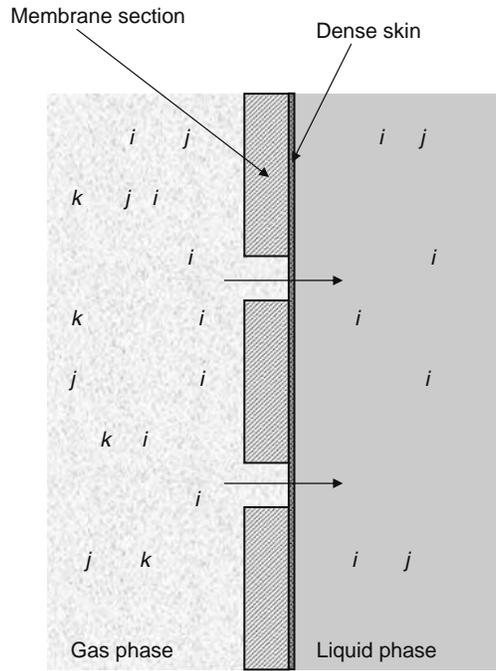

FIGURE 38.4 Composite membrane with a dense skin coated on the microporous surface.

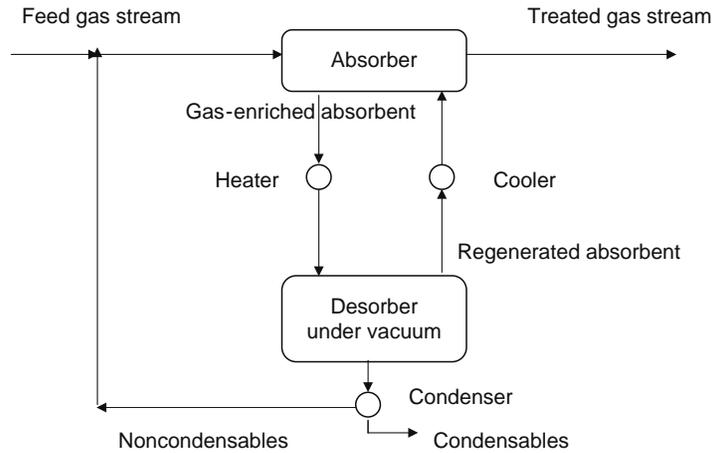

FIGURE 38.5 Schematic absorption-desorption flow sheet with the desorber operating under vacuum.

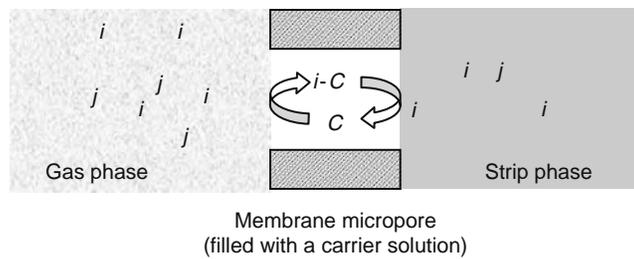

FIGURE 38.6 Example of a supported liquid membrane. The carrier ( $C$ ) contained in the membrane micropore selectively transports the species  $i$  from the gas to the strip phase.

A novel polymeric bicontinuous microemulsion (PBM) membrane, consisting of an interconnecting network of nanometer pore size water channels, was employed as liquid membrane support [13] for the immobilization of new porphyrin carrier [14] for facilitated oxygen transport. Although the membrane resulted to be stable due to the nanoporous structure, a modest (2.3–2.4) O<sub>2</sub>/N<sub>2</sub> selectivity was achieved.

In Section 38.4, studies and results obtained by applying membrane contactors to processes of industrial interest are reported and discussed. In particular, the research efforts made to improve membrane contactors performance are furnished for

- CO<sub>2</sub>, H<sub>2</sub>S, volatile organic compounds (VOCs), SO<sub>x</sub>, NH<sub>3</sub>, and Hg removal
- Olefin/paraffin separation
- Air dehumidification

Results on the use of membrane contactors for the sparkling water production are also presented.

### 38.4 POTENTIALITIES OF MEMBRANE CONTACTORS IN GAS TREATMENTS

Industrial productions lead to substantial emissions of gaseous streams containing pollutants such as acid gases, VOCs, SO<sub>x</sub>, NH<sub>3</sub>, and Hg. Each of them is responsible for severe impact on the environment. CO<sub>2</sub> is the main responsible gas of greenhouse; VOCs are one of the main sources of photochemical reactions in the atmosphere; H<sub>2</sub>S, SO<sub>x</sub>, NH<sub>3</sub>, and Hg are toxic compounds. Traditional techniques more often employed for their recovery are absorption in liquid solvents and adsorption on zeolites or activated carbon. These operations present some drawbacks such as reduced contact area, large-sized equipment, high energy consumption, and regeneration of spent carbon and zeolite beds. Furthermore, on the basis of the more stringent regulations, the desired removals are not easily achieved. When the compounds to be removed are present in the gas stream in ppm, gas separation by membranes can also be not effective because of the low driving force available. On the contrary, membrane contactors in membrane-based absorption process are able to drastically reduce their amount also acting on a very diluted feed.

Results on their performance for the olefin/paraffin separation are also of interest. This type of separation is highly energy intensive because the boiling points are extremely close and conventional cryogenic distillation is difficult and expensive. Another interesting field for membrane contactor applications is the humidity control of air. This process is extremely important in both living and working spaces. The direct-contact systems employed for carrying out this operation suffer from different problems, such as the carryover of solution droplets and the reduced contact area that depends on the relative flow rates.

Membrane contactors can be applied also to the sparkling water production. In beverage industry, the sparkling water is usually produced in two towers of large size (stripper and absorber); on the contrary, membrane contactors are able to carry out the process in the same unit with a substantial reduction in size.

#### 38.4.1 CO<sub>2</sub> AND H<sub>2</sub>S REMOVAL

The removal of CO<sub>2</sub> by membrane contactors has been investigated by several authors. Aqueous solutions of amines are commonly used as absorbers. The complexes that these solutions create with CO<sub>2</sub> are weak and can be easily broken by heating (regeneration step). Mavroudi et al. [15] used a commercial hollow fiber membrane contactor for absorbing CO<sub>2</sub> from a 15% CO<sub>2</sub>–85% N<sub>2</sub> mixture simulating a typical composition of flue gases from a coal combustion power plant. Both water and aqueous DEA were used as absorbents. At low gas flow rates, an increase in the water flow rate led to a higher removal, due to the reduction of the mass-transport resistance, whereas for high gas flow rates, the same removal can be achieved only in a higher volume module that provides more gas–liquid contact area. At low liquid DEA flow rates, the solution is saturated with CO<sub>2</sub> and there is a reduction in the mass transfer; the removal is increased by operating at high flow rates. Higher removals are achieved also at higher DEA concentration, due to the increase in the reaction rate. The removals obtained varied from 75% (water) to 99% (DEA). From a comparison with packed towers, it resulted that membrane contactors have HTU values significantly smaller, representing very compact and efficient systems. The compactness of these systems has been also pointed out by Falk-Pedersen and Dannstrom [16]. Authors studied the separation of CO<sub>2</sub> from offshore gas turbine exhaust by amine absorption. The work was related both to an absorption and a desorption membrane-based unit. The possible wetting of the membrane has been analyzed for different membranes (PP, PES coated with PDMS, PP coated with PDMS, GORE-TEX ePTFE). Among them, only GORE-TEX and PTFE were not wetted. The membranes were chemically stable in both absorber and desorber units. By comparing the conventional absorbers and desorbers and the gas/liquid contactors, for 86% of removal, it resulted in 72% and 78% size reduction for absorber and desorber, respectively and 66% weight reduction for both absorber and desorber. The effect of the

membrane wetting on the mass transfer has been studied also by Rangwala [17] who used water, aqueous NaOH, and DEA for absorbing CO<sub>2</sub> from an air stream in a hollow fiber membrane module equipped with polypropylene fibers. The feed CO<sub>2</sub> concentrations were in the range of 1–10 mol%. Due to the partial wetting of the pores, the mass-transfer resistance offered by the membrane increased significantly. Author calculated that even for less than 2% wetting of pores, the membrane resistance can be the 60% of the total mass-transfer resistance. The effect of DEA on two types of polypropylene microporous membranes (Celgard X40-200 and Celgard X50-215) has been investigated by Wang et al. [18]. The membrane surface morphology and surface tension were monitored with and without CO<sub>2</sub> loading. Both membranes suffered from changes in pore structure and surface roughness and hydrophobicity reduction. However, the Celgard X50-215, due to its thicker microfibrils, presented less morphological and hydrophobic changes. When CO<sub>2</sub> was loaded, carbamate ions were formed from interactions between CO<sub>2</sub> and DEA and the micropores deformation was reduced for both membranes. This result suggests that the use of a membrane with high porosity could lead to an enhancement of the system efficiency, due to the larger contact area between DEA and CO<sub>2</sub>.

CO<sub>2</sub> has been removed from flue gas of thermal power plants by using a PTFE hollow fiber gas–liquid membrane contactor [19]. MEA absorbent (5 mol/L) flowed inside a PTFE hollow fiber membranes while the gas stream (CO<sub>2</sub>, 15%; O<sub>2</sub>, 5%; N<sub>2</sub>, 80%) was fed outside. The membrane was stable for more than 6600 h and the overall volumetric mass-transfer coefficient for the membrane system was more than five times larger than that of the packed bed device. PTFE fibers are usually not available in small diameters and are more expensive than polyolefin membranes. Authors analyzed also the performance of a PE membrane that resulted more susceptible to wetting. By modifying its surface with fluorocarbonic materials, its hydrophobicity was increased. Researches of new absorption liquids for CO<sub>2</sub> have been carried out. TNO, The Netherlands, patented a new absorption aqueous liquid, called CORAL, based on amino acids and alkaline salts. With respect to conventional amines, the new absorber allows to operate for long time with cheaper membranes, such as polyolefins, because it does not wet them, has high oxygen stability, corrosion resistance, and better degradation properties. Furthermore, the vapor pressure of the active component is zero; therefore, its losses due to evaporation are avoided. Kumar et al. [2] reported on the wetting of microporous membranes by different classes of alkanolamines and amino acid salt solutions. The stability of the membrane absorber was tested in a single PP fiber reactor for 72 h. During this period, the CO<sub>2</sub> flux dropped by only 6% in the first 30 min. Feron and Jansen [20] carried out CO<sub>2</sub> absorption and absorber regeneration experiments to verify the feasibility of the process. CO<sub>2</sub> and air were mixed and fed to a prototype transversal-flow membrane absorber equipped with PP fibers. The liquid stream was fed through the membrane lumen and the gas fed outside the fibers. The CO<sub>2</sub> flux increased with the CO<sub>2</sub> partial pressure and the temperature and decreased when the cyclic liquid loading was increased. The CORAL liquid showed a higher mass transfer with respect to other membrane gas absorption systems reported in literature.

Quinn et al. [21] investigated as absorbents for CO<sub>2</sub> melts of salt hydrates such as tetramethylammonium fluoride tetrahydrate [(CH<sub>3</sub>)<sub>4</sub>N]F·4H<sub>2</sub>O and tetraethylammonium acetate tetrahydrate [(CH<sub>3</sub>)<sub>4</sub>N]CH<sub>3</sub>CO<sub>2</sub>·4H<sub>2</sub>O. They found that the CO<sub>2</sub> absorption capacity of salt hydrates is dependent on the water content of the salt, decreasing as the water content increases. The salts showed a large and reversible acid gas absorption capacity and when melts containing CO<sub>2</sub> were cooled to temperatures of solidification, the CO<sub>2</sub> was spontaneously desorbed [22]. This implies that the absorbent can be easily cycled by acting on temperature. Quinn et al. [23] immobilized the melts of salt hydrates in a hydrophilic Celgard 3401 membrane and studied their performance for the separation of CO<sub>2</sub> from H<sub>2</sub> and CH<sub>4</sub> by varying feed and sweep gas (helium) dew point, temperature, and CO<sub>2</sub> partial pressure. For the [(CH<sub>3</sub>)<sub>4</sub>N]F·4H<sub>2</sub>O melt, the CO<sub>2</sub>/CH<sub>4</sub> selectivity ranged between 12 and 120, whereas the CO<sub>2</sub>/H<sub>2</sub> selectivity was extremely low. This result has been attributed to the hydrogen permeability of the Celgard membrane. To reduce the permeation of hydrogen, the liquid melt has been supported on the surface of a film of poly(trimethylsilylpropyne). The new system led to CO<sub>2</sub>/CH<sub>4</sub> and CO<sub>2</sub>/H<sub>2</sub> selectivity ranging between 140–800 and 30–360, respectively, depending on the CO<sub>2</sub> partial pressure. Chen et al. [24] studied the performance of glycerol-based immobilized liquid membranes (ILMs) in the micropores of hydrophilic hollow fibers for the selective separation of CO<sub>2</sub> from N<sub>2</sub> for space suit applications. Two carriers have been considered: sodium carbonate and glycine–Na. The latter carrier is more soluble in glycerol than sodium carbonate, providing more carriers for CO<sub>2</sub> transport and decreasing N<sub>2</sub> permeance. Glycine–Na–glycerol has been immobilized in polysulfone microporous hollow fibers. Due to the low volatility of glycerol, the membranes showed a good stability after 300 h of prolonged runs. Tests have been carried out by feeding the mixture at the tube side and helium at the shell side. CO<sub>2</sub> permeance is increased with the carrier concentration and decreased with an increase of CO<sub>2</sub> partial pressure difference. Feed/sweep relative humidities (RHs) also influenced the performance, by acting on the species solubilities and diffusivities: lower permeance and higher CO<sub>2</sub>/N<sub>2</sub> selectivities were achieved at lower feed stream RHs. The highest obtained selectivity was over 5000. However, to achieve the CO<sub>2</sub> permeances needed for the application, the ILM thickness has to be reduced. The facilitated transport of CO<sub>2</sub> through liquid membranes has been also investigated by Teramoto et al. [25]. To overcome the typical drawbacks of supported liquid membranes, authors propose a system where a carrier solution (liquid membrane) is supplied to the feed side (at high pressure) and permeates through the membrane at the low-pressure side. In these conditions, the membrane is always wetted and its surface is covered with a thin layer of the membrane liquid. A poly(ether sulfone) ultrafiltration membrane and an aqueous solution of DEA as carrier have been chosen for the experiment. The feed mixture was CO<sub>2</sub> and CH<sub>4</sub> and the sweep gas was helium. An interesting result is that by increasing the carrier solution

circulation rate the  $\text{CO}_2$  permeance increases, due to the convective flow. The  $\text{CO}_2/\text{CH}_4$  selectivity was 1970 and the membrane kept its stability for more than 2 months.

As for carbon dioxide, several absorbents can be used for removing hydrogen sulfide from gaseous streams. A comparison among different extractants has been reported by Qi and Cussler [26]. They used a microporous symmetric polypropylene hollow fiber module with the liquid pumped at the tube side and the gas fed outside the fibers. The investigated aqueous solutions were NaOH, MEA, DEA, triethanolamine (TEA), 2-amino-2-methyl-1-propanol (AMP), and 2-(ethylamino)-ethanol (EAE). The mass-transfer coefficients were higher for the strong base (0.0073 m/s), but due to the fast reaction, the main resistance to the transport was located in the membrane. When using amines, the reaction is slower and the mass resistance offered by the liquid becomes more important. This solution is preferred also because amines are cheaper with respect to strong bases. Amine solutions can be effective also for the  $\text{CO}_2$  absorption. Often both gases are present in mixture, and when  $\text{H}_2\text{S}$  is the species to be preferentially absorbed, the  $\text{H}_2\text{S}/\text{CO}_2$  selectivity of the extractants has to be taken into account. Authors studied the simultaneous absorption of the two gases from air (20%  $\text{H}_2\text{S}$ , 17%  $\text{CO}_2$ ). From the experiments, the  $\text{H}_2\text{S}/\text{CO}_2$  selectivity was over 30 for TEA, 11 for AMP, and 5 for EAE. Li et al. [27] used a 10% NaOH solution for the removal of  $\text{H}_2\text{S}$  from a nitrogen stream ( $\text{H}_2\text{S}$  concentration, 16–24 ppm). The solution was fed into the shell side of an asymmetric hollow fiber membrane module, while the gaseous stream flowed countercurrently into the fibers. Two types of asymmetric membranes were prepared: asymmetric polysulfone (microporous) and asymmetric poly(ether sulfone) (dense). The former showed a mass-transport coefficient higher than the one obtained by Qi and Cussler [26] (0.0125–0.025 vs 0.0073 m/s), while the latter showed much lower values ( $5 \times 10^{-4}$  m/s), due to the dense layer formed. However, the membrane resistance controlled the process for both membranes. To improve the removal, it is important to increase the porosity of the layer and to reduce the substrate resistance, keeping the mean pore size of the membrane small to avoid the membrane wetting. Beside these problems, the authors pointed out that the reduction of the mass-transfer rate can be compensated by increasing the driving force (an increase of the feed gas pressure does not lead to bubble formation in the liquid side, due to the presence of the skin layer). Wang et al. [28] reported complete removal of  $\text{H}_2\text{S}$  from a nitrogen stream containing 17.9–1159 ppm  $\text{H}_2\text{S}$ , by using an asymmetric porous PVDF hollow fiber membrane and 2 M  $\text{NaCO}_3$  aqueous solution. The process was strongly influenced by the gas-phase pressure: a small pressure gradient across the membrane resulted in a viscous flow through the membrane that reduced the membrane resistance. Authors compared the results achieved by feeding the gas mixture to the lumen side with those obtained for a feed to the shell side. Due to channeling in the shell side, the gas-film resistance was significant in the latter configuration and the mass-transfer coefficient resulted to be half of that in the lumen side. Furthermore, the resident time is about eight times longer. The absorbent capability for  $\text{H}_2\text{S}$  of  $[(\text{CH}_3)_4\text{N}]\text{F} \cdot 4\text{H}_2\text{O}$  has been investigated by Quinn et al. [29], who immobilized it in a microporous hydrophilic membrane (Celgard 3401).  $\text{H}_2\text{S}$  was preferentially absorbed with respect to  $\text{CH}_4$  (selectivities ranging from 34 to 140) and  $\text{CO}_2$  (selectivities of 6–8). The presence of  $\text{H}_2\text{S}$  in the feed stream strongly reduced the  $\text{CO}_2$  permeation (e.g., from 1300 to 100 Barrer), due to the competition for the same carrier.

### 38.4.2 VOCs REMOVAL

The removal of VOCs from air and gaseous streams can be effectively carried out by membrane contactors. Poddar et al. [30] investigated the performance of a combined absorption-stripping process for removing VOCs from air. The considered VOCs were toluene, dichloromethane, acetone, and methanol. The absorber was a polypropylene microporous hollow fiber where contaminated air was fed at the lumen side and the absorbent was countercurrently sent at the shell side. Two absorbents (silicone oil and Paratherm), water insoluble and nonvolatile, were used. The silicone oil had higher diffusivities but lower stability. The spent absorbent was sent to a desorber, where it was regenerated by applying vacuum and recycled to the absorber unit. The membranes used in the desorber were hydrophobic polypropylene hollow fibers with an ultrathin and highly VOC-permeable plasma-polymerized nonporous silicone skin on the outer surface. The vacuum was applied at the tube side. The VOC concentration in the feed was around 1000 ppmv and the operative temperature was around 22°C. The investigated system resulted to be able to remove VOC. An interesting result achieved was that for dichloromethane, the coupled absorption-desorption system led to a lower removal than the absorption alone with fresh absorbent; whereas for methanol, the performance was almost the same. This difference can be related to the lower Henry's value for methanol that can be desorbed more effectively than dichloromethane. Possible ways for improving the regeneration step are to operate at higher temperatures and/or with a larger membrane area.

VOCs can also be removed by applying vacuum and using composite membranes as, for example, in the VaporSep process commercialized by the MTR, where a porous support is used for a silicone membrane coating in a spiral wound configuration. Hydrophobic polypropylene hollow fibers with an ultrathin and highly VOC-permeable plasma-polymerized nonporous silicone skin on the outer surface can be also effective [31–33].

As the membrane-based absorption process is usually efficient if the VOC concentration in the feed is ranging between 300 and 100 ppmv, whereas the membrane-based vapor permeation process is more effective at higher VOC concentrations, Poddar and Sirkar [34] studied the potentialities of a hybrid system where the two processes are coupled. The vapor permeation

and the desorber operated with the polypropylene having the ultrathin dense layer coating, whereas the absorber employed microporous polypropylene hollow fibers. The hybrid system was effective and led to very high removal of methylene chloride (99.97%).

As for CO<sub>2</sub>, VOCs can also be removed by using immobilized liquid membranes. Obuskovic et al. [35] immobilized a thin layer of silicone oil in the microporous of the hollow fiber polypropylene membrane beneath the dense-coated skin. The performance of the system has been proved for toluene, methanol, and acetone removal from N<sub>2</sub>. With respect to the simple hollow fiber, the presence of the oil layer led to a 2–5 VOC more enriched permeate (due to the reduction of nitrogen flux) with a separation factor of 5–20 times higher (depending on the VOC and the feed gas flowrate). The membrane was stable for 2 years.

### 38.4.3 SO<sub>2</sub> REMOVAL

The removal of SO<sub>2</sub> from gaseous streams can be achieved by absorption in hydrophobic membrane contactors. When strong bases, such as aqueous solutions of NaOH, are used, the main resistance to the mass transport is offered by the membrane [26]. Jansen et al. [36] used Na<sub>2</sub>SO<sub>3</sub> as reactive absorbent and studied its efficiency for removing SO<sub>2</sub> from both nitrogen and real flue gas coming from a coal-fired boiler. In both cases, high recoveries were obtained. The system kept its performance after a period of 500 h, without any problem of fouling or interactions with other flue gas components. On the basis of these results, the TNO group built a pilot plant with a capacity of 100 N m<sup>3</sup>/h in Holland; over 95% of recovery was obtained.

Pilot plant studied have also been performed by Larsen et al. [37], who obtained stable operation and more than 95% SO<sub>2</sub> removal from flue gas streams with a gas-side pressure drop of less than 1000 Pa. The importance of the membrane structure on the SO<sub>2</sub> removal has been studied by Iversen et al. [6], who calculated the influence of the membrane resistance on the estimated membrane area required for 95% SO<sub>2</sub> removal from a coal-fired power plant. Authors performed experiments on different hydrophobic membranes with sodium sulfite as absorbent to measure the SO<sub>2</sub> flux and the overall mass-transfer coefficient. The gas mixture contained 1000 ppm of SO<sub>2</sub> in N<sub>2</sub>. For the same thickness, porosity, and pore size, membranes with a structure similar to random spheres (typical of stretched membranes) showed a better performance than those with a closely packed spheres structure.

### 38.4.4 AMMONIA REMOVAL

Qi and Cussler [26] investigated the removal of ammonia by H<sub>2</sub>SO<sub>4</sub>. H<sub>2</sub>SO<sub>4</sub> being a strong acid, the mass resistance offered by the membrane controlled the process. An industrial membrane gas absorption unit for ammonia recovery from an ammonia containing off-gas stream produced in a dyes intermediates production plant has been installed by TNO. The membrane plant is able to remove 99.9% of ammonia and produces aqueous solutions of 27% ammonia that can be reused in the dyes process [38].

### 38.4.5 MERCURY REMOVAL

Free metallic mercury vapor contained in waste-incineration and soil thermal treatment off-gas, natural gas and the glycol-overhead in a natural gas dryer has been removed by van der Vaart et al. [39] by an oxidative gas absorption. Their study included the selection of the oxidizing agent and the selection of the most suitable membrane material. H<sub>2</sub>O<sub>2</sub> and K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> were chosen for carrying out tests on the basis of their impact on environment and the materials used, the mercury solubility, and the reaction products formed. The stability of several membranes with these oxidizers was also analyzed and the PTFE membrane was selected. The experimental tests were performed in a device patented by TNO, equipped by hollow fibers. At low oxidation potential (H<sub>2</sub>O<sub>2</sub>), the mass-transfer coefficient resulted to be dependent on the liquid flow rate, but at high oxidation potential the mass-transfer coefficient was higher and independent on it. The regeneration of the absorbent liquid was obtained by the precipitation of mercury sulfide. Authors estimated also the membrane area and the costs related to the process for obtaining the target removals of the three streams analyzed and they found that for the glycol-overhead stream, the economy of the process is controlled by the mercury removal step.

### 38.4.6 OLEFIN/PARAFFIN SEPARATIONS

The olefin/paraffin separation has also been studied in membrane contactors, mainly by using as absorbent a solution containing silver nitrate [40,41]. To prevent the wetting of pores by the aqueous solution, efforts have been made for developing a stable composite hollow fiber membrane to be used for ethylene/ethane separation [42]. Polypropylene hollow fibers were used as support material while different top layer materials (ethylene propylene diene terpolymer, EPDM; sulfonated poly(ether ether ketone), SPEEK; polyethylene oxide, PEO; and poly(butylene terephthalate), PBT) were tested and compared in terms of permeability, selectivity, and stability. The experiments included an absorption step coupled to a desorption by stripping gas. The EPDM offered high permeabilities but low selectivities (14.7–72.5), whereas the SPEEK resulted in high selectivities (>2700) and low permeabilities. PEO/PBT top layers gave permeabilities (40–50 Barrer) similar

to EPDM and selectivities of 165. The last system seems to be attractive mainly because it presents the advantage of a constant selectivity even at high liquid flow rates, where the ethylene permeability may exceed the permeability of EPDM.

Tsou et al. [43] removed efficiently ethylene from a mixture of 74/26 ethylene/ethane by using a hydrophilic hollow fiber membrane module with the silver nitrate solution at the tube side.

Selectivities of around 850 for 1-butene/*n*-butene have been achieved by Kovvali et al. [44] by using a glycerol-based immobilized liquid membrane.

### 38.4.7 AIR DEHUMIDIFICATION

Hydrophobic microporous membranes have been applied to the air dehumidification by Isetti et al. [45]. The moisture contained in the air stream was removed by using absorbent solutions such as LiCl and Ca(NO<sub>3</sub>)<sub>2</sub>. Desiccant reactivation can be achieved in a similar device with warm air. In particular, by operating the regeneration step with a thin membrane, the temperature required for obtaining a certain desorbed vapor flux is reduced. With a polyethylene membrane (thickness, 170 μm) vapor fluxes of 200 g/m<sup>2</sup> h are reached at a solution temperature of 323 K, whereas with a PTFE membrane (thickness, 28 μm), the solution temperature can be reduced of 10 K, with a consequent energy saving. Bergero and Chiari [46] used a cross-flow contactor equipped by polypropylene hollow fibers for air humidification with water and air dehumidification with LiCl-saturated solutions. For both cases, high mass-transfer efficiency has been achieved. As important result, they reported that the variation in the specific humidity of the air reduced as the air flow rate increased and was independent on the liquid flow rate; as the air flow rate increased, the contactor reduced its efficiency. GVS SpA (Italy) manufactures and commercializes flat membrane contactors to control air humidity. They are based on microporous hydrophobic materials such as supported (on polyester nonwoven) films in PTFE, PVDF, or PP superficially treated to increase the hydrophobicity. Typical absorbents used are LiCl, TEG, and CaCl<sub>2</sub>. The water vapor exchange achievable in these systems is 1.5 kg/m<sup>2</sup> h. The regeneration step can occur by dry air stripping or by heating the absorbent solution. Among various positive aspects, these membrane contactors have lower capital and operating costs, up to 50% less than traditional dehumidifiers, low-pressure drops, and low noise emissions [47].

### 38.4.8 SPARKLING WATER PRODUCTION

Membrane contactors can be efficiently used also for the sparkling water production. In this case, the water is sent at one side of the hydrophobic membrane and the CO<sub>2</sub> stream is sent at the other side for simultaneously removing the oxygen contained in the water and performing the carbonation. With respect to conventional systems that use two separate columns for the oxygen stripping and the CO<sub>2</sub> injection, membrane contactors are able to carry out the two processes in a single device. Criscuoli et al. [5] analyzed the performance of a commercial hollow fiber module (LiquiCel, Hoechst Celanese), when varying different operating conditions (temperature, pressure, flow rates, oxygen concentration in the water, etc.), in terms of degree of water carbonation, oxygen removal, mass-transport resistances involved. Experimental tests have been coupled to a mathematical model, developed with the aim to establish an appropriate correlation for the calculation of the mass-transfer coefficient at the shell side. In all experimental runs, the system kept its hydrophobicity and the liquid flow rate offered the highest mass-transfer resistance, controlling the transport of both gases between the two phases. Authors applied the model to calculate the membrane area required for treating, with the same efficiency, industrial flow rates. The achieved results were used for determining the costs related to membrane contactors and comparing them with those of traditional devices (Table 38.2). Membrane contactors are more compact, consume less CO<sub>2</sub>, and are less expensive in terms of investment costs, while having higher operating costs related to the membrane replacement voice (about €25,000/year). However, because both capital and operating costs have been calculated on the basis of the unitary cost of a single commercial module, their significant reduction in large-scale applications

**TABLE 38.3****Summary of the Main Improvements Achieved by MC for Some of the Investigated Applications**

Application	
CO <sub>2</sub> removal	Overall volumetric mass-transfer coefficient more than five times larger than that of the packed bed device [19] 72% reduction in size and 66% reduction in weight for the absorption step, and 78% reduction in size and 66% reduction in weight for the desorption step [16]
H <sub>2</sub> S removal	Complete removal from a nitrogen stream containing 17.9–1159 ppm H <sub>2</sub> S in one stage [28]
VOCs removal	99.97% removal of methylene chloride [34]
NH <sub>3</sub> removal	99.9% removal of ammonia and production of aqueous solutions of 27% of ammonia that can be reused in the dyes process [38]
Olefins/paraffins separations	Lower energy consumption because there is no need to operate at very low temperatures and high pressures
Air dehumidification	Elimination of carryover effects; prevention of any pollution of the hygroscopic solution Lower capital and operating costs, up to 50% less than traditional dehumidifiers; low-pressure drops; low noise emissions [47]
Sparkling water production	Water deoxygenation and carbonation carried out simultaneously in the same device; lower capital cost and CO <sub>2</sub> consumption; over 10 times reduction in size [5]

can be expected. Table 38.3 summarizes the main improvements achieved by membrane contactors for some of the applications described in this contribution.

### 38.5 MODULE DESIGN

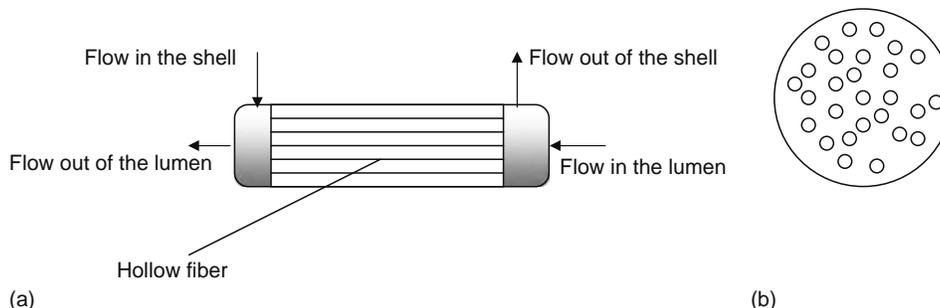

The design of membrane contactors is extremely important for improving their efficiency in mass transfer. A long module, for instance, leads to higher membrane area, but implies also an increase of pressure drop. Similarly, higher fibers packing fractions mean higher membrane area, but can result in nonuniform packing with a consequent bad distribution of flow; the difference of fibers diameters (they are not exactly the same) can also deal with an un-uniform flow. Furthermore, the module has to be designed in such a way that the breakthrough pressure is not exceeded.

The most used design for gas–liquid operations is the tube-in-shell configuration with shell side flow parallel (cocurrent or countercurrent) to the lumen side one (Figure 38.7a). However, this type of module suffers from the un-uniform packing and bad flow distribution at the shell side (Figure 38.7b). To guarantee uniform distribution of the flow and to improve the mass-transfer coefficients, alternative geometries and changes in the original parallel configuration have been investigated.

Wickramasinghe et al. [3] studied the performance of different modules for the removal of oxygen from water. The removal of 7% offered by a parallel flow cylindrical module was increased up to 72% with a crimped flat plate, to 82% with a cylindrical bundle, to 86% with a helical bundle, and to 98% with a rectangular bundle; all these configurations operated in cross-flow. The use of woven fibers has been also investigated by Wickramasinghe et al. [48] who claimed the superior performance of this system with respect to the modules built with individual fibers, due to the higher uniformity of fiber spacing.

The strip process has been studied in hollow fiber contactors containing a woven fabric of fibers also by Wang and Cussler [49]. The modules (one rectangular and one cylindrical) contained baffles for increasing the mass transfer, but the rectangular one offered lower mass-transfer coefficients because of stagnant liquid zones between adjacent fibers.

Bhaumik et al. [4] demonstrated the efficiency of transverse flow hollow fiber devices equipped with fibers in a mat wrapped around a central tube (distributor of the liquid) for the absorption of CO<sub>2</sub> in water.

**FIGURE 38.7** Scheme of a tube-in-shell configuration with shell side flow parallel to the lumen side one. (a) Module and (b) un-uniform packing/section view.

Vladisavljevic and Mitrovic [50] developed a three-phase hollow fiber membrane contactor with frame elements. The module consists of stacks of polygonal plates containing internal frames packed with hollow fibers and an external frame where headers for the inlet and outlet of the fluids flowing inside the fibers are provided. Plates can be monoaxial or biaxial, allowing two- and three-phase contact, respectively. Authors calculated, both at tube and shell side, the pressure drops of this system. At the same fluid flow rate, the pressure drop at the shell side was lower than that of the tube side and proportional to the gas flow rate. The pressure drops at the tube side were mainly related to the local obstacles in the module rather than the resistance in the fibers.

The efforts in the research led to the commercialization of different modules. Some of them are described below.

The Liqui-Cel Extra Flow module of the CELGARD LLC (Charlotte, North Carolina) is characterized by a higher mass-transport coefficient than parallel flow configurations because of the presence of a central baffle that forces the liquid stream (sent to the shell side) to flow perpendicular to the hollow fibers. The central baffle also minimizes the shell side bypassing; the system has been designed for avoiding large pressure drops.

Membrane Corporation (Minneapolis, Minnesota) developed a bubble-free gas-liquid mass-transfer module that contains various fiber bundles. To have 100% of gas transfer, the fibers are sealed at one end. The liquid flows outside the fibers that are fluidized. Low-pressure drops, high turbulence, and no plug for suspended solids eventually contained in the liquid stream are ensured by a quite low packing density.

For a bubble-free ozonation of water, W.L. Gore & Associates (Elkton, Maryland) commercializes the DISSO<sub>3</sub>LVE module made of ozone-resistant fibers in PTFE. A helix arrangement of the fibers leads to higher shell side mass-transfer coefficients than the parallel configuration.

TNO (Holland) designed a rectangular module (TNO transversal-flow membrane module) containing hollow fibers. The system performs with high mass-transfer coefficients and low-pressure drops. Furthermore, it shows a good scale-up potential. The module is commercialized by XTO Membrane Technology.

Patents on new module designs have been recently presented. Nitto Denko (Japan) patented a spiral wound design for membrane contactor applications [51]. The system includes a central feed pipe around which one or more membranes are wound. Tests on water ozonation demonstrated that it is possible to achieve a concentration of ozone 10% higher than in hollow fiber.

TNO housed hollow fiber membranes inside a pressure vessel, to be able to operate with gaseous streams at high pressures [52]. This system is useful for treating (by absorbent liquid) natural gas or petrochemical streams containing species such as CO<sub>2</sub> and H<sub>2</sub>S.

### 38.6 CONCLUDING REMARKS

Membrane contactors result to be effective for the treatment of gaseous streams. With respect to conventional operations, they are able to optimize the use of absorbent solutions (it is ensured a constant interfacial area for the all length of the unit and the carryover of droplets is reduced) and to lead to the desired removal (up to 99%) by using modules of reduced size and weight. Sparkling water can be also efficiently produced in modules of reduced size at lower capital costs and CO<sub>2</sub> consumption than conventional operations. Air dehumidification/humidification in membrane contactors is starting to be commercialized; some pilot plants for CO<sub>2</sub>, SO<sub>2</sub>, and NH<sub>3</sub> abatement are also in operation. Efforts made in the research of more stable membrane materials, more efficient module design, and new absorbent solutions deal with a significant improvement of the membrane contactors performance. However, further research needs to be done to overcome some of the drawbacks still present. For example, the mass transport has to be further enhanced by reducing the mass-transfer resistances involved; the relationships among the parameters that determine the membrane performance have to be more deeply studied for improving the membrane preparation techniques; the permeability and selectivity of coated membranes have to be increased; in supported liquid membranes higher permeability, more stable carriers and a reduced loss of the carrier solution have to be obtained; more general correlations for calculating the mass-transfer coefficient in the modules have to be developed, to facilitate the design and scale-up of the membrane units.

All these improvements coupled to further enhancements in the lifetime of the membranes and their compatibility with absorbents, as well as in the mass-transfer design, will allow to extend the use of membrane contactors in industrial productions.

## 39.1 INTRODUCTION

Increasingly high demands are being placed on new separation technologies due to stricter product quality requirements, environmental legislation, energy efficiency demands, and the need to reduce costs [1]. To meet these increasing demands, there is a tendency to combine processes into hybrids. In a membrane contactor, separation is fully integrated—with an extraction with stripping or an emulsion liquid membrane (ELM) operation with hollow fiber (HF) contactor or absorption process—into one piece of equipment. This allows the advantages of both processes to be fully exploited [2].

Interestingly, a large number of works have been published that deal with applications of supported liquid membranes [3–7]. When HF modules are used as contactors in this type of technology, the organic phase fills the pores of the HF and the aqueous phases flow along the fibers through the inner side and through the outer side. The main drawback of the technology is the instability of the supported liquid membrane (SLM), which can produce undesirable results [8–10]. Although an SLM process is very effective in reducing trace contaminants to very low levels owing to its ability to circumvent equilibrium limitations [11] and its use has been hampered by a lack of stability. The traditional SLM suffers from a gradual loss of the organic membrane phase to the aqueous feed and strip solutions because of emulsification (e.g., resulting from lateral shear forces) at the membrane–aqueous interfaces, and to the osmotic pressure difference across the membrane [12–13]. The osmotic pressure difference displaces the organic membrane phase from the micropores of the support, which ultimately allows the feed and strip solutions to mix and leads to the complete failure of the separation unit. An improved process is needed that can not only remove metal ions but also recover them.

## 39.2 WHY IS A NEW STRIP DISPERSION TECHNIQUE NEEDED?

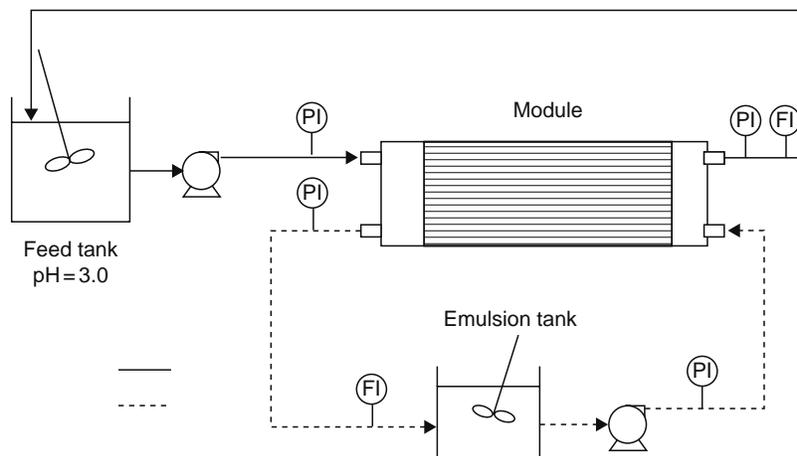

Membranes are flexible, modular, energy-efficient devices with a high specific surface area. The extraction or absorption process offers a very high degree of selectivity and a high driving force for transport, even at very low concentrations. As a result, a technique is required that provides all the benefits of the SLM but without stability problems (as discussed in the previous section). HF modules have therefore been used with different process configurations based on similar fundamentals

that aim to minimize the required membrane area by providing better stability and high mass transfer due to a large area per unit volume (advantages of the HF contactor), while incorporating the advantages of highly efficient ELMs. This new technique is known as supported liquid membrane with strip dispersion (SLMSD), pseudo-emulsion based hollow fiber strip dispersion (PEHFSD), or emulsion pertraction technology (EPP). In this case, the organic (extractant dissolved in diluent) and back-extraction phases are emulsified before injection into the HF module and can be separated at the module outlet. Although there are few references to this alternative method in the literature, there are reports on its viability for the recovery of hexavalent chromium and copper from polluted waters [14–17] and for the removal of hydrocarbons [18]. Nevertheless, this technique still needs to be tested in specific applications to evaluate the suitability of the technology for commercial use. Wienczek and his coworkers [19–20] described the use of microporous HF contactors as an alternative method to the direct dispersion of ELMs to minimize membrane swelling and leakage. HF contactors do not have the high shear rates that are typical of the agitators used in direct dispersion. This technique has been successfully demonstrated for the removal and recovery of metals from wastewaters and process streams [21–24]. PEHFSD provides the following advantages over normal extraction and other membrane process:

- Extraction and stripping can be carried out in one operation
- No possibility of emulsion formation in water phase
- Volume of extractant is relatively small
- Process parameters are very flexible
- Phase separation is not necessary
- Large specific surface area is provided by HF membranes
- Diffusion paths are short
- Modular equipment is compact
- Energy consumption is low

### 39.3 WORKING FUNCTION OF PSEUDO-EMULSION BASED HOLLOW FIBER STRIP DISPERSION

The schematic representation of PEHFSD is shown in Figure 39.1. An aqueous strip solution is dispersed in an organic membrane solution containing one or more extractants in a mixer; the water-in-oil dispersion formed is then pumped to contact with one side of a microporous support, which is passed through the shell side of a microporous polypropylene HF module. The aqueous feed solution, which contains a targeted species to be extracted, is on the other side of the support and is passed through the tube side. The continuous organic phase of the dispersion readily wets the pores of a hydrophobic microporous support, and a stable liquid membrane (the organic phase) is formed in the pores of the support. Figure 39.2 shows an enlarged view of the SLM with strip dispersion. A low pressure (less than ~55.1 kPa [8 psi]) is applied to the aqueous feed solution side ( $P_a$ , which is greater than  $P_o$  for the strip dispersion side) to prevent the organic solution of the strip dispersion from passing through the pores into the feed solution side. The dispersed droplets of the aqueous strip solution—with a typical size of 80–800  $\mu\text{m}$ —are orders of magnitude larger than the pores of the microporous polypropylene support employed for the SLM, which range from 0.01 to 0.2  $\mu\text{m}$ . Therefore, these droplets are retained on the strip dispersion side and cannot pass through the pores to the feed solution side. This PEHFSD technique has a constant supply of the organic membrane solution in the pores, which

**FIGURE 39.1** PEHFSD setup; continuous line: feed stream; dotted line: emulsion stream. (From Urtiga, A., *J. Membr. Sci.*, 257, 161, 2005. With permission.)

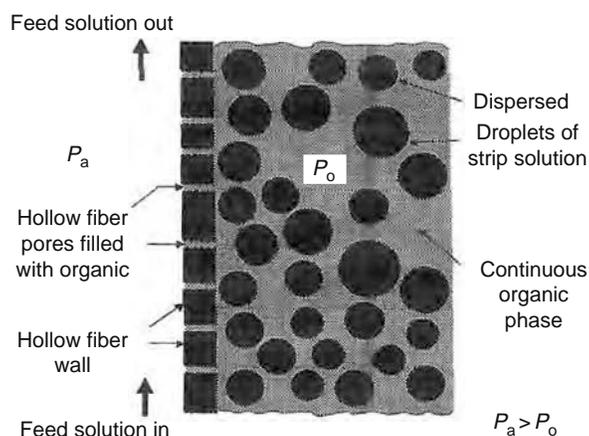

FIGURE 39.2 An enlarged view of the PEHFSD. (From Ho, W.S. and Poddar, T.K., *Environ. Prog.*, 20, 44, 2001. With permission.)

ensures stable and continuous operation. In addition, the direct contact between the organic and strip phases (with high-shear mixing, if necessary) on the strip dispersion side provides an additional area for stripping, which results in very efficient mass transfer. The stripping is more efficient than that achieved with the conventional SLM. As shown in Figure 39.1, PEHFSD combines extraction and stripping, which are normally carried out in two separate steps in conventional processes such as solvent extraction.

### 39.4 APPLICATION OF PSEUDO-EMULSION BASED HOLLOW FIBER STRIP DISPERSION TECHNOLOGY IN METAL SEPARATION

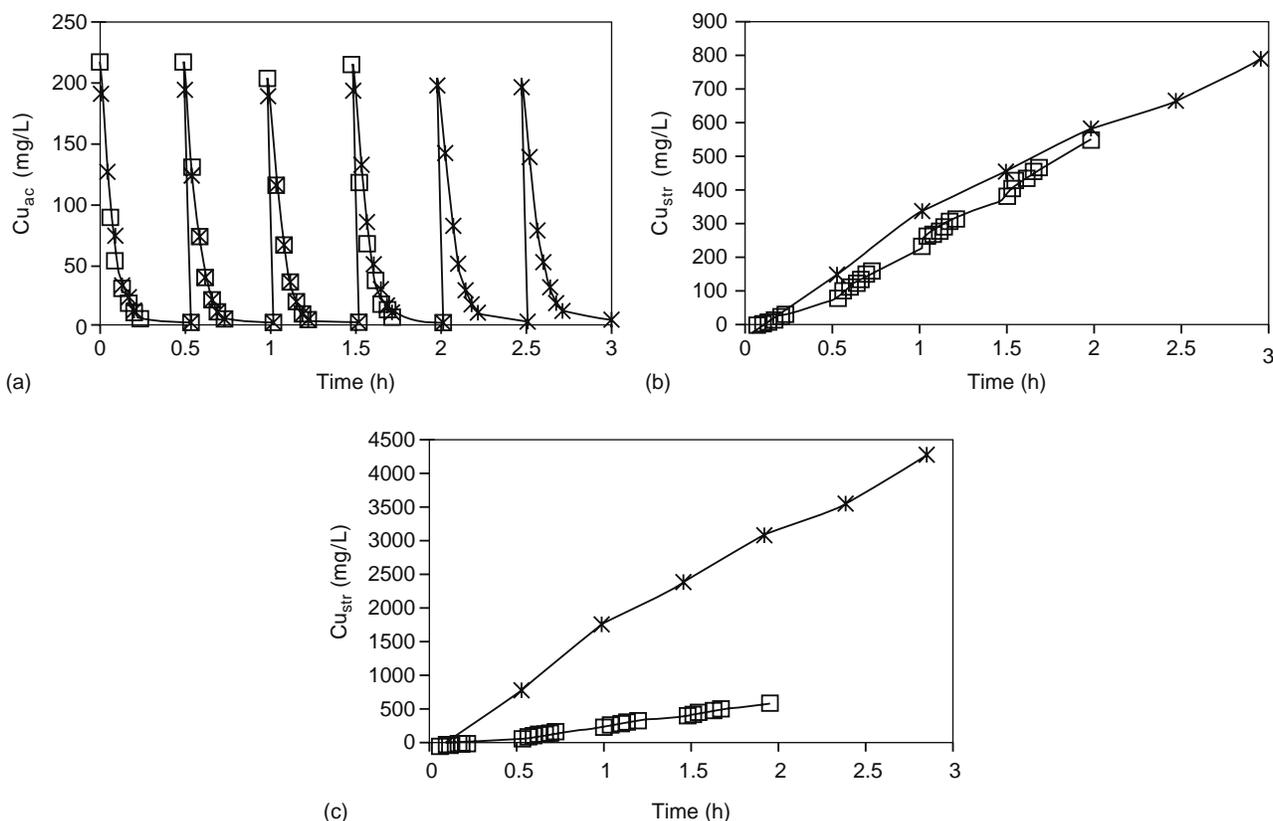

#### 39.4.1 PEHFSD IN METAL SEPARATION

Table 39.1 gives the details of a recently published study that analyzes the use of the pseudo-emulsion based hollow fiber strip dispersion (PEHFSD) technique for different metal ions [25–38]. In another recent study, Urtiaga et al. [39] described a methodology for modeling separation processes based on the use of emulsion pertraction technology. This work gives a comparative analysis of two types of separation process aimed at the recovery of metallic compounds from residual waters using HF modules as membrane contactors: emulsion pertraction (EPP) extraction and nondispersive solvent extraction (NDSX). The recovery of copper, which is the homogeneous catalyst in wet peroxide oxidation (WPO) processes, is analyzed from both an experimental and a theoretical perspective. The separation of the metal was enhanced by using LIX622N as a

**FIGURE 39.3** Comparison of (×) emulsion pertraction results in one membrane contactor and (□) NDSX results in two membrane contactors. [Cu] feed, initial = 200 mg/L, [LIX622N] = 5% (v/v). (From Urtiga, A., *J. Membr. Sci.*, 257, 161, 2005. With permission.)

selective extractant and the concentration took place in a concentrated sulfuric acid phase. These pertraction results were then compared with the results of the separation-concentration of copper obtained in a previous study [40] performed with NDSX and similar HF membrane contactors. The latter case used two HF modules, with an effective membrane area of 1.4 m<sup>2</sup> each. The first module was used for the extraction operation, in which copper is separated from the feed phase, and the second module was used for the back-extraction operation, in which the organic extractant is regenerated and copper is concentrated in the stripping phase. Comparative results are given in Figure 39.3. It is observed that the evolution of copper concentration in the feed phase (Figure 39.3a) is very similar in both techniques. Figure 39.3b shows the mass of copper in the stripping phase, which follows a similar trend with both techniques. The main difference is observed in Figure 39.3c, which shows that the copper concentration in the stripping phase after four experimental cycles is 5.2 times higher when the pertraction process is used. This value is approximately equal to the ratio of stripping volumes used in both techniques:  $V_{\text{NDSX}}/V_{\text{pertraction}} = 5$ . The small difference was attributed to experimental error and the slight modification of phase volumes produced during the collection of samples. The experimental results therefore demonstrate that, for the present application, emulsion pertraction technology offers significant practical and financial advantages over NDSX technology since the cost of acquiring the membranes—considered to be the most significant cost in membrane contactor operation—is reduced by half.

Similarly, Ho and Poddar [25] developed new SLM technology for the removal and recovery of chromium from wastewaters. The technology not only reduces Cr(VI), ranging from approximately 100 to 1000 ppm, to less than 0.05 ppm in the treated effluent allowable for discharge or recycle but also recovers the chromium product at the high concentration of about 20% Cr(VI) (62.3% Na<sub>2</sub>CrO<sub>4</sub>), which is suitable for resale or reuse. In other words, the authors claimed to have achieved the goals of zero discharge and no sludge. This technology is based on their finding that sulfuric acid flux depends on the Cr(VI) concentration in the feed (at pH 1.5). The sulfuric acid flux decreases significantly as the Cr(VI) concentration in the feed increases. The sulfuric acid flux at a feed Cr(VI) concentration of greater than ~100 ppm is far less than at a lower concentration. The stability of the SLM was ensured by adding the strip dispersion methodology, in which the aqueous strip solution is dispersed in a mixer and the strip dispersion formed is circulated from the mixer to the membrane module so that there is a constant supply of the organic solution in the membrane pores. The chromium flux over its entire range—from low Cr(VI) concentrations in the feed solution to high feed concentrations at which the carrier saturation of the facilitated transport mechanism occurs—showed good agreement with a film model that takes into account mass transfer resistances, both in the

**FIGURE 39.4** Strontium (Sr) concentrations in the feed and strip solutions as a function of time in recycle operation for four extractants (C12 Feed is the concentration in the feed solution or the C12 BOPPA extractant, C12 Strip is the concentration in the strip solution for the C12 BOPPA extractant, and similarly for the C6 HDPPA, C18 ODPPA/HDPPA, and C20 ODPPA extractants; the aqueous feed solutions also contained about 80 ppm of calcium; 20 ppm of magnesium, and 50 ppm of zinc in addition to Sr-87, respectively). (From Ho, W.S. and Wang, B., *Ind. Eng. Chem. Res.*, 41, 381, 2002. With permission.)

feed solution and in the membrane phase. The mass transfer coefficient for the feed solution in the tube side of a HF module was calculated from the well-known Leveque correlation with the estimated diffusivity. The mass transfer coefficient for the membrane phase was governed by the distribution coefficient, the diffusivity, and the thickness, porosity, and tortuosity of the membrane support. The model used the distribution coefficient calculated from a measured equilibrium constant and the diffusivity and tortuosity obtained from the flux data at the carrier saturation. In addition, the distribution coefficient calculated was in very good agreement with that measured for a very wide range of aqueous feed Cr (VI) concentrations from approximately 20–18,000 ppm.

In another study, Ho and Bang [38] proposed a strip dispersion system that removes strontium (nonradioactive Sr-87) to an acceptable level in treated water suitable for discharge or recycling, i.e., 8 pCi/L or lower. For this system, the authors used newly synthesized extractants, branched alkyl phenylphosphonic acids, that proved to be more effective than D2EHPA at low feed pH (e.g., pH 2.5). Figure 39.4 shows the results for all four extractants with 1M HCl as the stripping solution. As can be seen, all four extractants removed strontium from the aqueous feed solutions and recovered it in the aqueous strip solutions. The strontium concentration in the aqueous strip solutions was approximately 40 ppm, which is almost the maximum concentration that can be achieved for a feed-to-strip solution volume ratio of 8. Therefore, the stripping achieved with hydrochloric acid was very satisfactory and nearly quantitative. The aqueous feed solutions also contained approximately 80 ppm of calcium, 20 ppm of magnesium, 50 ppm of zinc, and strontium to simulate ground water. Having tested the performance with nonradioactive Sr-87, experiments were conducted with radioactive Sr-90. Table 39.2 shows the results for Sr-90 removal from aqueous feed solutions at pH 3 with 1 M HCl as the stripping solution. As can be seen, the strip dispersion technique containing C20 ODPPA (2-octyldodecyl phenylphosphonic acid) removed Sr-90 to the target concentration of 8 pCi/L (the drinking water standard) or lower from feed solutions containing 317–1000 pCi/L of Sr-90. This target concentration was also achieved using a feed solution containing 1000 pCi/L of Sr-90 in the presence of approximately 80 ppm of calcium, 20 ppm of magnesium, and 50 ppm of zinc. Figure 39.5 shows a comparison with the results for Sr-87 removal. As can be seen, the C12 BOPPA (2-butyloctyl phenylphosphonic acid) extractant decreased the Sr-87 concentration in the feed solution to lower values (for a given time): that is, it removed Sr-87 more effectively than D2EHPA. For example, C12 BOPPA reduced the Sr-87 concentration in the feed solution by more than a factor of 2 less than D2EHPA at 30 min. Another drawback of D2EHPA is that it typically requires a feed pH of 4.5, which is difficult to maintain because of the proton transfer due to extraction. D2EHPA also requires the removal of zinc before strontium can be removed at a feed pH of 4.5, as the extractant forms a precipitate with zinc in the feed solution.

The same strip dispersion technology was used by Klaassen and Jansen [42] under the new name of “emulsion pertraction.” The authors tested the strip dispersion technique on site at Rogal in Enschede, the Netherlands, to extend the lifetime of their passivating bath (Figure 39.6). The installation was equipped with Celgard Liquid-Cel membrane contactors. Passivating is an operation frequently used in the galvanic industry to improve the corrosion resistance of galvanized objects. The lifetime

<sup>a</sup> The feed solution also contained about 80 ppm calcium, 20 ppm magnesium, and 50 ppm zinc.

of the passivating bath liquid is limited due to the accumulation of zinc and iron. Once the zinc and iron concentrations reach a certain limit, the color and corrosion resistance of the passivated objects no longer meet specifications and the bath liquid has to be replaced. Selective removal of iron and zinc from the passivating bath with an emulsion pertraction installation can extend the lifetime of the bath. Klaassen and Jansen suggested that care must be taken to ensure that neither of the active elements, chromium or cobalt, is removed. On-site tests have shown that the emulsion pertraction installation is easy to operate and that no more than 20 min a week is required. Zinc and iron (III) are removed from the passivating bath with high selectivity. There is a negligible loss of chromium and cobalt. The membranes are resistant to the on-site conditions, and transport rates are sufficiently high that a compact installation can be built. Due to a reduction in the use of raw materials (fresh bath liquid) and in the amount of metal sludge that requires disposal, the installation generates an annual profit of \$10,000, whereas the total annual operation costs is only \$6,000.

In a recent study, Sonawane et al. investigated the strip dispersion technique, with a new name, PEHFSD, for the extraction separation of Au(I) from alkaline cyanide media using LIX79 as an extractant [43–46]. In PEHFSD used for Au(I) extraction from cyanide media, the feed solution containing the target species is circulated through the tube side of a microporous

hydrophobic polypropylene HF membrane contactor and a dispersion, prepared by continuous stirring of the organic phase and the aqueous stripping phase to form a water-in-oil pseudo-emulsion, is passed continuously through the shell side in counter current mode, using a single HF membrane contactor [43]. Figure 39.7a shows the Liquid-Cel HF contactor used in the present study. As a case study, the extraction of gold cyanide using PEHFSD was carried out using an LIX79/heptane system. The PEHFSD setup (Figure 39.7b) was used for gold recovery and chromium extraction. Figure 39.7c shows the extraction mechanism of Au(I) from alkaline cyanide media with LIX-79/*n*-heptane in a HF membrane module in which a pseudo-emulsion of LIX-79/*n*-heptane and 0.2 M NaOH flows in the shell side, and feed containing gold cyanide flows in the tube side. Experimental results are given in Figure 39.8a and are expressed as the Au(I) concentration in the feed, strip, and organic phase against time obtained in the HF module. Au(I) was almost completely transported from the feed to the organic phase within 100 min, whereas the transfer from the organic phase to the stripping solution took place in 2.5 h (150 min). In this study, the feed was continuously replaced with fresh solution but the stripping solution was recirculated (without replacing with a fresh solution). The extension of this work deals with Au(I) separation from alkaline cyanide media in presence of base metals using a single HF module for both extraction and stripping [44]. The setup described in [43] was used to circulate the feed solution containing  $\text{Au}(\text{CN})_2^-$  with other base metals in a cyanide medium through the tube side. A dispersion was prepared by continuous stirring of the organic phase (12% LIX-79 dissolved in *n*-heptane) and the aqueous stripping phase (0.2 M NaOH) to form a water-in-oil pseudo-emulsion, which was passed continuously through the shell side in countercurrent mode. The influence of different hydrodynamic and chemical parameters was investigated, such as the feed pH, cyanide concentration in the feed, LIX-79 concentration in *n*-heptane, NaOH concentration in the pseudo-emulsion phase, and initial Au(I) concentration in the feed. A detailed evaluation was made of the selectivity of Au(I) against different metal cyanide salts such as Fe(II), Cu(I), Ni(II), Zn(II), and Ag(I) ions. This study is of particular importance as all the chemical parameters were examined using a synthetic hydrometallurgical alkaline solution containing a mixture of gold with other metal cyanide salts and base metals. This was done to optimize the conditions, which are similar to those encountered in the recovery of gold from hydrometallurgical leach solutions containing mixtures of other metal cyanide salts such as Fe(II), Cu(I), Ni(II), Zn(II), and Ag(I). The present study demonstrates that LIX-79/*n*-heptane can be used effectively as a carrier in Au(I) permeation through PEHFSD. This PEHFSD technique was found to be a promising option for the simultaneous separation and concentration of Au(I) from synthetic alkaline cyanide media in the presence of other metal cyanides such as  $\text{Ag}(\text{CN})_2^-$ ,  $\text{Cu}(\text{CN})_4^{3-}$ ,  $\text{Zn}(\text{CN})_4^{2-}$ ,  $\text{Ni}(\text{CN})_4^{2-}$ , and  $\text{Fe}(\text{CN})_6^{4-}$  using LIX-79/*n*-heptane. The use of a stripping solution containing NaOH in the pseudo-emulsion phase provided fast and efficient stripping of Au(I). To achieve a clean separation of Au(I) in the presence of other metals, several experiments were performed with a synthetic hydrometallurgical solution under optimum conditions. A high degree of selectivity was found. The separation of Au(I) based on the experimental results obtained for the cyano ions using 12% LIX-79 (v/v) with 0.2 M NaOH as a stripping agent, a feed pH of 10.3, and a feed linear flow velocity of 1.23 cm/s gave the following order of selectivity:  $\text{Au}(\text{CN})_2^- > \text{Zn}(\text{CN})_4^{2-} > \text{Ag}(\text{CN})_2^- > \text{Ni}(\text{CN})_4^{2-} > \text{Fe}(\text{CN})_6^{4-} > \text{Cu}(\text{CN})_4^{3-}$ . The validity of this model was evaluated using experimental data and the results were found to tie in well with theoretical values. This technique was also applied to chromium extraction from 1 M HCl solution using 0.35 M CYANEX 921/solvesso-100 and 20 g/L hydrazine sulfate as stripping solution [45]. Figure 39.8b shows the performance of PEHFSD expressed as transport of Cr(VI) as a function of varying concentration of HCl in the feed in recycle mode.

(b) NDSX setup used for gold recovery (setup contains two gear pumps, two flow meters, two pressure gauges, and one Liqui-Cel hollow fiber contactor). (From Liqui-Cel, Charlotte, North Carolina. With permission.) (c) Extraction mechanism of Au(I) from alkaline cyanide media with 12% LIX-79/*n*-heptane impregnated in a hollow-fiber membrane module, flowing pseudo-emulsion of 12% LIX-79/*n*-heptane, and 0.2 M NaOH as receiving phase in the shell side and feed containing gold cyanide flowing in the tube side.

In another study, Bringas et al. [46] attempted to separate and recover anionic pollutants using emulsion perttraction technology and advised the remediation of polluted groundwater with C(VI). Polluted groundwater with the following composition (Table 39.3) was treated using emulsion perttraction technology, with Alamine 336 as the extractant and NaOH as the stripping agent, to reduce the concentration of chromate compounds and recover them in a concentrated solution. In the range of studied conditions, the concentration factors achieved were 18,733 for chromium, 29 for sulfate, and 59 for chloride. Kinetic experiments were carried out to analyze the behavior of the separation and concentration process over time. The kinetic model, which consists of a set of coupled differential equations and the solute mass balances of the fluid phases, was solved using the equilibrium expressions of the interfacial chemical reactions between the aqueous solutes and the organic extractants.

**FIGURE 39.8** (a) Concentration of  $\text{Au}(\text{CN})_2^-$  in the feed, strip, and organic phase as a function of time in recycle mode. (b) % Transport of Cr(VI) with variation of HCl concentration in feed in recycle mode.

Under the experimental conditions, it was concluded that the kinetic control is shared between the feed and the membrane mass transport phenomena, while the resistance associated with the organic phase contained in the emulsion globules can be considered negligible. This situation was found to be consistent with the large interfacial area of the droplets of the stripping phase, which allowed the concentration process to take place at a higher rate than the other separation process. The authors also suggested that the interfacial resistance in the aqueous phase can be reduced by increasing the Reynolds number ( $Re$ ) to values that produce an acceptable pressure drop in the HF's (3.8 bar). The following important findings were made from the analysis of the results obtained: (a) the pseudo-steady state of the system is reached rapidly ( $<0.2$  h), (b) the carrier used, Alamine 336, has a high selectivity for chromium species, and (c) the total chromium concentration decreases from  $9.62 \text{ mol/m}^3$  at the module inlet to  $0.015 \text{ mol/m}^3$  ( $0.8 \text{ mg Cr/L}$ ) at the module outlet in one pass when the residence time in the module is  $0.0014$  h.

### 39.4.2 PEHFSD IN THE SEPARATION/REMOVAL/CONCENTRATION OF ACTINIDES

On the basis of performance of the PEHFSD technique in hydrometallurgy, a comprehensive program was prepared in the laboratory of the author to use PEHFSD with a hydrophobic microporous HF contactor for the recovery of actinides from process effluents. Roy et al. [47–50] carried out a detailed study of actinide transport using PEHFSD. The objective was to evaluate the effect of various chemical and hydrodynamic parameters in optimizing the performance of PEHFSD for the extraction of U(VI), Pu(IV), and Am(III) from nitric acid media. The authors also attempted to apply this technique to the recovery of actinides from the different streams of low-level and medium-level acidic waste. As in hydrometallurgical applications, an organic solution is dispersed in an aqueous strippant and the resulting pseudo-emulsion is then pumped into the shell side of a microporous polypropylene HF module. The aqueous feed solution containing the U(VI), Pu(IV), or Am(III) to be extracted is passed through the tube side of the fibers. The continuous organic phase of the dispersion readily wets the pores of the hydrophobic microporous support and a stable liquid membrane (the organic phase) is formed in the pores of the microporous support. This ensures stable and continuous operation. In addition, the direct contact between the organic and strip phases on the strip dispersion side provides an additional surface area, which results in very efficient stripping.

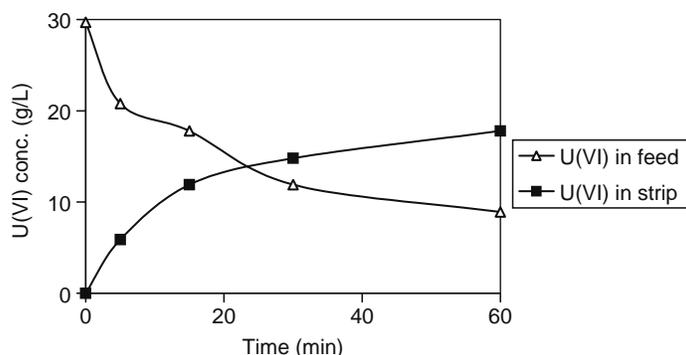

#### 39.4.2.1 U(VI), Pu(IV), and Am(III) Extraction

The extraction of U(VI) was performed by Roy et al. using the PEHFSD technique with TBP as an extractant [47–48]. A schematic view of the PEHFSD process for U(VI) (as a representative case  $0.01 \text{ M HNO}_3$ ) in recirculation mode (using a

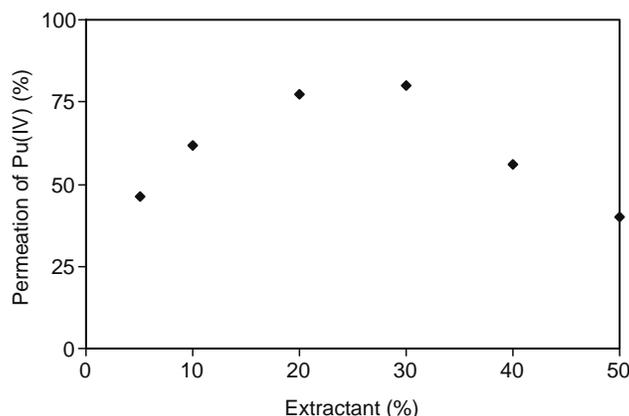

**FIGURE 39.9** Simultaneous extraction and stripping of U(VI) using PEHFSD technique. Feed acidity: 4 M HNO<sub>3</sub>, extractant: 30% TBP in nph, U(VI) ~29.7 g L<sup>-1</sup> (% recovery of U(VI): 68%).

peristaltic pump) is shown in Figure 39.1. In recirculation mode, the feed aqueous phase (300 cm<sup>3</sup>) flowed through the lumen of the fibers at a flow rate of ~12 L/h, and the pseudo-emulsion phase (prepared by stirring [~600 rpm] and the organic phase, TBP + strip solution at a ratio of 1:2) flowed through the shell side at a flow rate of ~5 L/h. In the present setup the pseudo-emulsion phase was 100 cm<sup>3</sup> of TBP diluted in normal paraffin hydrocarbon (nph) plus 200 cm<sup>3</sup> of 0.01 M HNO<sub>3</sub> aqueous stripping solution. By maintaining these conditions, the appearance of the organic phase on the aqueous side of the membrane was prevented as the pressure on the lumen side was higher than on the shell side. Since the emulsion is passed through shell side of HFC, the extraction of metal ions takes place at the pores of the hydrophobic membrane, which is wetted with the organic extractant. Once the pseudo-emulsion is loaded with metal ions, these are recovered instantaneously in the stripping phase (as stripping takes place due to an equilibrium shift caused by 0.01 M HNO<sub>3</sub>). Because of the pseudo nature of the emulsion, the organic and strip phases are separated after the experiment is stopped. This overcomes some of the deficiencies of conventional ELMs, such as the breaking and swelling of the emulsion. In addition, it is difficult to recover metal from the loaded emulsion as the techniques suggested for this purpose (for example, coalescence) are complicated. The transport of U(VI) through the HF membrane contactor was monitored by periodically sampling the feed/strip solution.

The experimental results in Figure 39.9 revealed that when the flow rate of the aqueous phase is higher than that of the organic phase in a hydrophobic membrane and with feed in 4 M HNO<sub>3</sub> and 20% TBP as an extractant, the transport of uranium across the membrane is fast. Therefore, a HF contactor in strip dispersion mode with 20% TBP in nph as an extractant could be successfully used for the separation and concentration of U(VI) from nitric acid media. The feasibility of this technique for the separation of U(VI) from dilute solutions using 0.01 M HNO<sub>3</sub> solution as strippant even in the presence of fission products from waste streams makes it a viable alternative to conventional methods.

The same PEHFSD setup was used for Pu(IV) extraction [49]. The extractant was TBP in nph. The transport proceeds through complexation at the feed phase/membrane interface and the formation of neutral solvated complex species (Pu(NO<sub>3</sub>)<sub>4</sub> · 2TBP), which dissolve in the organic phase. Experiments were performed at concentrations ranging from 5% to 50% of TBP in nph. As can be seen in Figure 39.10, the extraction of Pu increased up to a concentration of 30% and then

**FIGURE 39.10** Effect of extractant concentration on Pu(IV) transportation. Feed acidity: 4 M HNO<sub>3</sub>, strippant: 0.1 M NH<sub>2</sub>OH · HCl in 0.3 M HNO<sub>3</sub>, Pu(IV) concentration in feed: 1.5 × 10<sup>-5</sup> mol L<sup>-1</sup>.

**TABLE 39.4**  
**Effect of Strippant Concentration**  
**on Am(III) Transport**

S. No.	HNO <sub>3</sub> (M)	% Recovery
1	1.0	39.7
2	2.0	65.4
3	3.0	74.1
4	4.0	75.2
5	5.0	78.5
6	6.0	78.9

*Note:* Final value of transport measured after 90 min.

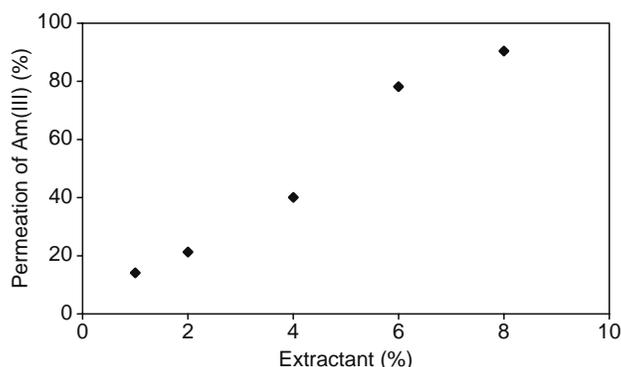

decreased at concentrations above this value. The diffusion-limited flux increased linearly with the carrier concentration, but at higher carrier concentrations the viscosity of the membrane phase also increased.

Similarly, Am(III) extraction was studied by Roy et al. using the same setup but with a different extractant, i.e., TOPO (trioctylphosphine oxide) in nph [50]. This study analyzed the effect of the concentration of nitric acid, the strippant used, and the variation in the organic–aqueous (O–A) phase ratio on Am(III) transport. The maximum permeation of metal ions was achieved with 6% TOPO in nph as the extractant and 5 M HNO<sub>3</sub> as the strippant. The optimum performance of the TOPO/nph system was attained with an O–A ratio of 0.5. To enable the stripping of metal ions, the nitric acid molarity was varied from 1 to 6 M. The results reveal (Table 39.4) that stripping reaches a maximum at 5 M HNO<sub>3</sub> and then remains steady above this value. Further experiments were carried out with O–A ratios from 0.09 to 0.5 and it was discovered that an O–A ratio of 0.5 gave the maximum permeation of Am(III) (78.5%). Figure 39.11 shows the effect of extractant concentration on Am(III) transport from nitric acid media. When the volume of strippant was decreased, metal recovery also decreased under similar experimental conditions.

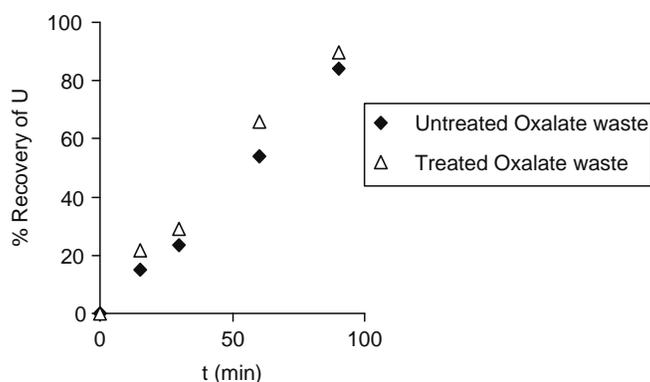

### 39.4.2.2 U(VI) and Pu(VI) Recovery from Oxalate Supernatant Waste

During plutonium reconversion in a reprocessing plant, oxalate supernatant is normally generated during plutonium precipitation by oxalic acid as plutonium oxalate. This is further converted into plutonium oxide. This waste solution will have the following composition: uranium (U): 5 gm dm<sup>-3</sup>, plutonium (Pu): 25 mg dm<sup>-3</sup>, ruthenium (Ru<sup>106</sup>): 0.0032 mCi dm<sup>-3</sup>, cesium (Cs<sup>137</sup>): 0.003 mCi dm<sup>-3</sup>, nitric acid: 3 M, and H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>: 0.1 M.

Using the same PEHFSD setup (similar to Figure 39.1), Roy et al. [51] carried out a series of experiments with treated (oxalate ion destroyed by KMnO<sub>4</sub> and H<sub>2</sub>O<sub>2</sub>) and untreated (without oxalate decomposition) waste to recover uranium and plutonium from these acidic solutions using TBP as an extractant in pseudo-emulsion form with nitric acid. The aqueous feed phase flowed through the lumen of the fibers at a flow rate of ~12 L/h and the pseudo-emulsion phase (prepared by stirring [~600 rpm] the organic plus strip solution at a ratio of 1:2) flowed through the shell side at a flow rate of ~5 L/h. The uranium

**FIGURE 39.11** Effect of extractant concentration on Am transport. Feed acidity: 0.3 M HNO<sub>3</sub>, extractant: TBP, strippant: 5 M HNO<sub>3</sub>, feed concentration: 10<sup>-6</sup> mol dm<sup>-3</sup> (final value of transport measured after 90 min).

**FIGURE 39.12** % Recovery against elapsed time for U(VI) and Pu(IV) transported for actual untreated and treated oxalate supernatant solution in the feed phase from the experimental results in recycle mode (composition of feed and detail of experiment in text).

and plutonium recovery was well above 80% in the case of untreated waste and over 90% in the case of treated waste (Figure 39.12). The presence of important fission products such as  $^{137}\text{Cs}$  and  $^{106}\text{Ru}$  did not affect the recovery of uranium. This clearly indicates that the present method could be successfully applied to the recovery of both U(VI) and Pu(IV) from oxalate supernatant waste.

## 40.1 INTRODUCTION TO WATER TREATMENT TECHNOLOGIES INVOLVING MEMBRANES AND ELECTRODES

Membranes are employed in various industrial processes because these materials provide an efficient and economical way to separate specific compounds from specific process streams. Membranes and membrane processes are developed and optimized to suit the needs of the separation process where they are to be implemented. The main parameters of membranes are selectivity and permeability toward specific compounds and membrane stability in the process environment. Organic membranes are usually more economical than inorganic membranes unless specific properties of inorganic membranes are required such as chemical inertness, high radiation resistance, or high thermal and mechanical stabilities. Organic and inorganic membranes offer a wide range of applications and occupy an important place in modern process industry, including food, biotechnology, environmental control, and electronics and petrochemical industries [1]. However, membranes have their limitations and many

impurities or pollutants cannot be efficiently or economically removed by the selective properties of ceramic or polymeric membranes only.

Electroseparation is defined as “the use of electricity or electromagnetic fields to produce and enhance chemical or physical separation” [2]. Tsouris and DePaoli [3,4] have presented brief reviews of this topic. Essentially the electrical potential applied between two electrodes is used to promote physical or chemical processes that are not favorable or are too slow under nonelectric process conditions. In the past few decades, scientists have tried to combine the advantages of both electrical and membrane processes. Electrodes with the porosity of a membrane (i.e., electromembranes) offer an advantage in terms of contact: pollutants that are forced through the pores of an electromembrane are more likely to be adsorbed, decomposed, oxidized, or reduced than when passing along the relatively low surface area of a dense electrode.

Electromembranes are commonly made from porous carbon, metals, or metal oxides. Originally, nonconductive ceramic materials such as  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  were modified into electrodes by deposition of electroconductive materials such as (1) carbon by pyrolysis of methane [5] or natural gas [6], (2)  $\text{RuO}_2\text{-TiO}_2$  via solgel techniques [7], (3) metals via electroless plating [6,7], or (4) electromagnetic sputtering [6]. Ebonex ceramic ( $\text{Ti}_4\text{O}_7$ ), the most common of the ceramic-based anode materials, is reported to exhibit electrical conductivity similar to that of graphite ( $6.3 \times 10^{-4} \Omega \text{ cm}$ ) [8]. Ebonex is nonstoichiometric titanium oxide comprised of Magneli phase titanium oxides,  $\text{Ti}_4\text{O}_7$  and  $\text{Ti}_5\text{O}_9$  [9–10]. A significant amount of research has also been conducted on the deposition of platinum onto Ebonex as well as the characterization of platinum-coated Ebonex electrodes [11–13].

This chapter describes water purification processes where an electrode process is combined with a membrane process. Special emphasis is placed on processes where the membrane acts as an electrode. Porous electrodes or electrodes that could potentially be used as membranes are also included in this chapter. The last two sections describe two case studies of electrosorption of ions from wastewater and anodic decomposition of phenol, respectively.

## 40.2 ELECTRICALLY ENHANCED MEMBRANE PROCESSES FOR WATER PURIFICATION

References on electrochemical/electrostatic enhanced water purification processes using ceramic membranes can be divided into two main groups; papers dealing with pollutants that are either

1. electrochemically modified, meaning that the pollutant takes part in an electrochemical reaction, or
2. removed largely by electrostatic attraction/repulsion

Sections 40.2.1 and 40.2.2 highlight the advantages and disadvantages and the role of ceramic membranes in both approaches.

### 40.2.1 ELECTROCHEMICAL MODIFICATION OF POLLUTANTS

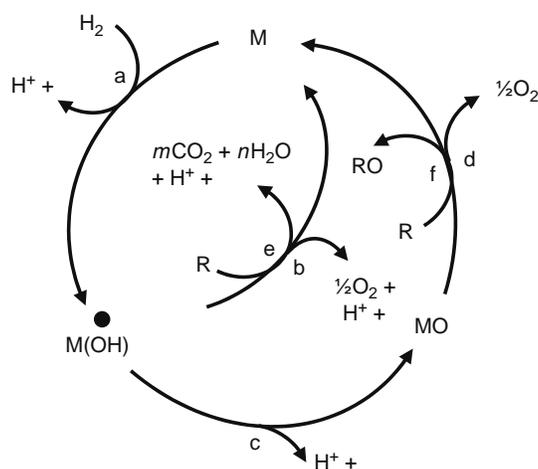

Water purification can be achieved by decomposition or destruction of the pollutant on contact with an electrically charged surface. In several cases permeable electrodes are used in a flow-through mode to ensure contact between the pollutant and the electrode. The type of electrode ranges from metal meshes and carbon cloths to ceramic membrane supports coated with a porous layer of electroconductive material.

Ceramic membranes in these kinds of processes are often desirable due to their thermal and chemical stabilities in the oxidative and reducing environment. The types of processes discussed here can be divided into three groups, namely electrochemical oxidation, electrochemical reduction, and electrochemical disinfection and are discussed in Sections 2.1.1, 2.1.2, and 2.1.3, respectively. Jüttner et al. [14] reviewed examples of each group with particular emphasis on anodic oxidation of phenol, aliphatic acids, cyanide, thiocyanide, and sodium dithionite, employing different electrodes, i.e., packed bed and electrodes of graphite, titanium-supported oxides ( $\text{IrO}_2$ ,  $\text{RuO}_2$ ,  $\text{PbO}_2$ , and  $\text{SnO}_2$ ), and Bi- or Fe-doped  $\text{PbO}_2$ .

#### 40.2.1.1 Electrochemical Oxidation

Anodic oxidation was shown to be a useful method for the removal of organic pollutants from aqueous solutions [15]. Partial decomposition of hazardous organic compounds to biodegradable compounds or complete decomposition to  $\text{H}_2\text{O}$  and  $\text{CO}_2$  can be achieved by the electrochemical treatment of waste [14]. Two different categories of electrochemical treatment of wastewater or waste can be distinguished:

- Direct anodic oxidation, whereby organics are oxidized at the electrode surface.
- Indirect oxidation, whereby electrochemically generated oxidants, such as ozone, hydrogen peroxide, hypochlorite, Fenton's reagent, or peroxodisulfate are applied for oxidation [16,17].

**FIGURE 40.1** Oxidation mechanism on active and non-active anodes. (From Comninellis, CH., *Electrochim. Acta*, 39, 1858, 1994. With permission.)

Mediated electrochemical oxidation (MEO) is a special case of indirect oxidation whereby metal ions with high oxidation potential (e.g., Ag(II), Ce(IV), and Co(III)) are electrochemically generated in a closed cycle [14].

#### 40.2.1.1.1 Direct Oxidation at the Anode

A generalized pathway for anodic oxidation of organics as described by Comninellis [18] is illustrated in Figure 40.1.

The pathway described in Figure 40.1 assumes that six major steps are involved:

1. Electrolysis of water, forming an adsorbed hydroxyl species
2. Electrochemical oxidation of physisorbed hydroxyl radicals ( $\text{H}_2\text{O}/\text{H}_2\text{O}_2$  redox couple)
3. Electrochemical oxidation of the surface (M/MO redox couple)
4. Release of oxygen during chemical decomposition
5. Electrochemical oxidation mediated by physisorbed (\*OH) radicals
6. Heterogeneous catalytic oxidation at electrooxidized active sites

The Ebonex ceramic anode has been used to study the electrolytic oxidation of trichloroethylene to  $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{Cl}^-$ , and  $\text{ClO}_3^-$  [19]. Ebonex and  $\text{PbO}_2$ -coated Ebonex electrodes were used for the electrochemical treatment of phenolic pollutants in water [20].

It was also reported that porous ceramic-based membranes, made from stainless steel supported  $\text{Al}_2\text{O}_3/\text{ZrO}_2$ , were employed as electrodes for the direct oxidation of methanol [21–22]. The electromembranes were prepared by electrodeposition of active materials such as tungsten and molybdenum. Aqueous effluents containing mainly phenol were passed through a flow-through electrochemical reactor equipped with an alumina-based ceramic membrane. The obtained permeate was analyzed and fed back into the reactor for 10 consecutive cycles. During the first three cycles, the phenol concentration was reduced from 100 ppm to 5 ppm. It was clear that *p*-benzoquinone was the most important intermediate product and its concentration increased considerably during the first few cycles. When most of the phenol was converted, a reduction in *p*-benzoquinone concentration could be observed on further cycles. After the tenth cycle the *p*-benzoquinone concentration was 20 ppm [23]. It should be noted that these low concentration could be more harmful than the initial concentration of phenol and full analysis of treated water is therefore recommended.

#### 40.2.1.1.2 Indirect Oxidation

In aqueous waste liquids containing low concentrations of undesired organic compounds (generally less than 100 ppm) only a limited selection of these compounds can be oxidized. Direct electrochemical oxidation at the anode would be an uneconomical option because of the low concentration of the organic compounds to be treated [24]. Hence electrochemically generated oxidants are suitable for these waters.

Chlorine or hypochlorite has been reported as a widely used electrochemically generated oxidant [14]. The  $\text{ClO}^-/\text{Cl}^-$  pair acts as an electron transfer agent that destroys organic pollutants [25]. Electrochemically generated  $\text{ClO}^-$  anions proved to have a positive influence in the fractional conversion of phenol by enhancing degradation over shorter electrolysis periods [26]. Phenol degradation can be carried out near the electrode surface by hypochlorite formed through the oxidation of chloride [27].  $\text{H}_2\text{O}_2$  can also be used as an oxidizing agent and can be electrogenerated via the two electron reduction of  $\text{O}_2$  at the cathode [17]. The oxidative power of the  $\text{H}_2\text{O}_2$  molecules can be enhanced when the reaction conditions favor the Fenton

reaction where the highly reactive one-electron oxidizing agent, the hydroxyl radical ( $\text{OH}^\bullet$ ), can be produced. Wang et al. [17] described how the TOC of a simulated dye waste was reduced to 30% by indirect electro-oxidation using the electro-Fenton reaction. The electrode in this case was an activated carbon.

#### 40.2.1.2 Electrochemical Reduction

Metal ions such as nickel, iron, copper, and zinc are those pollutants most readily treated by an electrochemical reduction method. Metal reduction becomes feasible at concentrations above 0.05 ppm if relatively costly metals can be recovered. In the case of electrochemical reduction the function of the membrane is usually limited to that of a diaphragm and the electrodes used are usually solid.

Another application where the reduction of metallic impurities is possible is in the purification of plating solutions containing negatively charged metal oxides, e.g., chromium plating baths [28]. In this application, negative metal oxide ions migrate away from the cathode where the positive impurities ( $\text{Cu}^+$ ,  $\text{Zn}^{2+}$ ,  $\text{Fe}^{2+}$ ) are reduced.

Bunce et al. [29] employed ion-selective membranes in the reduction of a synthetic acid mine drainage solution containing  $\text{FeSO}_4$  and  $\text{CuSO}_4$ . 50% current efficiencies were reached when the anion-exchange membrane was used as separator between the cathode and the anode compartments. However, as the conductivity of the catholyte solution decreases, increasingly higher potentials are needed to overcome the ohmic losses, and therefore higher energy costs are incurred. This is the case particularly where metal ions are reduced at the cathode and no new source of ion conductivity (such as  $\text{OH}^-$  ions) is generated [29]. A promising application of electrochemical reduction was described by Juang and Lin [30] in which case an electrochemical Cu reduction and citrate recovery system was tested. More than 50% current efficiency and 95% Cu recovery were obtained for concentrations above  $20 \text{ mmol} \cdot \text{L}^{-1}$  at a current density of  $139 \text{ A} \cdot \text{m}^{-2}$ . Patent US4948489 [31] describes an electrochemical cell in which heavy metals can be removed from wastewater in the form of oxides. By applying potentials up to 25 V the oxides of heavy metals (having a standard reduction potential more negative than that of hydrogen) were formed. The oxides can be removed by filtration.

It is not always the direct reduction of metal ions that may lead to their removal. Some metal ions, especially  $\text{Fe}^{2+}$ , are removed by precipitation as a result of an increase in the pH near the cathode [28].

#### 40.2.1.3 Electrochemical Disinfection

Potential applied over granular-activated carbon [32] and compacted activated carbon [33] can be used to kill bacteria, and a potential usually between 0.6–1 V versus the saturated calomel electrode is required. Desorption of dead bacteria from electrode cells can be accomplished via electrostatic repulsion by applying negative potentials. The work of Matsunaga et al. [32] concentrated on the electrochemical oxidation of intracellular coenzyme A and not on the generation of disinfectants by electrochemical oxidation. However, the release of carbon from the electrode was mentioned as one of the drawbacks. In a more recent article, Matsunaga et al. [34] described the application of an alternating positive potential to a titanium nitrate (TiN) mesh electrode that resulted in effective disinfection of water containing several types of bacteria. The TiN films employed exhibited low electrical resistance and good chemical and thermal stabilities. An applied potential of 1.2 V versus the saturated calomel electrode reduced the survival ratio of microorganisms to between 0% and 38% depending on the type of microorganism.

### 40.2.2 ELECTROSTATICALLY DRIVEN POLLUTANTS

Processes whereby purification results by the use of an electrical field, which is not accompanied by decomposition or destruction of the pollutant, can be divided into four different groups: electrodialysis (ED), electrofiltration, electrosorption, and electroremediation. The main electrochemical reaction in these types of processes is decomposition of water.

The process of ED is, by definition, a membrane-based separation process in which ions are driven through an ion-selective membrane under the influence of an electric field [35]. Conversely, in electrofiltration a charged pollutant particle is prevented from moving through a membrane by the influence of an electric field. Electrosorption is an electrically enhanced ion-exchange process and electroremediation is a process developed for the decontamination of polluted soil. Each different process is discussed separately.

#### 40.2.2.1 Electrofiltration

Membrane fouling is an important phenomenon that has a significant effect on the efficiency of a membrane system. This fouling increases the energy consumption of water purification process. The problems associated with fouling are commonly reduced by the following main membrane antifouling strategies: (1) modification of the membrane material, (2) changing of the hydrodynamic conditions in the flow channel, and (3) application of an external force, e.g., electrical field [36]. Most biological colloids in nature possess a small surface charge that will allow small drift velocities when placed in an electrical field [37]. Under the right conditions these drift velocities can help prevent fouling. This principle is schematically

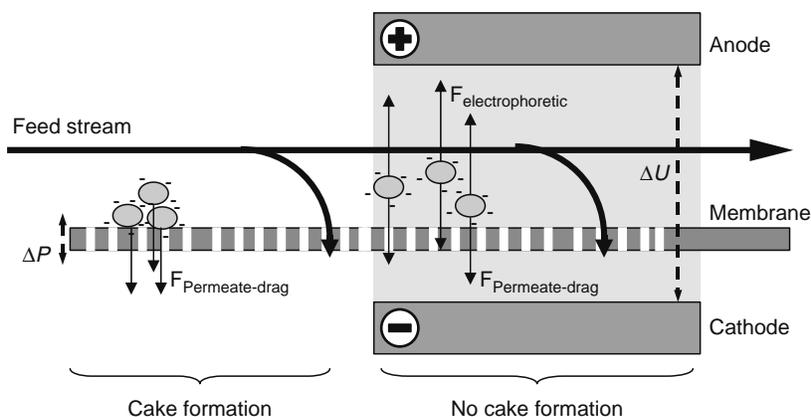

FIGURE 40.2 Schematic representation of the principle of electrofiltration.

represented in Figure 40.2. The force caused by the flow of permeate toward the porous surface accumulates the particles at the pore entrance. With an additional electrophoretic force applied, the net force upon the particle toward the surface decreases and the formation of a “cake layer” (i.e., a layer comprised of rejected particles at the upstream face of the membrane) can be prevented or significantly delayed.

Several researchers have shown that the application of an electrostatic field over the cross section of a membrane leads to a significant reduction in the energy cost per unit of permeate for microfiltration [38–40], ultrafiltration [41–44], and nanofiltration systems [45].

In conventional filtration systems the cake layer adds significantly to the resistance of flow through the membrane, and therefore to the overall operating costs. Several articles [36–40] and some reviews [2,46] describe electrofiltration in more detail. In particular the focus is on specific aspects of electrofiltration for different membranes or pollutant surface charges, and the influence of the magnitude of the imposed field gradient, as well as the role of cross-flow velocity and particle sizes of pollutants. Application of the correct electrical potential can prevent the formation of the cake layer, allowing the steady-state flux to be 10 times higher than the same membrane process without the applied potential [39,41,46]. Electrofiltration becomes especially important for the treatment of effluents with a high total solid content. Such effluent is for example produced during the post-chemical mechanical polishing (CMP) process, an essential step in the production process of integrated circuit (IC) chips. Large volumes of ultrapure water (UPW) are used to remove impurities from wafer surfaces, specifically fine particles from the polishing slurry resulting in wastewaters with a high solid content. Wang and Yang [47] found that this effluent could be treated with electrofiltration very efficiently.

Electrofiltration was investigated using both organic membranes (such as polyamide [41] and polyether sulfone [39]) and inorganic membranes [40]. The main advantage of inorganic membranes when used in electrofiltration is that the membrane can act as the membrane and electrode simultaneously. This not only makes the system simpler but also reduces the distance between electrodes and therefore the necessary potential difference. Robinson et al. [43] investigated the use of alternating current to reach optimum performance of electrofiltration units and argued that direct current is only needed when the particles are uniformly charged (for example, in biological suspensions at relevant pH values). Theoretical models that describe the membrane permeability under the influence of an electrical field are presented in several papers [36,40,46].

#### 40.2.2.2 Electrodialysis

Electrodialysis (ED) is the electrochemical separation process in which an electrical potential difference and ion-selective membranes are used to separate ionic species from an aqueous solute and other uncharged components. A schematic representation of the ED system is given in Figure 40.3. ED systems usually consist of a large number of compartments between two electrodes. The compartments are separated using alternate anion-exchange membranes (AEM) and cation-exchange membranes (CEM), and compartments are filled with polluted water. When a sufficiently large potential difference is applied between the anode and the cathode to start an electrochemical reaction (usually the reduction of water at the cathode and oxidation of water or chloride at the anode), cations are driven through the CEMs into adjacent compartments in the direction of the cathode. Conversely, anions migrate through the AEMs toward the anode. As a result, adjacent compartments will contain either concentrated or diluted solutions, respectively [48]. Note that the rate of the oxidation and reduction reactions on the electrodes is directly coupled to the transport of charges through the ion-exchange membranes to maintain electrical neutrality in each compartment. During the past three decades, a polarity reversal process known as electrodialysis reversal (EDR) has been developed. In this process the polarity is reversed on a regular basis in order that scale is broken up and

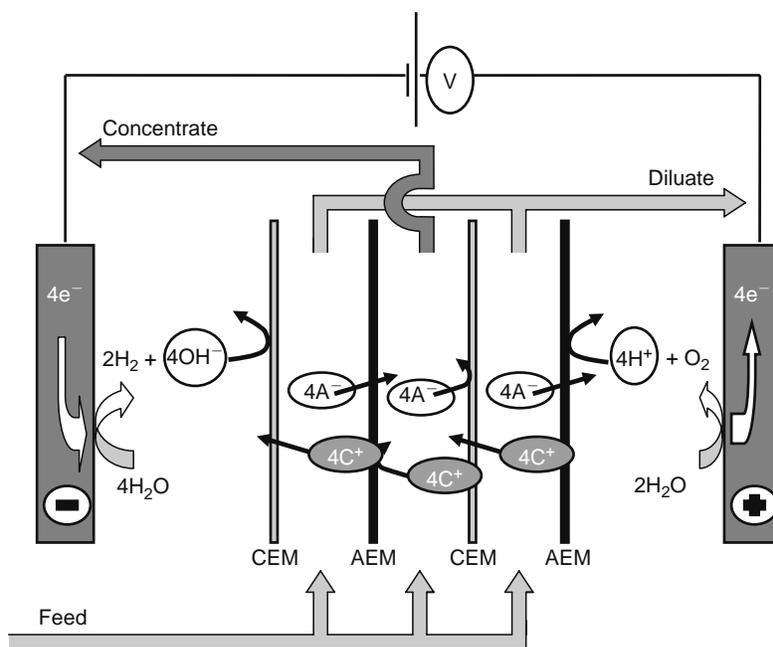

FIGURE 40.3 Schematic representation of the ED process.

flushed out. This makes EDR less sensitive to scaling than ED. However, the complexity of EDR systems leads to relatively high capital and process costs [49].

Major ED/EDR applications include desalination of brackish water, recovery of metals and water from electroplating rinse waters, and demineralization of whey, wine, and sugar process waters [49]. Of all the electroseparation processes, ED has received the most attention and is one of the few electrically assisted membrane technologies to find large-scale industrial applications. Many publications consider different aspects of ED, for example, fouling [50,51], modeling [51,52], use of bipolar membranes [53], ion-selective membranes, and ED-hybrid systems (ion exchange-ED [54], and combined systems such as ED with a bioreactor for denitrification [55,56]). In this chapter, attention will be given to less common, ceramic-based ion-selective membranes. For further information on ED using organic membranes refer to Chapter 12 of Ref. 49.

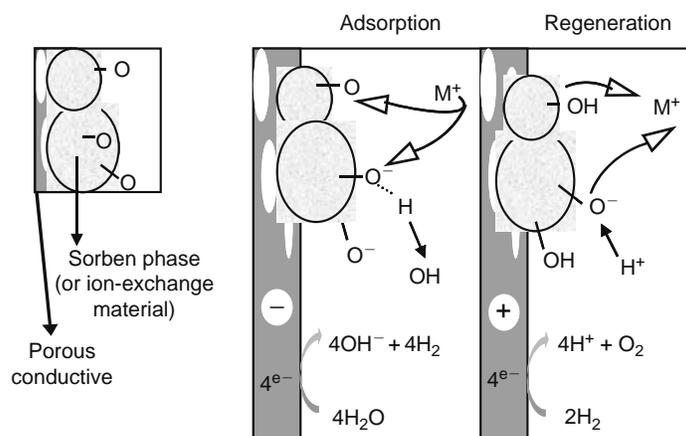

#### 40.2.2.2.1 Ceramic Ion-Selective Membranes

Sodium super ion-conductors (NaSICON) containing rare earth elements (RE-NaSICON) are commercially available for processes such as the chloro-alkali process. These membranes can also be used in wastewater treatment. Kurath et al. [57] described the electrochemical salt splitting process based on sodium-selective ceramic membranes (i.e., NaSICON containing dysprosium and neodymium). Sodium was removed selectively at  $38 \text{ mA} \cdot \text{cm}^{-2}$  with a current efficiency over 90% from nuclear waste streams to reduce disposal volumes. The ceramic membrane investigated was specifically suitable due to its resistance to radiation damage, superior  $\text{Na}^+$  selectivity, and resistance to fouling owing to its tendency to exclude di- and trivalent cations that can precipitate during salt splitting. Hobbs [58] compared the properties of the NASID inorganic membrane from Ceramtec with the NAFION 324 membrane from DuPont in the recovery of caustic waste from nuclear waste. NASID exhibited superior selectivity toward Na but lower Na conductivity than NAFION 324. One of the drawbacks of the above-mentioned ceramic membranes is their high price. Linkov and Belyakov [59] described a zirconium phosphate based membrane with cation-selective properties suitable for ED. These membranes are much cheaper.

#### 40.2.2.3 Electrosorption

The electrosorption process can be viewed as an ion-exchange bed process in which the resin is regenerated using electrical current. When DC voltage is applied between two electrodes, protons and hydroxyl ions are generated by electrolysis on the surface of the anode and cathode, respectively. As a result of the local change in pH, active sites in the ion-exchange material are produced and may adsorb cations at the cathode and anions at the anode. Subsequent reversal of the voltage enables the adsorbed ions to be eluted so that the working electrode can be regenerated. A schematic representation of electrochemically activated sorption is illustrated in Figure 40.4 [60].

Researchers have described the electrosorption of organics, ions, and bacteria onto carbon [61–65] and polypyrrole composite [66]. Electrosorption electrodes are usually porous since their sorption capacity relates to their surface area; the electrodes do not normally fulfill any separation function. Bladergroen and Linkov described the tubular electrosorption

**FIGURE 40.4** Schematic representation of the electrochemically activated sorption process. (From Bladergroen, B.J. and Linkov, V.M., *Sep. Purif. Technol.*, 25, 350, 2001. With permission.)

membrane prepared from a  $ZrO_2/Al_2O_3$  microfiltration membrane, which was first modified with electroconductive carbon coating and subsequently impregnated with inorganic ion-exchange materials ( $ZrO_2$  and  $Zr(HPO_4)_2$ ) to produce electrosorption membranes [60,67]. Activation and regeneration of ion-exchange sites was accomplished by the products of water electrolysis. Synonyms found within the literature for electrosorption include electro-ion-exchange (EIX), electro-deionization (EDI), and capacitive deionization (CDI).

#### 40.2.2.4 Electroremediation

Electroremediation using electrical current is the final purification method discussed in this chapter. Here, an array of anodes are placed in the soil opposite an array of cathodes. When electric potential is applied the following processes occur: electrolysis of water in the soil, dissolution of polluting ions, migration of ions under the influence of the applied potential field, and reduction or pH based precipitation at the cathode [68,69]. This technique, also known as electroreclamation or electrochemical soil decontamination, does not require a membrane; however, improved electroremediation has been reported when ion-exchange membranes were incorporated into the system [70]. The function of the membrane is to retain  $OH^-$  ions produced at the cathode. Migration of these  $OH^-$  ions is prevented to avoid precipitation of the heavy metal ions in the soil.

### 40.3 DISCUSSION

In the previous section examples are presented where the application of an electrical potential difference between two electrodes resulted in a degree of water purification, by a decrease in concentration of organic compounds, pathogens, or ions. These effects are usually more pronounced when the electrode is porous due to its larger surface area compared to that of flat electrodes. When the pollutants are pumped through a membrane electrode the degree of purification may again be increased because of the more intense interaction between the electrode surface and the pollutant. The combination of membrane and electrode processes has been developed into new or advanced purification processes such as electro dialysis and electrofiltration. All separation techniques using a combination of electrodes and membranes have specific advantages dependent upon the specific types of effluent and wastewaters. In this section the following three points are discussed separately:

1. Which electrically enhanced separation process treats which effluent most efficiently?
2. Which new water treatment applications can be identified specifically for electrically enhanced separation processes?
3. Future of electrically enhanced separation processes.

#### 40.3.1 WHICH ELECTRICALLY ENHANCED SEPARATION PROCESS TREATS WHICH EFFLUENT MOST EFFICIENTLY?

In many cases, membrane processes seem to be the most energy efficient separation processes available for industry. However, the costs related to cleaning or replacement of membranes, the need for skilled personnel, and the associated turn down costs determine their economical feasibility. Table 40.1 lists the various electrically assisted membrane processes with the type of effluents that could be treated most efficiently by each process. For most of the electrically assisted membrane processes (1–4), it is expected that the treatment of effluents would be most feasible when ion or particle concentration is high. These are also the effluents where alternative purification processes require a significant part of the process cost to be spent upon membrane

**TABLE 40.1**  
**List of Electrically Assisted Membrane Processes and the Type of Effluents That Will Be Treated Most Efficiently**

Electrically Assisted Membrane Process	Specification of the Most Suitable Effluent to be Treated	Possible Application
Electrofiltration	Effluent with high solid particle content	Effluent from CMP. Chip manufacturing industry
ED	Effluent with high ion content	Potable water production from sea or brackish water
Electro-sorption	Effluents from plating industry with high ion content	Valuable metal recovery and toxic metal removal
Electrochemical reduction	Effluents from plating industry with high ion content	Valuable metal recovery
Electrochemical oxidation	Effluents containing organic pollutants	Decomposition of relatively stable organic compound such as phenol
Electrochemical disinfection	Relative clean surface water containing pathogens	Potable water production

cleaning, fouling prevention, or replacement. Besides, at high levels of impurities the electrical resistance of the effluent and parasitic currents are minimal. Both result in higher energy efficiency of the process.

Electrochemical oxidation becomes a viable option if biological systems cannot utilize a specific organic compound as energy source. Incineration is in most cases the least cost effective option. The process of indirect or direct electrochemical oxidation has to compete with chemical oxidation processes where the purchase cost of oxidizing agents, their transport, storage, and the required dosing systems determine the process cost. If the electrocatalytic system is sufficiently optimized, electrochemical oxidation could become a feasible treatment process for various types of effluents. However, it should be noted that the water should be adequately conducting, and that power consumption is proportional to concentrations of organics to be oxidized.

In contrast with all other electrically enhanced processes, electrochemical disinfection can be employed at low concentration of pollutants (in this case microorganisms). No highly conductive electrolyte is required for effective disinfection. Electrochemical disinfection will have to compete with chemicals normally used for water disinfection, such as chlorine, or ultrafiltration membrane systems. In remote areas (such as rural village water supply) the electrochemical disinfection system, which does not necessarily need a pump, is competitive especially for small-scale processes [71].

#### 40.3.2 WHICH NEW WATER TREATMENT APPLICATIONS CAN BE IDENTIFIED SPECIFICALLY FOR ELECTRICALLY ENHANCED SEPARATION PROCESSES?

Many existing water purification processes not enhanced by an electrical field are potential interesting fields of research. Li et al. described promising results for the adsorption of fluorine on amorphous alumina supported on carbon nanotubes [72]. It is possible that their method can be enhanced by the use of electric field, as other researchers have shown with other electrically enhanced adsorption processes.

The catalytic reduction of nitrates using  $H_2$  or  $NH_4$  as reducing agent was investigated [73–75] using Pd–Cu catalysts supported on  $\gamma$ -alumina. The direct electrochemical reduction of nitrate or indirect reduction by electrochemically produced hydrogen has not received much attention and could be an interesting area of research.

#### 40.3.3 FUTURE OF ELECTRICALLY ENHANCED SEPARATION PROCESSES

With the rapid increase and activities in nanotechnology it may be expected that the volume of effluents containing stabilized nanoparticulates will increase. Electrofiltration processes are specifically suited to treat effluents with nanoparticulates of one specific kind. Because the contaminant particulates will have comparable surface charges, electrical field strength can effectively be optimized to prevent cake formation.

Since the electrical resistance of the effluent and parasitic currents are minimal at high level of impurities, specific interest in electrically assisted membrane processes could increase due to more strict laws and legislation around effluents. The depletion of freshwater resources and the necessity to process brackish or seawater to produce potable water could promote the use of electrically assisted membrane processes in the future. Electrodialysis will have to compete with pressure-driven membrane processes such as reverse osmosis. The growing awareness of the unique cleaning ability of electrically ionized water (EIW) [47], a byproduct of electrodialysis, may be a factor to consider in the choice between ED and RO systems.  $^{17}O$  NMR relaxation measurements were used to determine the water cluster size of electrically ionized water EIW. It is known that the water cluster size of EIW is significantly smaller than that of tap water. The smaller water cluster size is believed to enhance the penetration and extractive properties of EIW. Recently, EIW has been produced and used in several cleaning processes [47] in industry.

The success of indirect electrochemical oxidation and disinfection lies in the production of safe drinking water especially in rural areas where the necessity for skilled maintenance personnel should be avoided. The simplicity, stability, and low power consumption of devices such as the sodium hypochlorite generator described by Bashtan et al. [71] and the TiN reactor described by Matsunaga et al. [34] make these devices most cost effective for small-scale applications in remote locations.

The potential of electrosorption of various ions and anodic decomposition of organic compounds is evident from the results of the case studies in Sections 40.4 and 40.5, respectively.

#### 40.4 CASE STUDY: ELECTROSORPTION MEMBRANES FOR WASTEWATER TREATMENT

The objective of this case study is to show the potential of electrosorption membranes and their application in the treatment of industrial wastewater. A complete report on this study was submitted to the Water Research Commission of South Africa who funded the research (Report number 964/1/02) [76]. A procedure for the preparation and testing of electrosorption material in the form of plates was established by Belyakov, who optimized the following properties of the plate electrosorption membranes [77]:

- Electroconductivity
- Porosity
- Good mechanical properties
- Ability to adsorb cations and anions in an ion-exchange process

##### 40.4.1 PREPARATION OF THE ELECTROSORPTION MEMBRANE

Sorption electrodes in the form of plates were prepared using nonwoven ceramic-based material, Kaowool 700 Grade Paper (Thermal Ceramics, United States), prepared from oxides of multivalent metals. The main characteristics of the ceramic paper are presented in Table 40.2.

To confer electroconductivity upon porous ceramics these materials were coated with a layer of pyrolytic carbon. The deposition of carbon was carried out in the gas phase by pyrolysis of natural gas. The ceramic materials were placed in a quartz reactor under 50 mL/min flow of natural gas. The pyrolysis took place at 900°C for 30 min.

Phosphates of zirconium were selected as additional active sorption components to be introduced into the porous matrices of the sorption electrodes. This choice was justified by the following reasons:

- (a) Phosphates of zirconium are well known inorganic ion exchangers, which possess relatively high ion-exchange capacity.
- (b) Phosphorus-unsaturated materials based on phosphates of zirconium are capable of adsorption of both anions and cations from aqueous solutions.
- (c) Phosphates of zirconium possess high ionic conductivity, which is a very important property for their effective application in the process of electrochemically activated sorption.

The following laboratory method was used for the introduction of zirconium phosphate into ceramic porous structures. The method is based on impregnation of the porous materials with crystalline sol of zirconium dioxide.

For the preparation of sol, 25% solution of NH<sub>3</sub> was added in small portions (2 mL) to 1 L of 1 M solution of ZrOCl<sub>2</sub> while heating under mechanical stirring. The temperature of solution did not exceed 90°C. Each following portion of NH<sub>3</sub> solution was added only after complete dissolution of the zirconium hydroxide precipitate. The addition of the NH<sub>3</sub> solution was terminated once the zirconium hydroxide precipitate did not dissolve within 20 min. The raw sol obtained was boiled using a reflux condenser for 25 h to allow the formation of the crystalline structure. Thereafter the sol was cooled to ambient temperature and filtered. Ceramic materials were immersed in 1 M sol of zirconium dioxide that was prepared as described

**TABLE 40.2**  
Main Characteristics of Kaowool 700 Grade Paper That Was Used for Preparation of Electro-Sorption Membranes

Trade Mark of Ceramic Paper	Chemical Analysis (wt%)		Nominal Density (kg · m <sup>-3</sup> )	Fiber Index (%)
	Al <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>		
Kaowool 700 Grade Paper	47	53	175–210	55

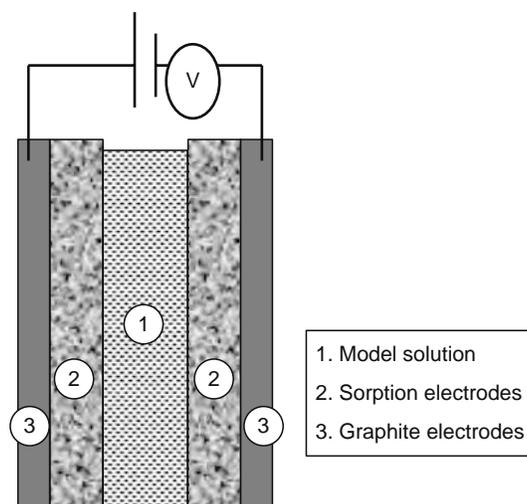

FIGURE 40.5 Schematic representation of the electro-sorption experiment.

above. The immersion time was 12 h. After removal from the sol, the membranes were wiped with filter paper and placed into 15% solution of phosphoric acid for 15 h. This operation was aimed at the transformation of zirconium dioxide into zirconium phosphate.

After phosphoric acid treatment the membranes were washed with distilled water, air-dried for 24 h at room temperature, and then dried for 3 h at 200°C.

To achieve the maximum density of zirconium phosphate deposition inside the membrane porous matrices, the impregnation operations described above were repeated up to three times. A phosphorus–zirconium molar ratio of 1 in the impregnated material was found to be optimal for both cation and anion adsorptions.

#### 40.4.2 METHODS OF ANALYSIS

The concentration of sodium ions was determined by flame photometry. Analysis of nickel, calcium, and magnesium ion concentration was carried out by atomic absorption spectrophotometry (Pye Unicam 8800, United Kingdom). The concentration of sulfate ions was determined by titration with barium chloride ( $\text{BaCl}_2$ ) solution in the presence of rhodizonate as indicator. Chloride ions were determined using ion-selective electrodes (manufactured by Radelkis, Hungary).

#### 40.4.3 TESTING OF ELECTROSORPTION MATERIALS

The sorption electrodes with a total surface area of 315 cm<sup>2</sup> (15 cm × 21 cm) were placed in an electro-sorption cell for sorption capacity measurements. A schematic drawing of this cell is given in Figure 40.5. The design of the electro-sorption cell allowed good contact of the electro-sorption membranes with the graphite current collectors. Working solutions were pumped through the cell at a flow rate of 100 mL · h<sup>-1</sup> using a peristaltic pump. The internal free volume or working volume of the module was 100 cm<sup>3</sup>. The module was sealed with rubber washers.

The polarization of the electro-sorption membranes was carried out at a potential difference of 5 V and 10 V. Electro-sorption tests were carried using a simulated solution of an industrial nickel effluent and a mine water source. The chemical composition of both solutions is given in Table 40.3.

**TABLE 40.3**  
**Chemical Composition of Two Model Effluent Solutions Used in Electro-Sorption Experiments**

Solution	Industrial Nickel Effluent (mg · L <sup>-1</sup> )	Mine Water Effluent (mg · L <sup>-1</sup> )
Sodium	183	1150
Sulfate	1739	1920
Chloride	210	230
Nickel	635	—

**TABLE 40.4**  
**Chemical Composition of Ni Effluent before Electro-Sorption, after Electro-Sorption, and after Desorption Experiment ( $\text{mg} \cdot \text{L}^{-1}$ )**

Constituent	Initial	After Electro-Sorption at		Regenerate
		dU = 5 V	dU = 10 V	
Sodium	183	103	18	1,490
Sulfate	1,739	998	65	17,200
Chloride	210	98	5	220
Nickel	635	424	<1	6,430

Note: dU = The applied potential difference between the electrodes.

The results of the electrosorption experiments with the simulated nickel effluent are summarized in Table 40.4. Nearly 100% of Ni and > 90% of  $\text{Na}^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{Cl}^-$  ions were removed during the electrosorption experiment running at 10 V.

The results of the electrosorption experiments with the simulated mine effluent solution are summarized in Table 40.5. Between 50% and 83% of ion removal was observed depending on the flow rate and the total amount of feed solution.

#### 40.4.4 CONCLUSION

The case study showed a successful method for manufacturing composite sorption materials for ion removal by electro-sorption. The prepared electrosorption membranes that were electrochemically activated at 10 V and removed approximately 100% of Ni and > 90% of  $\text{Na}^+$ ,  $\text{SO}_4^{2-}$ , and  $\text{Cl}^-$  ions from a simulated nickel effluent solution. The energy consumption at  $6.4 \text{ kW} \cdot \text{kg}^{-1}$  removed matter at dU = 5 V and at  $11 \text{ kW} \cdot \text{kg}^{-1}$  removed matter at dU = 10 V. No membrane fouling was observed. For a mine water model solution, 83% of ion removal was observed. At the optimal feed flow rate the energy consumption was  $4 \text{ kW} \cdot \text{kg}^{-1}$  removed matter.

### 40.5 CASE STUDY: ELECTROCATALYTIC MEMBRANES FOR DECOMPOSITION OF ORGANIC POLLUTANTS

In this case study, ceramic-based flexible sheets impregnated with electrocatalysts were used for the treatment of industrial effluents polluted with phenols. The technological objective of this study was to develop a novel purification system in which a feed solution containing organic compounds is passed through an electrochemically charged ceramic-based membrane whereby the organic compounds are decomposed on contact with the electromembrane surface. A simplified explanation of the process is illustrated in Figure 40.6.

The electrocatalytic materials were deposited onto ceramic sheets in the form of nanosized particle-containing inks. The electrocatalytic ink was prepared from carbon black-supported antimony-doped tin oxide. Comparisons were made between the commercially available Sb-doped  $\text{SnO}_2$  as well as the Sb-doped  $\text{SnO}_2$  prepared by a solgel method.

#### 40.5.1 PREPARATION OF ELECTROCATALYTIC MEMBRANES

Commercially available composite ceramic sheets (Lydall, United States), with properties listed in Table 40.6, were used as the catalyst support. The Sb-doped  $\text{SnO}_2$  solutions were prepared from two alkoxides [23] obtained directly from chlorides. 8.37 g of  $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$  was dissolved in 100 mL of absolute ethanol. The antimony solution was simultaneously prepared from a

**Purification Degree of Mine Effluent Model Solution as a Result of Electro-Sorption Experiment**

Flow Rate ( $\text{mL} \cdot \text{h}^{-1}$ )	Passed Volume (mL)	Purification Degree (%)	Energy Consumption ( $\text{kW} \cdot \text{kg}^{-1}$ )
200	100	83	5.16
400	150	72	4.06
800	200	50	4.38

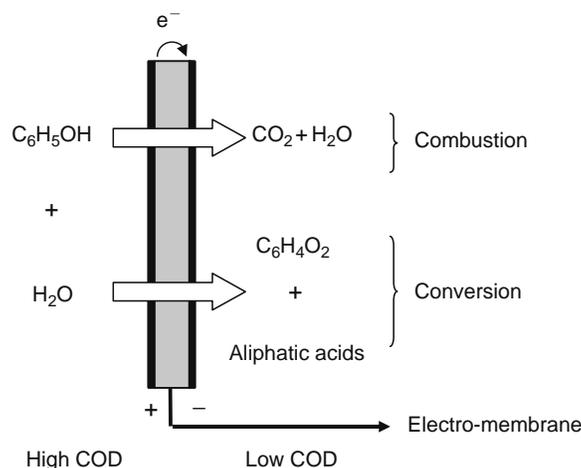

FIGURE 40.6 Schematic of the ceramic-based electromembrane process for the oxidation of phenol.

given amount of  $\text{SbCl}_3$  dissolved in 20 mL of absolute ethanol. Both mixtures were separately stirred and heated in a closed vessel. The vessels were then opened and the solvent completely evaporated to yield two powders. The resulting powders were mixed together in 50 mL of ethanol. The doped mixture was finally stirred and heated at  $50^\circ\text{C}$  for 2 h.

For the preparation of the electrocatalyst or catalytic ink, a predetermined amount of carbon black (VULCAN XC 72) was added to the Sb-doped  $\text{SnO}_2$  sol and stirred at room temperature for several hours. The carbon black was then washed thoroughly with water and dried at  $100^\circ\text{C}$  for 1 h followed by further drying at  $500^\circ\text{C}$  under nitrogen for 30 min.

The ceramic sheets were cut into the correct shape to fit in the electromembrane reactor and then impregnated with the electrocatalyst. A slurry or ink of the carbon black-supported Sb-doped  $\text{SnO}_2$  was prepared in an appropriate solvent followed by ultrasonic treatment for 30–60 min. The resulting ink was sprayed onto the ceramic membrane surface by using commercially available spray guns. The resulting membranes were then dried at room temperature overnight.

#### 40.5.2 TESTING OF ELECTROCATALYTIC MEMBRANES

The electromembrane reactor used in the study was a flow-through undivided electrocatalytic cell. The principal feature of the cell is the ceramic-based sheet, which was coated with the carbon-supported catalyst on one side. The coated side was used as the anode and the cathodic side was not coated with any electroconductive substance or catalyst. Current was supplied to the anode and cathode by means of backing layers, which are connected, to the external power source by means of a conducting wire. The backing layers that were used in this study are carbon cloths 6100–200 purchased from Lydall, United States.

The untreated water was pumped into the electromembrane reactor through the inlet where the feed is guided by means of a stainless steel flow channel. The water came into contact, first, with the carbon cloth on the anodic side and then with the

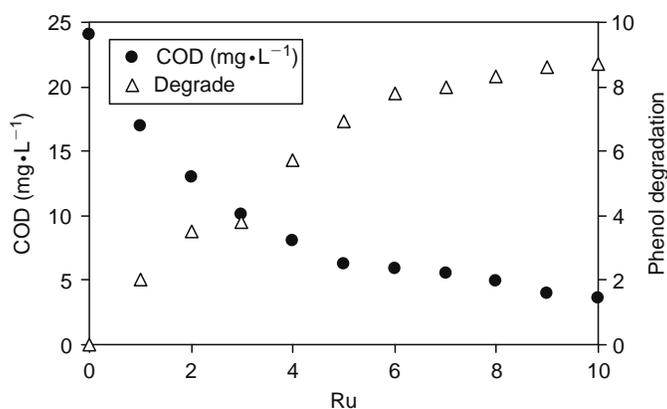

FIGURE 40.7 Degradation of phenol and reduction of COD in the presence of chloride ions.

electrocatalyst on the surface of the ceramic support. The feed was subsequently pumped through the membrane and the oxidized or “treated” water was collected as permeate and analyzed. After collection of the entire batch, the collected water was reintroduced into the reactor and, depending on the nature of the catalyst and experimental conditions, a number of runs were carried out and phenol concentration, oxidation products, and COD were monitored with each run. The geometric surface area of the electrocatalytic membrane in the reactor was 320 cm<sup>2</sup>.

*p*-Benzoquinone was the sole aromatic intermediate detected in the collected samples. The degradation of phenol was improved by applying a higher voltage with phenol completely degraded in nine runs through the electromembrane reactor. The concentration of *p*-benzoquinone increases as the concentration of phenol decreases but since phenol is oxidized simultaneously with its intermediates, *p*-benzoquinone concentration also decreases with time.

Several experiments were conducted to study the influence of feed flux through the electromembrane reactor. The fluxes were varied in the region of 50–200 L · m<sup>-2</sup> · h<sup>-1</sup> and the variation in the flow rate of the feed solution through the electromembrane reactor had a significant effect on the phenol degradation, formation of intermediates, and COD removal. The best results were achieved at fluxes of 150 ± 20 L · m<sup>-2</sup> · h<sup>-1</sup> for phenol degradation (complete degradation) and formation of aromatic intermediates (*p*-benzoquinone < 20.0 mg · L<sup>-1</sup>). COD reduction of 60% was achieved under these conditions.

### 40.5.3 INFLUENCE OF CHLORIDE IONS ON THE ELECTROCHEMICAL OXIDATION OF PHENOL

The need to study the influence of chloride ions on the electrochemical oxidation of phenol was necessitated by the fact that real (industrial) effluents contained chlorides in significantly high concentrations. Chloride ions, in solution, have the ability to produce chlorinated organic products, especially in acidic media. Halocompounds are usually more harmful to the environment than the organic compounds they result from. It has been reported that under certain conditions, electrogenerated chlorine converts to hypochlorite, which is a powerful oxidant but weak chlorinating agent [78].

For the results shown in Figure 40.7, an experiment was conducted using a feed solution of 0.1 g · L<sup>-1</sup> phenol in 0.1 M NaCl electrolyte at flux of 150 L · m<sup>-2</sup> · h<sup>-1</sup> and applied potential of 2.5 V. 87% degradation of phenol was achieved but what is worth noting and of extreme importance is that there were no aromatic intermediates detected in the resulting permeate. This can also be supported by the fact that the initial COD was reduced by 85%.

### 40.5.4 CONCLUSION

The reduction of COD is one of the most challenging tasks for any water treatment process. Electrochemical water treatment is no exception, and even though phenol could be completely degraded, COD as high as 40% can present itself in the form of reaction byproducts. When NaCl was used as electrolyte solution, no aromatic intermediates were detected at the end of the treatment process. The reduction of COD by 87% shows that most of the phenol was degraded to CO<sub>2</sub>. The presence of Cl<sup>-</sup> improved COD reduction, possibly due to the action of hypochlorite formed through oxidation of chloride.

### ACKNOWLEDGMENTS

The authors wish to thank South Africa’s main power utility (ESKOM), the Water Research Commission (WRC) and National Research Foundation (NRF) of South Africa for funding, Professor V.N. Belyakov for close collaboration on various aspects of electromembrane research, and L. Petrik and R. White for their suggestions.

## 41.1 INTRODUCTION

Industries dedicated to the treatment of skins are big consumers of water and, as a consequence, big producers of liquid effluents. These effluents are characterized by their high chemical oxygen demand (COD), as well as colors and a high content of salts, oils and fats, and solids, due to the reagents used during the production process. As a result, these effluents have a high pollutant potential and need to be treated before their discharge or elimination.

Effluents from the leather industry of the city of Lorca (Murcia, Spain) have long been a serious problem for this province, because they were commonly discharged into the river Guadalentín, without previous treatment, causing serious environmental problems. The effluents in question contain a great number of polluting products that are impossible to eliminate by standard wastewater treatment processes, which, together with the large volumes involved, increase the difficulty of the purification process.

In an attempt to solve these problems, the Aquagest Levante SA company, belonging to the AGBAR Group (Spain), has constructed a plant in the industrial estate of The Serreta (Lorca) designed to treat the effluents produced by the above mentioned leather industries (5000 m<sup>3</sup>/day) and, in the future, all the effluents from the other industries of the estate.

In the research and development phase, before the design and assembly of the industrial-scale installation, treatment of the effluents of the tanneries concerned was studied in pilot plant units, via collaboration with the Department of Chemical Engineering at the University of Murcia (Spain). The pilot plant was composed of several units: first, a physical–chemical treatment step; then, secondary treatment of the effluent from the first stage in an ultrafiltration tubular membrane bioreactor; followed by a third stage of reverse osmosis basically to eliminate the salts of the ultrafiltration permeate, complying with the specifications concerning the conductivity of wastes; and in the final stage, the brines generated by the concentrate from the reverse osmosis unit were evaporated. The industrial installation was completed with sludge centrifuges and drying tunnel. The data obtained in these pilot plants served as a basis for the design of the industrial plant. A flow diagram of the industrial plant is shown in Figure 41.1.

In this plant, wastewater to be treated is transmitted from the pumping station to the treatment plant. An initial pretreatment eliminates the fats (96%) and the largest solids before the water enters the mixing tank (4000 m<sup>3</sup> capacity), into which oxygen is injected (3500 kg/day) producing a desulfurization process; in this tank the sulfide is converted into sulfate and there is a 30% reduction of the organic matter content. From the tank, the water flows to the settler, where the sludge and the clarified liquid are separated, before the process splits into two differentiated lines: the sludge and the clarified water line.

The sludge passes to the thickeners, where flocculants and coagulants are added to concentrate it. Once thickened, the sludge is treated in the centrifugal system (two centrifuges, with a capacity of 60 m<sup>3</sup>/h) with the objective of separating any remaining fractions of water and to dry the sludge, which, after conditioning, is taken to a secure dump.

The clarified water from the settlers still possesses a high organic load and high conductivity, so that it must be treated before it can be used or disposed of.

The waters in question are pumped to a membrane bioreactor equipped with an air injection system, where part of the feed is recycled, making it move across a membrane ultrafiltration system, to prevent the presence of suspended microelements in the later phase of reverse osmosis. From the ultrafiltration process, two streams are obtained: a concentrated stream of salts and microbial mass, which is recycled to the bioreactor, and a permeate stream that passes to the reverse osmosis plant.

In the reverse osmosis stage of the plant, the water passes through the membranes and is again separated into two streams: one with a high salt concentration destined for the brine evaporation stage and the other clarified, which is directed to a tank of clean water mixture, where other streams of the process meet.

The highly saline stream from the reverse osmosis unit, together with a fraction of the concentrated stream from the ultrafiltration process, undergoes an evaporation stage. Furthermore, this produces two streams: one that goes to the tank containing the clean water and the other, a sludge, which passes to the drying tunnel. Studies carried out in the membrane bioreactor and reverse osmosis pilot plants are described below.

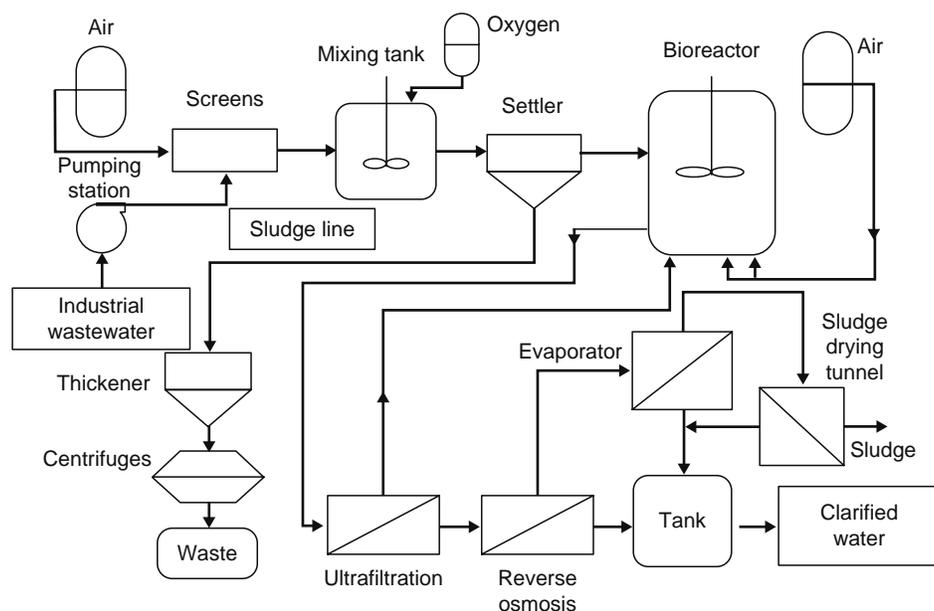

FIGURE 41.1 Flow diagram of the industrial plant.

## 41.2 MEMBRANE BIOREACTOR PILOT PLANT

### 41.2.1 LAYOUT

The principal part of the pilot plant comprises a biological reactor (bioreactor) in whose interior the biomass is placed, and two external modules of ultrafiltration membranes placed in series. Figure 41.2 depicts a flow diagram of this pilot plant, which is described in more detail below.

The reactor of the pilot plant has a volume of 2900 L and it is built of a hard plastic material. The feed enters the biological reactor directly from the settlers used in the physical–chemical process of the industrial plant.

An opening in the top of the reactor allows samples to be obtained from the interior, the corresponding analyses to be carried out and the behavior of the biomass to be followed. The level inside the reactor is controlled by means of a differential controller, while the appropriate oxygen concentration is maintained by means of a blower that blows air into the reactor, although there is also a connection with a pure oxygen supply in case of failure in the blower. The air enters by means of two pipes: one, a venturi and the other linked to four diffusers. Both can be regulated by manual valves.

Oxygen levels were regularly measured in samples taken from the bioreactor by means of a portable oximeter, to maintain the oxygen inside the bioreactor at 2–4 mg O<sub>2</sub>/L. The exit stream of the reactor is impelled to the membranes by a centrifugal pump located at the exit (see Figure 41.2), at a rate of 56 m<sup>3</sup>/h at 4 bar.

The ultrafiltration membranes have the following characteristics:

Length	3 m
Material	Poly(ether sulfone)
N° modules	2
Surface	3 m <sup>2</sup> /module
Transversal flow rate	6 m/s
Pore size	0.1 μm
Maximum working temperature	45°C

The two sequentially connected modules are composed of Berghof tubular membranes, which allow a tangential flow through their interior. Each module is formed of 31 tubes of 10 mm diameter.

The water from the reactor is pumped to these membranes, where two streams are formed: the permeate, which is the water that has passed through the pores and the concentrate, in which biomass remains and which is recycled to the reactor. The entrance pressure at the membranes is 4 bar and the exit pressure is approximately 2 bar.

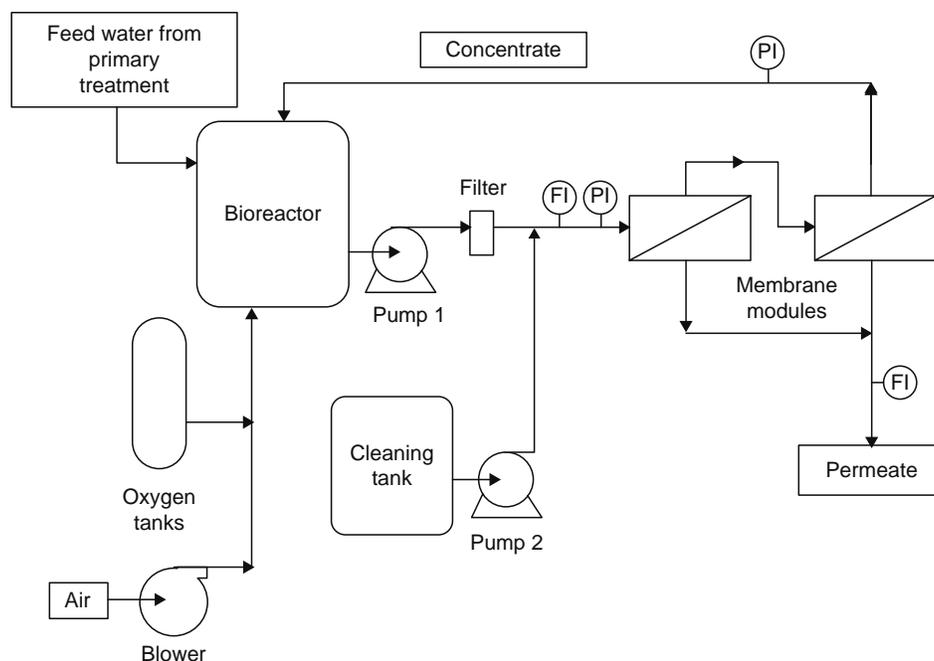

FIGURE 41.2 Flow diagram of the membrane bioreactor pilot plant.

At the exit of the pump that impels the water from the reactor to the membranes, a filter retains the largest solids to prevent obstruction of the membranes.

The main problem arising with the membranes is that they become fouled and it is therefore necessary to flush them daily with water and to occasionally use chemical products. The plant has a 0.5 m<sup>3</sup> cleaning tank of hard plastic that is used for daily cleaning of the membranes with clean water. After stopping the plant, this tank is filled with water several times and the water is pumped through the plant to clean the membranes. The same tank is used for cleaning with chemical products.

The pilot plant is equipped with two gauges: one at the membrane entrance and the other at the exit. The plant is also equipped with two flowmeters: one located at the entrance to the membranes to record the pumped flow and the other in the permeate stream to measure the discharge flow. The plant has a control panel, for starting and stopping the process and for controlling the blower and pump that feeds the bioreactor. The control panel can be set to automatic and the level inside the reactor is kept constant by means of the differential control.

#### 41.2.2 OBJECTIVES AND WORKING PLAN

The objective of the experiments carried out in this pilot plant was to determine the optimal values of some operational parameters, such as biomass concentration, transmembrane pressure, flow rate, and hydraulic retention time, the last defined as the relationship between the volume of the bioreactor and the daily flow discharge of permeate. The working plan was as follows:

The pilot plant was started daily during the 113 days of the experimentation. Samples were taken from the permeate stream, from the bioreactor, and from the water reaching the bioreactor after the physical–chemical treatment. A series of daily, weekly, and monthly analyses were carried out on these samples. The daily analyses included pH, conductivity, temperature, dissolved oxygen in the reactor, COD, and permeate turbidity. The weekly analyses included BOD<sub>5</sub>, suspended solids, volatile solids, ashes, ammonium, nitrates, nitrites, total nitrogen, and total ortho phosphorus. The monthly analyses included sulfides, total chromium, and salts, all referred to as sodium chloride.

Throughout the experiments, the hydraulic retention times varied in light of the values obtained for the different parameters analyzed, which reflected the degree of purification of the wastewaters studied.

#### 41.2.3 RESULTS AND DISCUSSION

As an example of all the results obtained, Table 41.1 summarized the operational data for five working days of the plant, while Table 41.2 shows the results of one of the analyses carried out weekly.

The hydraulic retention time was gradually reduced, with the purpose of acclimatizing the biomass to the bioreactor entrance fluid. The criteria used to reduce this parameter and so increase the discharge flow were mainly based on the reduction in the values of COD, BOD<sub>5</sub>, and concentration of suspended solids in the bioreactor. The retention times for the different periods of operation were the following:

Days 1–13	3 days	Days 55–58	15 h
Days 14–30	2 days	Days 59–70	12 h
Days 31–35	1 day	Days 71–113	19 h
Days 36–54	18 h		

**TABLE 41.1**  
**Operational Data of the Membrane Bioreactor Pilot Plant**

Parameter	Day 1	Day 2	Day 3	Day 4	Day 5
Inlet pressure, bar	4	4	4	4	4
Outlet pressure, bar	2	2	2	2	2

Total phosphorous, mg/L	1.35	40.6	—
Ortho phosphorous, mg/L	0.29	39.4	—
Turbidity, NTU	—	1.1	—

#### 41.2.3.1 Chemical Oxygen Demand

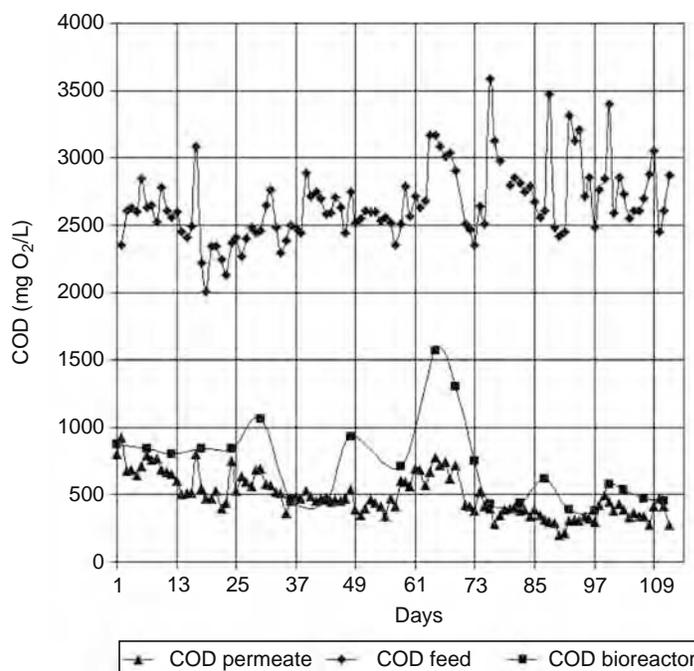

Figure 41.3 shows the COD in the feed, bioreactor, and permeate during the 113 days of experimentation. The results show that, for a hydraulic retention time of 19 h, low levels of COD were obtained in the permeate and in the bioreactor. This time was therefore selected for the operation. The maximum percentage of COD elimination obtained for this period was 91.5%, with a mean value of 86.3%.

#### 41.2.3.2 Suspended Solids and Volatiles

The concentrations of suspended solids and volatiles in the permeate are depicted in Figure 41.4, where it can be seen that levels stabilized with the same hydraulic retention time of 19 h, already considered as suitable. The concentrations reached were approximately 6500 mg/L for the suspended solids and 4600 mg/L for the volatile solids.

#### 41.2.3.3 Biological Oxygen Demand (BOD<sub>5</sub>)

Figure 41.5 represents the evolution of the organic load in the form of BOD<sub>5</sub> in the permeate stream, bioreactor, and feed. As can be seen, the reactor began working with oxygen levels of 400 mg/L, which were decreased in both reactor and permeate to

**FIGURE 41.3** COD evolution in the plant streams.

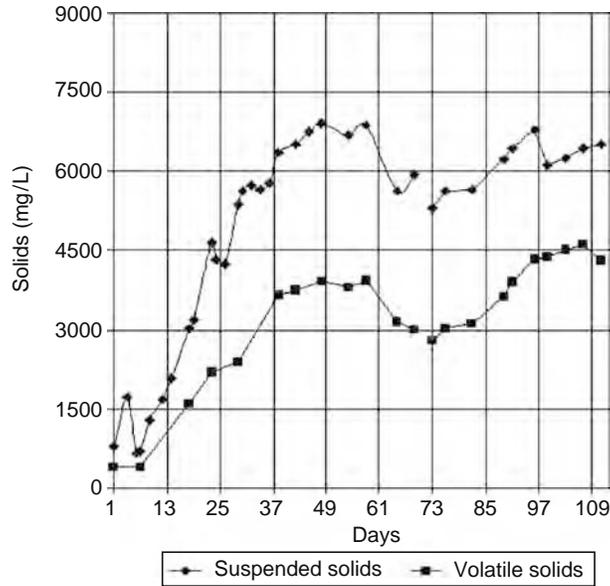

FIGURE 41.4 Evolution of the suspended solids and volatiles in the permeate.

reach minimum values of  $10 \text{ mg O}_2/\text{L}$ . The  $\text{BOD}_5$  values of the feed during the 7 months of experimentation varied between 600 and  $1800 \text{ mg O}_2/\text{L}$ . A maximum  $\text{BOD}_5$  elimination of 99.3% was obtained with the hydraulic retention time of 19 h, the average for this period being 93%.

#### 41.2.3.4 Nitrogen

A beginning to nitrification was achieved after 81 days of operation with a retention time of 19 h. However, nitrification was not complete since the nitrite values remained high, probably due to factors such as temperature, pH, chemical product content of the entrance water, and dissolved oxygen within the reactor, among others. The most appropriate values to achieve nitrification were a pH of between 7 and 7.6 and a temperature of around  $37^\circ\text{C}$ . Figure 41.6 shows the time-course concentrations of total nitrogen, nitrogen in ammonium form, nitrates, nitrites, and organic nitrogen in the permeate stream. As can be seen, nitrification began on day 81 of operation, leading to a decrease in the quantity of  $\text{N}-\text{NH}_4^+$  and organic nitrogen; the quantity of  $\text{N}-\text{NO}_3^-$  and, particularly,  $\text{N}-\text{NO}_2^-$  increased, this last due to the inhibition previously mentioned. Ammonium elimination of around 97% was reached.

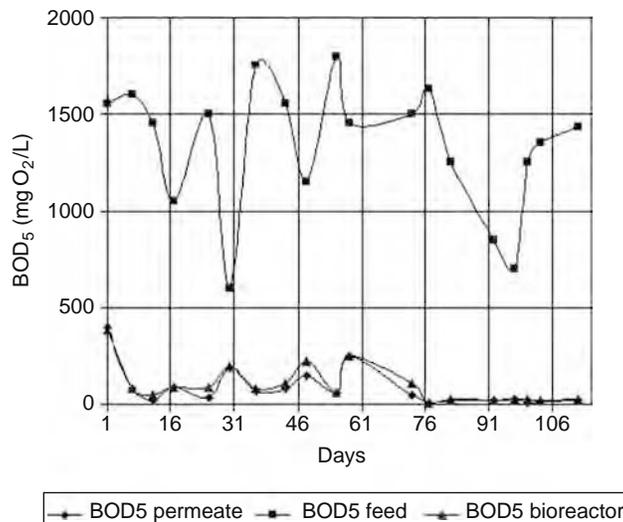

FIGURE 41.5  $\text{BOD}_5$  evolution in the plant streams.

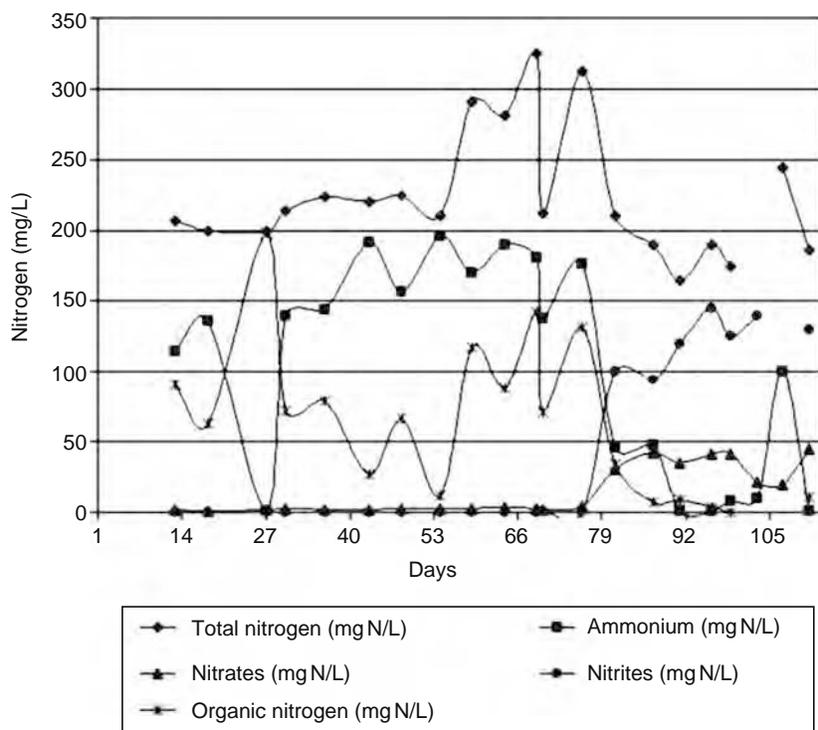

FIGURE 41.6 Nitrogen evolution in the permeate.

#### 41.2.3.5 Chrome and Sulfides

With reference to the monthly monitored parameters, a good degree of chromium and sulfide elimination can be observed in Figures 41.7 and 41.8.

The chromium, Figure 41.7, which showed great variations in the feed stream, was almost totally eliminated from the permeate due to its retention in the sludge, since it is not metabolizable by microorganisms.

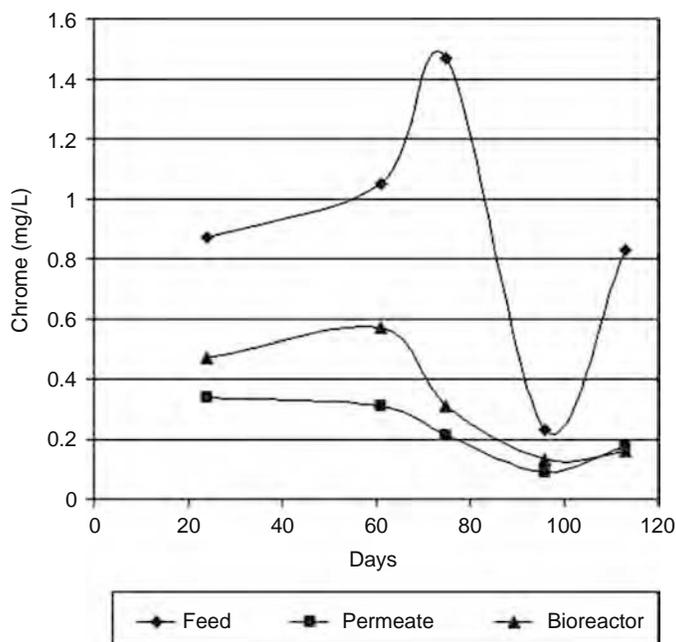

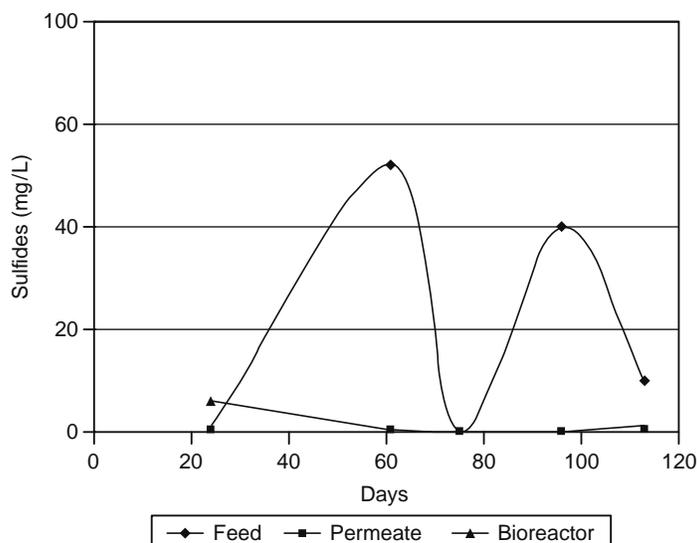

FIGURE 41.7 Monthly analyses evolution of the chrome.

**FIGURE 41.8** Monthly analyses evolution of the sulfides.

The sulfides that may be contained in the feed stream and which have not been eliminated in the previous physical–chemical process become sulfates, as a result of the aerobic-oxidant conditions of the process. Figure 41.8 shows that they disappear in the bioreactor or in permeate.

#### 41.2.3.6 Phosphorus

Phosphorus is a nutrient and therefore influences the elimination of  $BOD_5$ . For biological aerobic processes, BOD/N/P ratio of 100/5/1 can be considered sufficient for the normal development of microorganism's metabolism and growth in wastewater.

The industrial waste from the Lorca tanneries that enters the bioreactor has a low concentration of phosphorus (2–4 mg/L), making it necessary to add a certain quantity of orthophosphoric acid daily, to maintain an appropriate concentration of phosphorus in the bioreactor.

#### 41.2.3.7 Chlorides and Sodium

The chlorides and the sodium, which are responsible for most of the conductivity, together with the sulfates, are not altered in the process, since they are not retained by the biological sludge or by the ultrafiltration membranes, which is why the following reverse osmosis stage is necessary to lower the salinity to levels approved for subsequent dumping.

### 41.3 REVERSE OSMOSIS PILOT PLANT

#### 41.3.1 DESCRIPTION OF THE PLANT

The reverse osmosis plant, Figure 41.9, had a feed tank of 100 L. The feed was impelled by means of a centrifugal pump toward the external part of the cartridge containing the reverse osmosis membrane, passing first through the pressure pumps (modules) to reach a pressure above osmotic pressure. The polyamide membrane had a spiral configuration, and the permeate was collected by the centre of the same before being stored in a 25 L tank, while a similar tank served as cleaning tank.

The pilot plant contained three flowmeters (FI) to measure the permeate, concentrate, and recirculation streams. The flows of the recirculation and concentrate streams could be controlled by means of valves to provide the flows wanted for the experiment, while the permeate stream was a function of the other two. The recirculation flow was fixed at 2.4 m<sup>3</sup>/h and it remained constant in all the experiments.

The centrifugal feed pump provided a flow of 3 m<sup>3</sup>/h at 5 bar. The operating pressure was adjusted with the help of three sequential pressure pumps, each one providing a pressure of 12 bar and able to work in a range of 5–30 bar.

The feed into this plant is the permeate of the ultrafiltration pilot plant, to which antiscalant at a concentration of 16 g/m<sup>3</sup> was added to modify the solubility point of the salts and to prevent their precipitation on the membrane. The ultrafiltration plant effluent has a conductivity of around 14,000  $\mu$ S/cm.

Recovery from the permeate stream is defined as the ratio between the permeate flow and the total flow of permeate plus concentrate.

$$\frac{\text{Permeate flow}}{(\text{Permeate flow} + \text{concentrate flow})}$$

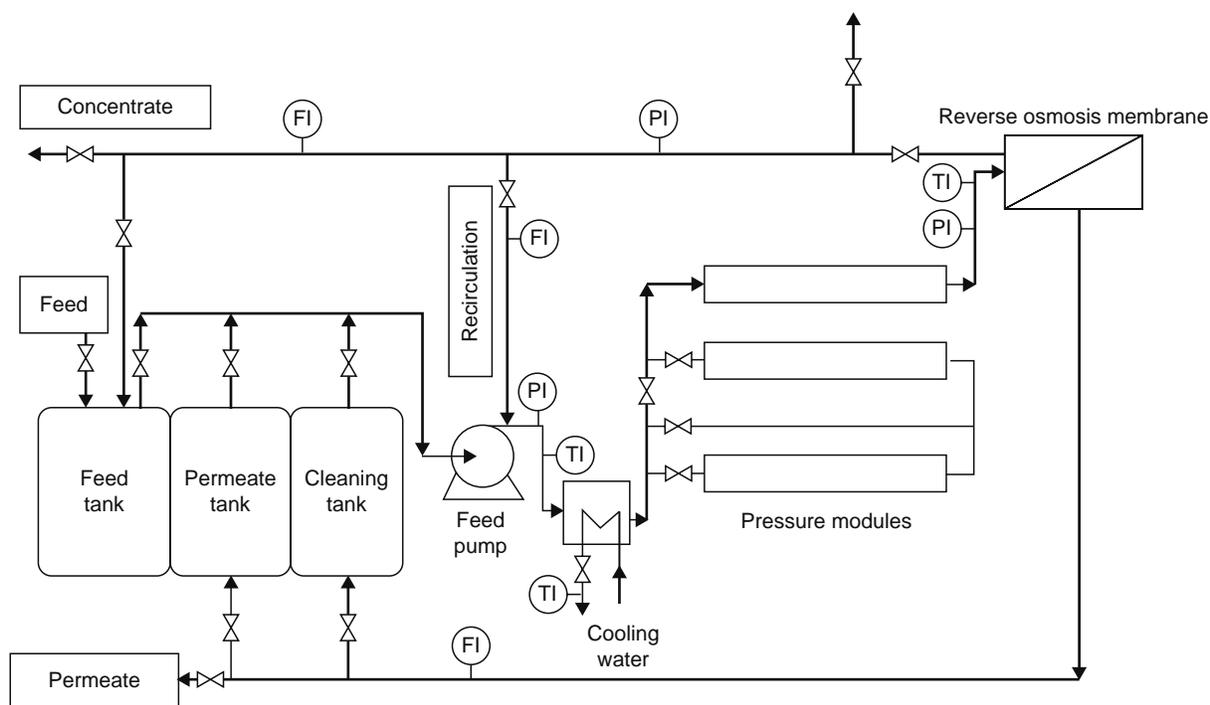

FIGURE 41.9 Flow diagram of the reverse osmosis pilot plant.

The pilot reverse osmosis unit worked with a recovery of 30%–80%, which was obtained by manipulating the valve of the concentrate stream. In this way, the stages that take place in the industrial plant can be simulated. The pilot plant worked 8 h/day, providing continuous streams of permeate and concentrate.

The permeate flow tended to decrease with the operating time due to progressive fouling of the membrane. Depending on the quality of the feed, a film was formed on the surface of the membrane that reduced permeate flow and the quality of the exit water, causing an increase in the pressure difference. To prevent this and the consequent pollution, the membranes were cleaned periodically with acids and alkaline detergents, as well as antiscalant and biocides. Several different membranes from Toray and Osmonics were assayed to choose the most suitable one.

#### 41.3.2 OBJECTIVES AND WORKING PLAN

The objectives of the experiments carried out in this pilot plant were to select a membrane and to simulate industrial operation, varying the percentage of permeate recovery.

According to the foreseen design for the industrial plant of reverse osmosis, this would be formed by three blocks of membranes, each block containing two filtering stages: the first working at a pressure of 15 bar and the second at about 23 bar. Each stage comprises several modules, each of which is formed by six membranes in series. The first unit shows a permeate recovery of 50%, which continues to increase until a value of 80% in the sixth unit.

To attain the above objectives, and bearing in mind the design of the industrial plant, the following experimental steps were followed:

- First, having established a recovery of 80%, long-term experiments were carried out with two membranes, one from Toray and other from Osmonics, to select the most appropriate based, fundamentally, on the permeate and concentrate flows, and on the conductivity of these streams.
- Second, using the selected membrane, a wide sweep of the permeate recovery percentage was made, to simulate the different units of the industrial modules.

In all the experiments, the permeate and concentrate flows leaving the system were measured, as well the conductivities of these streams. Similarly, in the experiments to select the membrane, the following were measured to check whether the permeates complied with dumping specifications: COD, BOD<sub>5</sub>, suspended solids, total solids, total nitrogen, ammonium, nitrates, nitrites, and organic nitrogen, in the feed, permeate, and concentrate streams.

**TABLE 41.3**  
**Technical Characteristics of the Reverse Osmosis Modules**

Characteristics	Toray	Osmonics
Configuration	Spiral	Spiral
Material	Polyamide	Polyamide
Superficial area, m <sup>2</sup>	7	5.5

Maximum temperature, °C	45	45
pH range	2–11	1.5–10.5
Axial flow rate, m <sup>3</sup> /h	2.4	2.4
Permeate flow, L/m <sup>2</sup> · h	26	23

### 41.3.3 RESULTS AND DISCUSSION

#### 41.3.3.1 Membrane Selection

As mentioned, two membrane modules, Toray and Osmonics, were compared. The technical characteristics of these reverse osmosis modules are detailed in Table 41.3.

Operating conditions for the Toray membrane

Entrance pressure	18.3 bar
Exit pressure	17.5 bar
Temperature	25.2°C
Recovery	80%
Operating time	12 days

The permeate and concentrate flows, and their respective conductivities, are depicted in Figure 41.10 for Toray membrane.

Operating conditions for the Osmonics membrane

Entrance pressure	18.8 bar
Exit pressure	17.8 bar
Temperature	22.2°C
Recovery	80%
Operating time	17 days

Figure 41.11 shows the variation with time of the flows and the conductivities for the permeate and concentrate for Osmonics membrane.

The permeate flow obtained with the Osmonics membrane was lower than that obtained with the Toray membrane. Better separation was observed with the Osmonics membrane, as the conductivity graph indicates, although a bigger decrease of the permeate flow was observed over the whole operating time. It was therefore concluded that the Osmonics membrane presented a bigger risk of fouling.

Table 41.4 presents the analytical results obtained for one of the days of operation, using the Toray and Osmonics membranes. It can be seen that both membranes provided a permeate stream that fulfilled the dumping specifications.

After studying the performance of these two membranes, the Toray membrane was selected to continue the study, since it permitted a bigger permeate flow than the Osmonics membrane. Although its separation performance was worse, its separation potential was considered acceptable and priority was given to obtaining bigger permeate flows.

The permeate flow obtained by these membranes was 20 L/h · m<sup>2</sup> for the Toray membrane, and 16.36 L/h · m<sup>2</sup> for the Osmonics membrane.

#### 41.3.3.2 Variation of the Recovery Percentage

In this study, four experiments were carried out varying the recovery percentage between 30% and 70%. The entrance pressure was set at 18–19 bar, and the exit pressure at 17–18 bar, while the temperatures varied between 32°C and 36°C. The results obtained in these experiments are shown in Table 41.5.

**TABLE 41.4**  
**Analytical Results of an Operation Day in the Reverse Osmosis Pilot Plant**

Membrane	Magnitude	Feed	Permeate	Concentrate
Toray	COD, mg/L	297	60.01	237
	BOD <sub>5</sub> , mg/L	20	5	15
	Suspended solids, mg/L	33.2	6.4	20
	Total solids, mg/L	8096.7	1253.3	7321
	Total nitrogen, mg/L	310	64.1	248.3
	Ammonium, mg · N/L	80	15.21	70.3
	Nitrates, mg · N/L	2.4	0.397	2.336
	Nitrites, mg · N/L	1.21	0.26	1.04
	Organic nitrogen, mg/L	226.39	48.233	174.624
Osmonics	COD, mg/L	241	41.1	149
	BOD <sub>5</sub> , mg/L	50	11	38
	Suspended solids, mg/L	14.4	2	13.8
	Volatile solids, mg/L	9520	2026.7	8840
	Total nitrogen, mg/L	327	63.2	257.8
	Ammonium, mg · N/L	163	10.7	89.2
	Nitrates, mg · N/L	2.64	2.004	0.864
	Nitrites, mg · N/L	0.68	0.16	0.52
	Organic nitrogen, mg/L	160.7	50.336	167.216

In view of the results, it can be concluded that conductivity increases with permeate recovery, that is, the higher the ratio between the permeate and concentrate flows, the lowest the quality of the permeate stream. As a consequence of this, there was a concentration of salts in the concentrate stream, because a higher flow of permeate than of concentrate was being separated from the feed.

#### 41.4 BRIEF DESCRIPTION OF THE INDUSTRIAL PLANT

From the results obtained in the ultrafiltration membrane bioreactor and reverse osmosis pilot studies, the industrial plant was designed with the following general characteristics.

The aerobic bioreactor is a tank measuring 32 m in diameter by 6 m in height, which gives a useful volume of about 5000 m<sup>3</sup>. It has four ABS pumps, each with a power of 45 kW, by means of which the content of the reactor is constantly recirculated at a rate of 1400 m<sup>3</sup>/h per pump, with the objective, obtaining perfect homogenization inside the reactor.

The aeration is produced by diffusion through the pipes that transport the air to four horizontal tubes submerged in the reactor. Three blowers of between 75 and 110 kW inject the air into the sludge or mixture when this is being recycled, just before it returns to the bioreactor. To obtain correct aeration, the bioreactor has an automated system for recording and controlling the quantity of dissolved oxygen that is present in the mixture at each moment. The bioreactor is also equipped with meters to continuously monitor the level and pH.

The ultrafiltration plant is composed of seven blocks of membranes, each with a length of 4.2 m, a width of 3.1 m, and an approximate height of 2.2 m. The length of each module is 3000 mm with a tube diameter of 210 mm and an area of 27 m<sup>2</sup>, the internal diameter of the membranes being 8 mm. The number of modules per block is 14, so that the total membrane surface area installed is 2646 m<sup>2</sup>.

**TABLE 41.5**  
**Results of the Recovery Percentage Variation**

Parameter	Assay 1	Assay 2	Assay 3	Assay 4
Permeate flow rate, L/h	75	105	110	175
Concentrate flow rate, L/h	40	85	105	400
Permeate conductivity, $\mu\text{S}/\text{cm}$	1,331	700	667	400
Concentrate conductivity, $\mu\text{S}/\text{cm}$	25,000	22,000	20,300	18,000
Recovery, %	65.2	55.3	51.1	30.4

The membrane is made of organic, poly(ether sulfone), with a separation limit of approximately 100 kDa, and a transversal flow rate of 1–6 m/s. The entrance pressure to the module is from 6 to 7.5 bar and that of exit is 0.5–1 bar.

The reverse osmosis plant is formed by three blocks of Toray polyamide membranes rolled in spiral, each 7.5 m long, 2.4 m wide, and 2.35 m high. Each block contains two filtering stages: the first composed of eight membrane modules that work at 15 bar and the second composed of five membrane modules at 23 bar. In total, there are 13 pressure tubes, each formed of six membrane units.

In total there are 234 units, providing an average of approximately 75% permeate production, and 99% retention of salts, at 30°C–40°C.

The quality of the effluent obtained by these two treatments can be summarized as follows:

In the membrane bioreactor, there is a reduction of 81% COD, 97.5% BOD<sub>5</sub>, 93% suspended solids, and 80% sulfides. In the reverse osmosis plant, there is a reduction of 96.2% COD, 97% BOD<sub>5</sub>, 80% sulphides, and 93% suspended solids. The conductivity decreased by 98%.

To date, the industrial plant is working satisfactorily, treating the effluent for 30 tanneries at a rate of approximately 5000 m<sup>3</sup>/day. The effluent obtained is suitable for agricultural irrigation purposes.

## ACKNOWLEDGMENTS

We thank Enrique Nicolás, Juan Gozalbo, Philippe Rouge, M. Teresa Pérez, Wolfram Scholz, Manuel Terry, Inmaculada López-Guillén, and Ernesto Sánchez for their contribution in this research and design work. We would also like to thank Aquagest Levante, S.A., Murcia, Spain; AGBAR-Aguas de Barcelona, Barcelona, Spain; and BLC Leather Technology Centre, Northampton, United Kingdom for their support.

## 42.1 OVERVIEW OF NANOFILTRATION

### 42.1.1 INTRODUCTION

Separation processes as a whole have grown in importance because of increasingly stringent requirements for product purity [1]. Among the different membrane techniques, pressure-driven processes such as microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) were the first to undergo rapid commercialization [2–4]. These processes basically differ in pore size distribution of membranes used and the types of compounds recovered. A typical schematic of the exclusion of various compounds through different membrane processes is illustrated in Figure 42.1.

Nanofiltration is a rapidly advancing membrane separation technique for concentration/separation of important fine chemicals as well as treatment of effluents in pharmaceutical industry due to its unique charge-based repulsion property [5]. Nanofiltration, also termed as loose reverse osmosis, is capable of solving a wide variety of separation problems associated with bulk drug industry. It is a pressure-driven membrane process and indicates a specific domain of membrane technology that lies between ultrafiltration and reverse osmosis [6]. The process uses a membrane that selectively restricts flow of solutes while permitting flow of the solvent. It is closely related to reverse osmosis and is called “loose RO” as the pores in NF are more open than those in RO and compounds with molecular weight 150–300 Da are rejected. NF is a kinetic process and not equilibrium driven [7].

The NF process has the advantage of lower operating pressures compared to RO and higher rejection of organics compared to UF. NF is generally used to separate water from multivalent ions and organic components with relatively low-molecular weights (200–1000 g/mol). It is generally expected to remove between 60% and 80% of hardness, greater than 90% of color, and all the turbidity if applied in a water treatment plant.

### 42.1.2 BACKGROUND

The history of NF dates back to the 1970s when RO membranes with a reasonable water flux operating at relatively low pressures were developed to avoid high pressures traditionally used in RO, which resulted in a considerable energy cost. Thus, membranes with lower rejections of dissolved components, but with higher water permeability, would be a great improvement for separation technology. Such low-pressure RO membranes came to be known as NF membranes [8]. By the second half of the 1980s, NF had become established, and the first applications were reported [9,10]. In the last two decades, considerable effort has been invested in the development of membranes that combine the high retention of RO with the lower pressures of UF. This has resulted in the development of nanofiltration membranes. To date, NF is becoming increasingly important, filling the niche between UF and RO. The pore diameter of NF membranes is ~2 nm or smaller and therefore species in an intermediate range can be retained as a result of their larger size. Additionally, NF materials are charged, and by means of electrostatic effects they can partly retain charged species that are about one order of magnitude smaller than their pore size. By controlling these electrostatic effects, the effective pore size of NF membranes can, to some degree, be regulated and therefore the separation of charged species can be performed without having to resort to smaller pore sizes and, consequently, higher pressures.

### 42.1.3 THEORY

Nanofiltration is a pressure-driven process where the solvent is forced through the membrane by pressure, and other feed constituents randomly pass through the membrane by diffusion. The relative rates of solvent and solute passage determine the quality of the product. Nanofiltration membranes are adept at the separation of small, neutral, and charged solutes in aqueous solutions because they allow the passage of monovalent ions and retain multivalent ions due to their charge. Nanofiltration membranes exhibit two important features in their actual applications. They provide

1. Intermediate molecular weight cutoff (MWCO) [11]
2. Solute rejection caused by the charge effect [12]

In aqueous solutions, NF membranes become charged, allowing separation of specific ionic species. It is believed that sieving (steric hindrance) is the dominant rejection mechanism in NF for colloids and large molecules, while the physico-chemical interactions of solute and membrane become increasingly important for ions and low-molecular-weight organics [13].

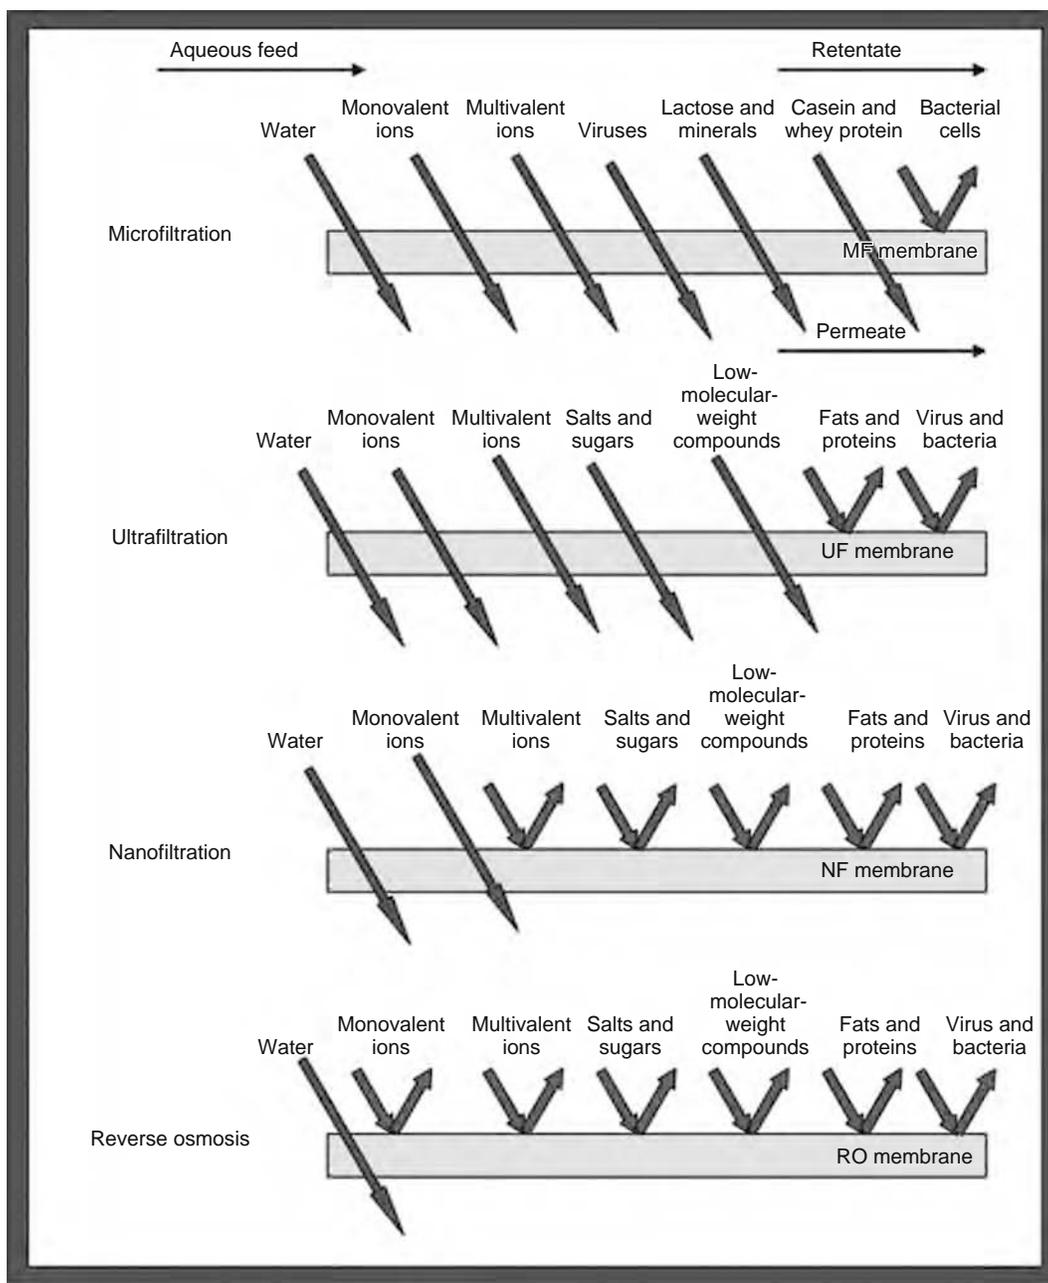

FIGURE 42.1 Exclusion of various compounds through different membrane processes.

Figure 42.2 shows a hypothetical polymeric NF membrane with carboxylic groups attached to the surface of the membrane, which is brought in contact with an aqueous solution of electrolytes. The presence of dissociated carboxylic groups on the membrane surface causes the occurrence of membrane charge.

Based on the above factors separation occurs by the following mechanisms:

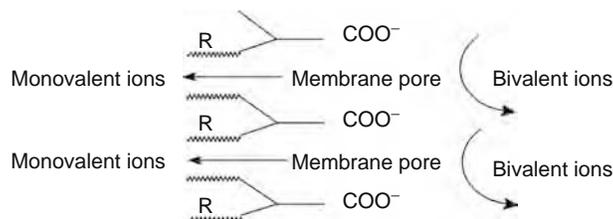

FIGURE 42.2 Principle of nanofiltration. (From Bessarabov, D. and Twardowski, Z., *Membr. Technol.*, 9, 6, September 2002. With permission.)

#### 42.1.3.1 Sieving Effect due to Steric Hindrance

The NF membranes have an intermediate MWCO between reverse osmosis and ultrafiltration membranes, which ranges from 200 to 1000. The solutes having larger molecular weight than the MWCO value of a membrane are almost completely rejected by the membrane and the ones having lower molecular weight will permeate easily through the membrane [14]. This is called sieving effect. Thus, solutes can be separated based on the differences in molecular sizes and shapes.

#### 42.1.3.2 Donnan Effect due to Electrostatic Nature

The Donnan effect of a membrane refers to the electrostatic interactions between the ions and the membrane [15]. The membrane is mostly negatively charged, since the thin film of NF membranes is made of polyelectrolytes. Ions having the same sign of charge as the membrane are excluded and the ions having the opposite sign of charge can be attracted. Separation of ions having different signs and valencies can be manipulated according to the rejection characteristics of the membrane.

#### 42.1.4 TERMINOLOGY

1. *Nanofiltration*: According to the International Union of Pure and Applied Chemistry (IUPAC) recommendations [16] nanofiltration is a “pressure-driven membrane-based separation process in which particles and dissolved molecules smaller than about 2 nm are retained.”
2. *Diafiltration*: Diafiltration [17] is a step in addition to nanofiltration wherein the retentate is further diluted with water and re-nanofiltered to reduce further the soluble components and concentrate further the retained components.
3. *Osmotic pressure*: The osmotic pressure,  $\Pi$ , represents the amount of pressure that can be created between a concentrated solution and pure water separated by a permeable membrane. The equation given below represents the osmotic pressure for a single electrolyte solution [18].

$$\Pi = C_T RT \phi$$

where

- $C_T$  is the total anionic and cationic molar concentration
- $R$  is the ideal gas constant (8,312 Pa/M–K)
- $T$  is the temperature (K)
- $\phi$  is the molar osmotic coefficient

When considering solutions near infinite dilution, the molar osmotic coefficient,  $\Phi$ , reaches unity. The osmotic coefficient will vary for different membrane materials [19].

4. *Transmembrane pressure*: Transmembrane pressure,  $P_{tm}$ , refers to the amount of pressure applied across the membrane filter [20].

$$P_{tm} = \left( \frac{P_i + P_o}{2} \right) - P_p$$

where

- $P_i$  is the element inlet pressure
- $P_o$  is the element outlet pressure
- $P_p$  is the permeate pressure

5. *Transmembrane flux*: At any given temperature or pressure for a given NF module, permeate flow can then be used to determine the amount of water crossing a membrane surface. The transmembrane flux,  $J_t$ , can be defined as [20]

$$J_t = \frac{Q_p}{A_m}$$

where

- $Q_p$  is the permeate flow rate
- $A_m$  is the membrane surface area

6. *Specific flux*: The specific flux,  $J_s$ , allows for the normalization of the transmembrane flux with the transmembrane pressure [20].

$$J_s = \frac{J_t}{P_{tm}}$$

7. *Solute Rejection*: For individual components of the feed solution, the solute rejection,  $X_i$ , is given by

$$X_i = 1 - \frac{C_p}{C_f}$$

where

$C_f$  is the solute concentration in feed

$C_p$  is the solute concentration in permeate

8. *Concentration polarization*: Concentration polarization is important for membrane operation and modeling. It represents increased concentrations of rejected solutes near the membrane surface. The concentration-polarization layer is described with the classic film model [19].

$$\frac{C_w - C_p}{C_f - C_p} = \exp\left(\frac{J_v \delta}{D}\right)$$

where

$D$  is the molecular diffusion coefficient

$C_w$  is the solute concentration at membrane wall

$J_v$  is the water flux

$\delta$  is the thickness of concentration-polarization layer at membrane surface

The performance of membrane operations is diminished by polarization phenomena (concentration and temperature polarization), although the extent to which these phenomena can occur differs considerably.

With all polarization phenomena, the flux at a definite time is always less than the original value. When steady-state conditions have been attained a further decrease in flux will not be observed, i.e., the flux will become constant as a function of time. Polarization phenomena are reversible processes, but in practice, a continuous decline in flux can be observed. Such continuous decline is a result of membrane fouling, which may be defined as the irreversible deposition of retained particles, colloids, emulsions, suspensions, macromolecules, salts, etc. on or in the membrane. This includes adsorption, pore blocking, precipitation, and cake formation.

9. *Membrane fouling*: Fouling is the deposition of solute constituents on the surface of the membrane [21–23]. Membrane fouling is a complicated phenomenon and typically results from multiple causes. In spite of its complexity, electrostatic and hydrophobic/hydrophilic interactions that involve both the membrane and the fouling materials are recognized to have significant bearing, especially for the more-difficult-to-clean membrane fouling dominated by natural organic matter (NOM) and microbial activities. Figure 42.3. shows the influence of concentration polarization and fouling on flux.

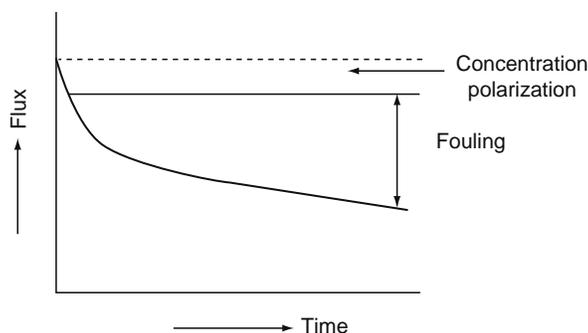

FIGURE 42.3 Pictorial representation of variation of flux with time due to concentration polarization and fouling. (Adapted from Mulder, M., *Basic Principles of Membrane Technology*, Kluwer Academic, Dordrecht, The Netherlands, 1996.)

### 42.1.5 MEMBRANES

In nanofiltration, an array of feed streams must be dealt with for which three relevant areas such as material selection, membrane synthesis, and system configuration must be integrated.

Right from the early 1960s, when work on membrane separations began, a wide range of materials including metals, zeolites, polymers, ceramics, and biological materials are being used for the manufacturing of membranes. However, polymers form the most widely used material for membrane manufacturing at present.

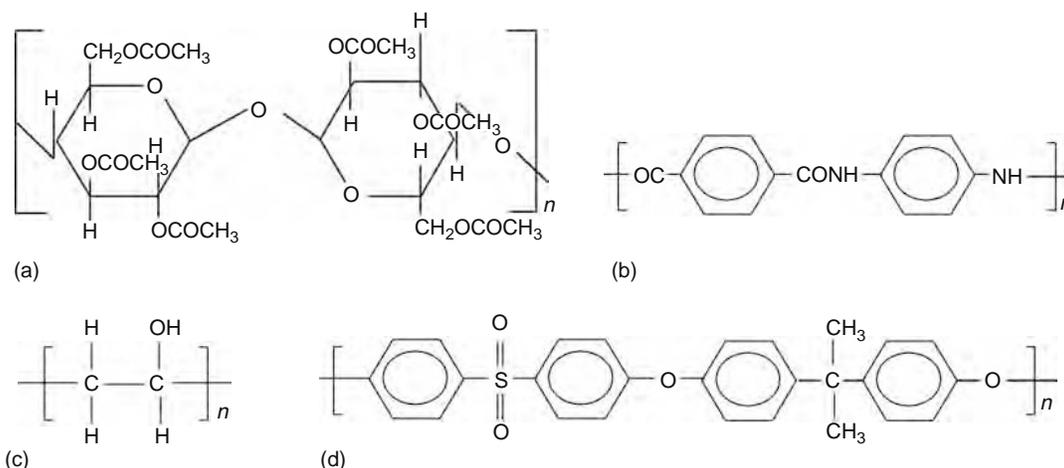

A major consideration in this section will be the selection of polymer materials, membrane synthesis, and modifications, which can be made to such structures that have enabled them in being the most appropriate membranes for nanofiltration. Before exploring the membrane materials used for NF, the preferable membrane morphologies that yield optimum separation must be envisaged. Generally the membranes used for laboratory scale setup for the aqueous mixture filtration by NF are always homogeneous and symmetric, however to attain commercial viability, the membranes successful on the laboratory scale are prepared in asymmetric or composite form [24–26]. These two morphologies offer a possibility of making a barrier with a thin effective separation layer, which enables high flux while maintaining desirable mechanical strength.

#### 42.1.5.1 Membrane Materials

Most MF, UF, RO, and NF membranes are synthetic organic polymers. NF membranes are made from cellulose acetate blends, cellulose triacetate (CTA), or polyamide composites such as the RO membranes, or they could be modified forms of UF membranes such as sulfonated polysulfone [27]. On the other hand, poly(vinyl alcohol) (PVA) is a significant polymer for nonaqueous applications. Chemical structures of a few of the prominent polymers are shown in Figure 42.4.

FILMTEC/Dow has commercialized the NF55, NF70, and NF90 (water flow of NF55 > NF70 > NF90) membranes [28–33], which work in the range of nanofiltration, being able to reject at least 95% magnesium sulfate. The top layer of these membranes is fully cross-linked aromatic polyamide. FilmTec NF50 membranes [28], which were used to replace coagulation, filtration, and ammonia treatment processes in water treatment plants, yielded 96% color removal, besides a reduction of total organic carbon (TOC) by an average of 84% and reducing trihalomethane formation to regulatory levels.

The authors have studied the recovery of sodium thiocyanate, which is used in the manufacture of acrylic fiber, an imperative raw material employed in the textile industry. For this study, the application of the highly advanced hydrophilized polyamide (HPA); a derivative of PA was considered. PA-300 was prepared by interfacial polymerization technique, while the HPA membranes were prepared by coating a novel proprietary copolymer onto a microporous polysulfone substrate followed by cross-linking of the top layer. Thus, the morphology of these membranes was thin-film composite (TFC). Commercial PA and CTA membranes in India were generally available with only one particular MWCO each, 300 and 700, respectively, while the availability of HPA series range has changed the scenario with more widely distributed membranes in the MWCO range of 50–400. Table 42.1 lists the standard nanofiltration membranes available worldwide [1]. The table shows that the maximum extent of rejection of monovalent NaCl through NF membranes is only 50%, while for bivalent salts such as MgSO<sub>4</sub> and Na<sub>2</sub>SO<sub>4</sub> the rejection is as high as 95%–98% on a consistent basis. The table also shows that NF has the potential for concentrating organics such as glucose.

#### 42.1.5.2 Membrane Modules

The central part of any membrane plant is the module, i.e., the technical arrangement of the membranes. Some important aspects to be taken into consideration for the module design include packing density, cost-effective manufacture, easy access for cleaning, and cost-effective membrane replacement. Based on the above, the modules can be distinguished into five major types:

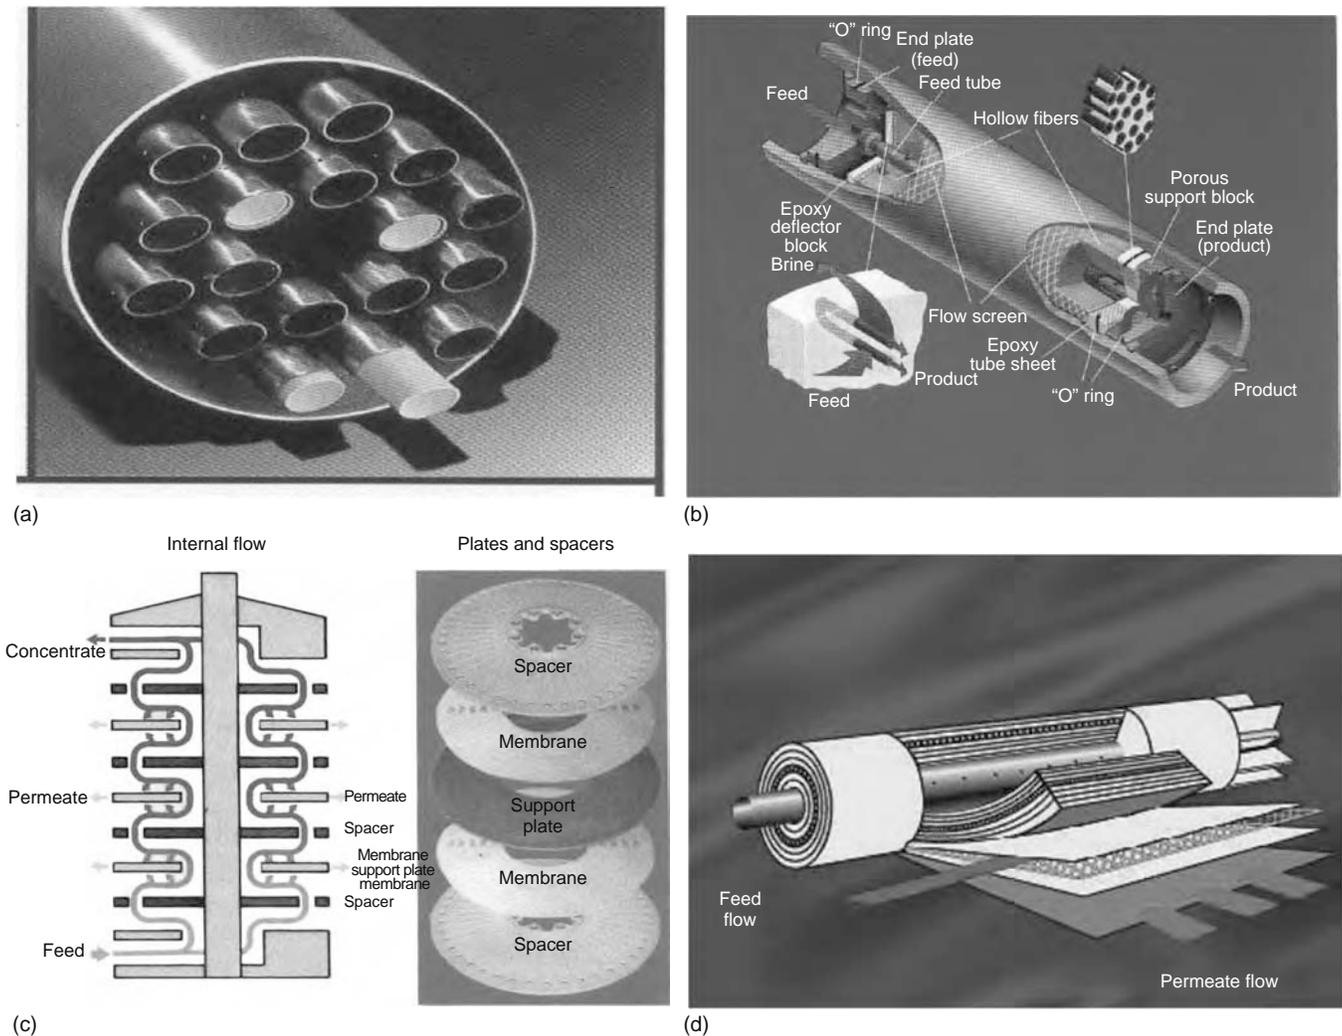

1. *Tubular module*: The membrane here is in hose form [34] on the inside of pressure-tight tubes having 12–24 mm internal diameter (Figure 42.5a). If the material of the support tube is impermeable, then a thin porous tube is fitted between the support tube and the membrane. In many cases, several tubular membranes are assembled in a common support block to increase the packing density. Nanofiltration membranes were developed first in this kind. Though the manufacturing cost of these modules is high, these modules offer excellent resistance to fouling with low-pressure drop, but are not suitable for high-pressure operations.
2. *Hollow fiber module*: Essentially this module consists of a pressure vessel containing a bundle of individual fibers (Figure 42.5b) [34]. The open ends of the fibers are potted into a head plate. The feed solution flows radially or parallel to the hollow fibers. The permeate is collected at the open end of the fibers and hence the parallel flow can be cocurrent or countercurrent depending on the direction of permeate flow with respect to the feed. According to Gill and Bansal [35,36], countercurrent flow is always superior to cocurrent flow in parallel flow conditions. The module lends the membrane higher packing density, enabling production of modules at a lower cost per unit product. These modules offer poor resistance to fouling and are not suitable for high-pressure operations [37].
3. *Plate and frame systems*: Here the feed solution flows through flat, rectangular channels (Figure 42.5c) [34]. Packing densities of about 100–400 m<sup>2</sup>/m<sup>3</sup> are achievable. For NF, plate and frame design has been excluded due to their expensive nature. They are primarily used to treat fouling-prone feed streams and to produce potable water in small-scale applications.
4. *Spiral wound modules*: These are characterized by high packing density (>900 m<sup>2</sup>/m<sup>3</sup>) and a simple design. Essentially, two or more membrane pockets are wound around a centrally located permeate collecting tube with a special mesh used as spacer (Figure 42.5d). The membrane pocket consists of two membrane sheets with a highly porous material in between, which are glued together along three edges. The fourth edge of the pocket is connected to the collecting tube. Several such pockets are spirally wound around the perforated permeate tube with a feed-side spacer placed between the pockets [38]. Usually several such membrane elements are arranged in one pressure vessel. The feed-side flow is strictly axial, while the permeate flows through the porous support inside the pocket, along the spiral pathway to the collecting tube [39]. This module is simple, and is also resistant to fouling at higher pressures.

Most of the commercially available NF membranes are made in spiral wound configuration.

#### 42.1.5.3 Membrane Synthesis

The different procedures for synthesis of NF membranes are listed below:

1. One of the oldest methods in preparing NF membranes is the phase inversion technique involving precipitation of a polymer film from its solution cast film in a nonsolvent bath. The prerequisite for this method is that the solvent of the polymer and the nonsolvent must be thoroughly miscible, while the polymer should not dissolve in the nonsolvent [40–45].

**FIGURE 42.5** Membrane modules. (a) Tubular module, (b) hollow fiber module, (c) plate and frame, and (d) spiral wound module. (Photo courtesy of Genesis Membanes Pvt. Ltd. With permission.)

- Interfacial polymerization between a piperazine, or an amine-substituted piperidine, or cyclohexane, and a polyfunctional acyl halide [46,47].
- Contacting an RO membrane with a strong mineral acid such as phosphoric acid at 100°C–150°C, followed by treatment with a rejection enhancing agent, such as tannic acid, to plug microscopic leaks and defects [48].
- Contacting the cross-linked RO polyamide membrane with ions to form a membrane ion complex, treating the membrane ion complex with an aqueous solution of alkali metal permanganate to form manganese dioxide crystals in the membrane, and finally dissolving the crystals [49].
- Opening the pores of an RO membrane by treatment with triethanol amine. RO cellulose acetate membranes can also be opened by hydrolysis at very high and very low pH [50].
- Coating of ultrafiltration/microfiltration membrane supports such as polyvinylidene fluoride (PVDF) or polysulfone (PSF) with solutions of polymers such as poly(ether-*block*-amide) [51].
- Low-temperature plasma-induced grafting modifications of ultrafiltration membrane to yield hydrophilic nanofiltration membranes. In an investigation by Zhao et al. [52], preparation of hydrophilic nanofiltration membranes has been successfully accomplished using a procedure consisting of plasma irradiation and subsequent grafting in gas of acrylic acid monomers on poly(acrylonitrile) UF membrane.

#### 42.1.5.4 Membrane Modification

From the aforesaid study, it is clear that polyamide membranes have become the main type of membranes used for NF. Despite their excellent performance and superior economics the TFC-based technology is prone to severe organic fouling [53].

The problem seems to have no easy solution and necessitates the use of expensive pretreatment and cleaning systems. The propensity of TFC to undergo fouling arises primarily from the hydrophobicity of the polyamide active layer, onto which many natural organic compounds easily adsorb, eventually leading to irreversible deterioration of the performance. Periodic cleaning does not solve the problem completely and the membranes eventually have to be replaced. Unfortunately, as far as the performance is concerned, no substitute to polyamides has been found so far. A potential way to circumvent the problem is the surface modification. Surface modification is a versatile process to design membranes with tailor-made filtration properties [54]. Nanofiltration membranes can be modified to change their adsorption and solute rejection properties and their susceptibility to fouling.

#### 42.1.5.4.1 Modifications for Improving Performance

*Ion implantation:* This study involves modifying the surface of nanofiltration membranes by ion implantation for increased salt rejection [55].  $F^-$  ions at two different intensities— $1E10$  and  $5E10$  atoms/cm<sup>2</sup>—were implanted on the surface of commercially available nanofiltration membranes to increase the negativity of the membrane surfaces. The objective was to increase the Donnan exclusion effect to improve salt rejection by the modified membranes. It was also noted that this modification did not significantly damage the semipermeable membrane surface.

*Deposition of polyelectrolytes:* Lajimi et al. [56] explored the surface modification of nanofiltration cellulose acetate (CA) membranes by alternating layer-by-layer deposition of acidic chitosan (CHI) and sodium alginate (ALG) as the cationic and anionic polyelectrolyte, respectively. The supporting CA membranes were obtained by a phase separation process from acetone/formamide. The permeation rate of salted solutions was found to be higher than that of pure water. The rejection of monovalent salt was decreased, while that of divalent salt remained constant so that the retention ratio increased. Increasing the concentration of feed solutions enhanced this selectivity effect.

*Polymer grafting:* Surface modification using grafting of a hydrophilic polymer onto the membrane surface is a possible route to improving the fouling properties of polyamide TFC membranes. One way of carrying out this technique would be to graft a hydrophilic polymer onto the polyamide surface making it more hydrophilic and decreasing or weakening the adherence of the organic matter. This approach could be particularly attractive, if one could modify the existing commercial membranes in situ, e.g., inside a module using an inexpensive procedure. It has been shown that the fouling resistance of membranes could be improved without significantly affecting the retentive properties [57–62]. Freger et al. [63] employed grafting of monomers with focus on the acrylic acids. The chemical changes produced an active layer on the membrane surface and they also noted that the effect of modification on the surface roughness was negligible.

*Ultraviolet-photografting:* With this technique [64,65], the chemical bonds in the membrane polymer can be cleaved to form radical sites. In the dip photografting method [66], the monomer to be grafted is present in the superficial liquid film and inside the membrane pores. For a given solution concentration, the quantity of monomer available for grafting depends on the liquid film thickness and on the monomer concentration profile inside the pores. It, therefore, depends on the operating rate and on the contact time in the monomer solution during the dipping. An increase in rate gives an increase in superficial film thickness and a decrease in the amount of monomer in the pores. These phenomena, coupled with the light power of the radiation received and the UV residence time, influence the final permeability.

*Blending:* Ferjani et al. [67] experimented and found that the addition of a small amount of polymethylhydrosiloxane (PMHS) in the dope formulation of CA membranes drastically changed the performance by increasing the NaCl rejection factor and decreasing the permeation rate. This effect can be explained by the morphological changes due to the presence of PMHS. For similar retention values, the blend membranes exhibited better productivity. A thin PMHS top layer coated on the surface of asymmetric CA films produced composite membranes having a similar NaCl rejection factor to that of CA membranes used in RO. This effect stresses out the role played by the hydrophobic nature of PMHS in salt retention. However, the composite membranes were less permeable to the solvent than the corresponding asymmetric membranes.

#### 42.1.5.4.2 Modifications for Improving Fouling Resistance

*Surfactants:* The usage of surfactants for enhancing the fouling resistance of the membranes has also been suggested by Wilbert et al. [68]. Commercial samples of cellulose acetate and polyamide reverse osmosis, and nanofiltration membranes were treated with a homologous series of polyethylene-oxide based surfactants to improve fouling resistance. The fouling solution degraded the untreated cellulose acetate (CA) blend membrane. Triton X100 and Pluronic P84 provided significant protection. Polyamide (PA) membranes treated with surfactant experienced a severe flux decline. A similar decline was caused by fouling of the untreated PA membrane. The treated PA membrane did not have further flux decline with fouling.

*Improvement in hydrophilicity:* A large number of attempts have been made to improve the fouling behavior of available membranes by increasing the hydrophilic character of the membrane surface. The logic behind this approach is clear: for any protein or cell to adsorb (or adhere) to the membrane, it must first displace the water molecules that are chemically associated with the surface groups on the membrane. Several studies have specifically demonstrated that increased hydrophilicity can result in a significant reduction in both protein adsorption and cell adhesion [69,70] and in turn biofouling.

*Introduction of negative charges:* Most proteins and cells are negatively charged in aqueous solution, thus the introduction of negative charges on the membrane surface should (at least in principle) increase the electrostatic repulsion between the membrane and the cells/proteins. Most studies of surfactant-modified membranes provide very clear evidence for this general phenomena, with negatively charged surfactants being much more effective at reducing fouling than the corresponding cationic surfactants [71].

#### 42.1.6 APPLICATIONS

Nanofiltration membranes allow partial permeation of monovalent salts such as sodium chloride, while they completely reject bivalent salts and hardness from aqueous solutions. This has led to the use of NF membranes as water softeners by removal of total hardness and sulfates from seawater and for removal of NaCl from cheese whey. NF membranes have also been successfully utilized for treating textile dye and olive processing wastewaters to recover recyclable water. Another common application is removal of color from effluents and process solutions. One such example is the separation of color causing compounds such as lignin sulfonates from paper pulping wastewater.

*Treatment of groundwater:* The removal of pesticides and some micropollutants from groundwater has been studied by many researchers [72–75]. The NF70 membranes tested on well water in Iowa showed 98% rejections of calcium and magnesium, and 90% and 100% rejections of strontium and barium, respectively. Chloride, alkalinity (CaCO<sub>3</sub>), fluoride, sulfate, iron, silicon, phosphorous, and boron rejections were 45%, 59%, 29%, 98%, 100%, 28%, 60%, and 4%, respectively. The separation of nitrate from well water was another application suggested by Rautenbach and Groschl [31]. Nitrate rejections of the NF40 membrane were low for feed containing sulfate. Sulfate added to well water containing nitrate would result in nitrate passing through the membrane, while sulfate and other highly charged species would be rejected. The permeate could then be treated with ion exchange to remove the nitrate. The NF70 membrane was also used for fluoride removal and for reducing feed levels from 4 to 0.4 mg/L yielding a fluoride rejection of 90%. Kettunen and Keskitalo [76] studied the removal of fluoride and aluminum from groundwater sources in Finland. In addition to the removal of the hardness of nitrates, iron, and strontium, fluoride removal was also mentioned by Pervov et al. [77].

*Treatment of surface water:* The use of NF70 TFC membranes as water softener in removing organics was reported by Cadotte et al. [30]. The low-pressure RO system can lower hardness and TDS, reduce organics that impart color and odor in a single step, thereby replacing multiple processes such as lime softening followed by activated carbon adsorption. Removal of organic micropollutants was also investigated by other researchers [78,79]. Koyuncu and Yazgan [79] had good results in treating salty and polluted water from Kucukcekmece lake in Istanbul using the TFC-S NF membrane. Using a novel NF membrane (NF 200), removal of organics (up to 96%) in a large NF plant in Paris [80] was achieved. NF has also been used to remove both arsenic(V) and arsenic(III) from surface water [81]. These studies showed that (using NF membranes) the rejection of As(V) is relatively high, up to 90%, while As(III) is just around 30%.

*Treatment of wastewater:* Trihalomethanes (THM) such as chloroform, bromodichloromethane, and tribromomethane are carcinogens present in finished drinking water from many treatment plants. The exclusion of these renders them disposable without causing significant harm to environment. High rejections of humic acids (THM precursors) using NF40 membrane were indicated by Bhattacharya and Williams [32]. These membranes gave high rejections even at high water recoveries (80%) with little drop in permeate flux. Hafiarle et al. [82] investigated the removal of chromate from water using a TFC-S NF membrane as a possible alternative to the conventional methods of Cr(VI) removal from an aqueous solution. The results showed that the rejection depended on the ionic strength and pH. Better retention was obtained at basic pH (up to 80% at a pH of 8). Results also showed that NF is a very promising method of treatment for wastewater charged with hexavalent chromium. The same membrane was used by Koyuncu [83] to treat opium alkaloid processing industry effluents. Application of NF in the treatment of textile wastewater has also been conducted by many researchers [84,85].

*Treatment of seawater:* Desalination has been the interest of many researchers [86–89]. The application of NF50, NF70, NF40, and NF40HF for partial water desalination was reported by Eriksson [29]. Studies on surface water treatment in Florida using the NF50 membrane at 0.45 MPa produced a TOC rejection of 94%, color rejection of 96%, 76% alkalinity (as CaCO<sub>3</sub>) rejection of 76%, chloride rejection of 52%, and TDS rejection of 84%. The high rejections rendered this membrane suitable for water softening. Pontie et al. [90] studied the possibility of obtaining a partial demineralization of seawater using two successive NF stages. The treated water (salinity 9 g/L) could be used in the field of human health (i.e., preparation of nasal sprays, medical dietetics, and hot mineral springs).

*Industrial applications:* Nanofiltration has the potential to reduce COD and BOD of industrial effluents, especially those from distilleries and textile industry. Simpson et al. [33] reported the use of nanofiltration for the removal of hardness and organic impurities from a textile mill wastewater. Rejections of the membrane included 29% of conductivity, 33% of sodium, 48% of calcium, 67% of magnesium, and 47% of soluble organic carbon present in the waste stream.

An overview of the possible applications of NF is given in Table 42.2 [72–164]. Except for the removal of solvent from sunflower oil, all applications are in the treatment of aqueous systems. Table 42.2 shows the diversity of opportunities for

**TABLE 42.2**  
**Overview of Possible Applications of Nanofiltration in Industries**

Industry	Application
<i>Water production</i>	
Groundwater	Removal of pesticides [72–75] Hardness removal [76,77]
Surface water	Removal of natural organic matter (acridine orange [ao] color) [78,79] Removal of heavy metals (As, Pb), Fe, Cu, Zn, and Si [80,81]
Wastewater	Removal of trihalomethanes (THM) [82] Removal of degreasing agents from water [83,84]
Seawater	Treatment of brackish water [85] Desalination of water [86–90]
Food	Demineralization of sugar solutions [91] Demineralization of whey [92–95] Recycle of nutrients in fermentation processes [96] Separation of sunflower oil from solvent [97] Recovery of cleaning-in-place solutions [98,99] Recovery of regeneration liquid from decoloring resins in sugar industry [100–103] Effluent treatment [104,105] Purification of organic acids [106–108] Separation of amino acids [109,110] Removal of dyes from wastewater [111]
Textile	
Clothing and leather	Recovery of water and salts from wastewater [112–119] Recovery and reuse of chromium(III) and chromium(II) [120–122]
Paper and graphical	Recovery of wastewater from effluent [123–127]
Chemical	Recovery of bleaching solution [128–130] Sulfate removal preceding chlorine and NaOH production [131–133] CO <sub>2</sub> removal from process gases [134–136] Preparation of bromide [137] Recovery of caustic solutions in cellulose and viscose production [138] CaSO <sub>4</sub> precipitation [139]
Metal plating and product/electronic and optical	Removal of metal sulfates from wastewater [140] Cleaning of machine rinsing solutions [141] Removal of nickel [142] Recovery of Cu <sup>2+</sup> ions from ore extraction liquids [143–145] Al <sup>3+</sup> removal from canning industry wastewater [146]
Landfills agriculture	Removal of phosphate, sulfate, nitrate, and fluoride [147–151] Removal of algal toxins [152,153] Purification of landfill leachate [154–164] Removal of selenium from drainage water [165]

nanofiltration and it can be expected that many are to follow or already exist. However, most of the examples mentioned are developed on a trial-and-error basis and not from basic process knowledge. This means that these processes can run at suboptimal conditions and even membranes with better properties for the application might be available. Improvement of these processes either by finding the optimal conditions or using better membranes will result in economic gain. Additionally, current development times for new pressure-driven membrane processes are typically between 1 and 2 years, which is relatively short and at this moment often results in suboptimal solutions.

#### 42.1.7 FUTURE PROSPECTS

With respect to the aforementioned discussions, it can be noted that even though researchers have attempted to synthesize/use different types of membranes for effective separations, some restrictions for its applications are still encountered. The research direction for NF membranes is mentioned below:

- (i) *Development of high performance NF membranes:* A thorough understanding of the interrelation between membrane chemical characteristics and membrane performance is of paramount importance in membrane research. Improvement of membrane productivity by higher flux membranes has been achieved through the development of TFC with a very thin selective skin layer. In addition, Kurihara and Fusaoka [165] attribute the higher productivity

of current membranes to an increase in surface roughness. Other methods which have been used to improve membrane performance include development of mixed-matrix membrane materials including hybrid organic–inorganic materials and surface modification of membranes [166]. These improvements are not only limited to higher flux at lower operating pressures, but also in terms of less fouling propensity, higher chlorine tolerance, and increased solvent resistance [167]. For NF membranes, in particular, the role of membrane charge in separations of ions has also been studied considerably. Further understanding of the exact nature of charge formation as well as how they contribute toward rejection [168] will definitely lead toward significant improvement on NF membrane performances.

- (ii) *Reduction in fouling*: Fouling refers to the deposition of impermeable substances, present in the feed, on the membrane surface. The suitability of a membrane material for a specific separation problem is also limited by possible interaction with aggressive components in the feed. This can cause reduction in the flux and ultimately renders the membrane useless. Fouling can be prevented by
  - a. Using a highly turbulent flow regime
  - b. Cleaning the membrane semicontinuously
  - c. Using surface modification techniques to change the membrane structure that reduces the interaction between the membrane surface and microorganisms
- (iii) *Development of accurate and practical characterization methods*: The separation mechanisms in NF membranes have been attributed to steric and charge effects as well as the transport mechanisms of diffusion, convection, and electro migration [169,170]. Other factors that may also contribute indirectly include surface roughness, pore size distribution, flow channels, and hindrance mechanisms within the membrane. Identifying and relating the membrane characteristics with all of the above-mentioned effects are not easy to do and, therefore, present NF membranes are normally characterized in terms of pore radius, effective charge, thickness, and porosity. For pore radius, the most common method currently used is fitting solute rejection data of uncharged solute [171]. Several researchers have also attempted to use AFM [172] to determine the pore size distribution. Bubble point method used in UF is not suitable for NF membranes due to the nanometer-range pore sizes [173]. For effective charge, the method used is by measurement of zeta/streaming potential [168,174,175]. Other techniques include fitting of salt rejection data using models such as those based on Nernst–Planck equation [171]. To obtain more accurate characteristics of NF membrane, more innovative and practical approaches should be proposed.
- (iv) *Development of good predictive modeling technique*: A good predictive model will allow users to obtain membrane characteristics, to predict process performance, and to optimize the process. The ability to successfully develop such modeling technique will result in a smaller number of experiments and subsequently save time and money in the developing stage of a process. For NF membranes, the most commonly adapted models have been those based on extended Nernst–Planck equation [169,171]. The Donnan–steric pore model (DSPM) proposed by Bowen and coworkers [171] is one model, which describes rejection in terms of steric and Donnan effects. In addition, the transport of ions through the membrane depends on hindered diffusion and convection as well as electro migration. The model requires the membrane to be characterized in terms of pore radius, effective charge density, and effective membrane thickness over porosity.

From the above descriptions, it is obvious that an understanding of the basic mechanisms underlying the separation is necessary. With this understanding a translation to the development of industrial applications should be made, a step, which is currently not in practice. Keeping in view these research guidelines along with the attempts to enhance membrane life, the application level of NF will definitely rise beyond RO in the near future.

## 42.2 CASE STUDY

### 42.2.1 DESCRIPTION OF THE PROCESS

Acrylic fiber is a vital raw material used in textile industries to manufacture polyester and silk. Several industries worldwide manufacture acrylic fiber by a process where an aqueous solution of 55% sodium thiocyanate (dope) is used for dissolution of polyacrylonitrile (PAN) polymer for spinning the fiber. During the dope-making step, which involves dissolution of the polymer in sodium thiocyanate (NaSCN) solution with addition of a small amount of sodium metabisulfite as oxygen scavenger, the monomer reacts with sodium metabisulfite to form organic impurities such as  $\beta$ -sulpho propionic acid ( $\beta$ -SPA) and  $\beta$ -sulpho propionitrile ( $\beta$ -SPN). During coagulation of the fiber in the spinnerets, NaSCN gets released and is sent for solvent recovery at 20% concentration. This spent NaSCN solution picks up impurities such as color, sodium sulfate,  $\beta$ -SPA,  $\beta$ -SPN, iron, calcium, sodium chloride, low-molecular-weight compounds, and some other unknown impurities.

The conventional techniques applied to recover thiocyanate are solvent extraction, distillation, and gel filtration. These processes suffer disadvantages. The process that resorts to solvent extraction needs a large amount of energy for cooling. The process that utilizes distillation under pressure also needs a huge quantity of energy and gives off toxic thiocyanate gas,

although it yields a pure thiocyanate [176]. The separation of thiocyanate by gel filtration [177] varies from one process to another. One method employed [178] consists of supplying an impure aqueous solution of thiocyanate to a layer of cross-linked dextran, and eluting impurities and then the thiocyanate. Sometimes activated carbon is also employed before gel filtration [179]. The processes that involve gel filtration columns (GFC) are not only expensive (the gel being an imported product), but also slow and inefficient in handling larger feed capacities.

Therefore, the need of the hour was to develop an economical alternate separation technology capable of replacing the GFC system by providing rejection of all impurities in a single step with permeation of NaSCN and water. The membrane-based nanofiltration technique appeared to be a suitable alternative based on some of the aspects discussed in the scope of the work [180–184].

Pilot-scale NF experiments were carried out with intermittent feed dilution using spirally wound membrane modules to extract at least 98% of NaSCN free of most impurities. Among the membrane types tested, PERMA-250 gave optimum results and was chosen for detailed studies. Pilot-plant data were consolidated and fed into a simulation software developed in Microsoft Excel to provide design of a commercial NF plant capable of handling 8 m<sup>3</sup>/day of 10% NaSCN feed solution containing 2%–4% impurities.

## 42.2.2 SCOPE AND OBJECTIVES

### 42.2.2.1 Scope of the Work

The aqueous process stream from acrylic fiber industries generally contains 10% sodium thiocyanate besides 2%–4% of impurities which impart undesired yellow color and cause fiber degradation. The composition of 10% NaSCN process solution is given in Table 42.3. NaSCN needs to be isolated and then concentrated to 60% for spinning of acrylic fiber. Since the impurities present in the aqueous solution are mostly bivalent salts (Na<sub>2</sub>SO<sub>4</sub>, salts of Fe and Ca) or larger compounds ( $\beta$ -SPA,  $\beta$ -SPN, and low-molecular-weight polymer), there is considerable feasibility to extract the monovalent NaSCN using an NF membrane. If successful, NF could offer advantages such as operational flexibility, faster rate of purification (for increased plant capacity), low water consumption, nearly complete removal of color and impurities in a single step, high NaSCN concentration (>3.5%) in purified solution besides low capital and operating costs.

### 42.2.2.2 Objectives of the Pilot-Plant Study

1. Identification of the best polymeric membrane, which not only removes color but also gives maximum rejection of impurities at optimum flux
2. Production of a permeate containing at least 3.5% NaSCN at a flux ranging between 20 and 45 L/m<sup>2</sup> h to minimize membrane fouling
3. Recovery of at least 98% of NaSCN present in the feed and generating a final reject concentration of <0.25% NaSCN for disposal in accordance to environmental regulations
4. Optimization of experimental conditions such as dilution ratios, stage cut, feed pressure, etc. in achieving the above objectives
5. Designing of a commercial membrane system for feed capacity of 8 m<sup>3</sup>/day of 10% NaSCN solution

**TABLE 42.3**  
**Composition of 10% Sodium Thiocyanate Process Solution**

Impurity	Chemical Structure	Negative Impact	Present Concentration	Acceptable Level
$\beta$ -SPA	$\begin{array}{c} \text{CH}_2 - \text{CH}_2 \\   \quad   \\ \text{SO}_3\text{Na} \quad \text{COOH} \end{array}$	Deterioration of solution color	0.3%–0.5%	0.1%
$\beta$ -SPN	$\begin{array}{c} \text{CH}_2 - \text{CH}_2 \\   \quad   \\ \text{SO}_3\text{Na} \quad \text{CN} \end{array}$	Deterioration of solution color	0.8%–1.5%	0.2%
Sodium sulfate	Na <sub>2</sub> SO <sub>4</sub>	Scaling, increased steam consumption	0.4%–2.0%	0.1%
Iron	FeCl <sub>2</sub>	Deterioration of solution color	1–2 ppm	Traces
Calcium	CaCl <sub>2</sub>	Corrosion of evaporator tubes	30–40 ppm	10 ppm
Sodium chloride	NaCl	Corrosion of pipelines	0.3%–0.4%	0.1%
Other impurities	Low-molecular-weight polymer, unreacted monomer	Deterioration of solution color	0.7%–1.0%	0.2
Color	—	Degradation of fiber quality	200–300 APHA	25 APHA
Total impurities			2.0%–4.0%	0.8%

### 42.2.3 EXPERIMENTAL PROCEDURES AND PROTOCOLS

#### 42.2.3.1 Materials

The aqueous process solution containing sodium thiocyanate with impurities was provided by a local industry. All the membrane modules, pressure vessels, and accessories for the nanofiltration pilot plant used in this study were purchased from Permionics Membranes Pvt. Ltd. (Baroda, India) and assembled in the laboratory. Citric acid, tetra sodium salt of ethylene diamine tetraacetic acid (EDTA), trisodium phosphate (TSP), and sodium metabisulfite for cleaning and maintenance of the membranes were procured from Loba Chemie (Mumbai, India).

#### 42.2.3.2 Types of Membranes and Their Preparation

The spiral wound membranes tested for extraction of impurity-free NaSCN from aqueous process solution were polyamide (PA-300), CTA-700, PERMA-400, and PERMA-250. PA-300 was prepared by interfacial polymerization technique, while the PERMA membranes were prepared by coating a novel proprietary copolymer onto a microporous polysulfone substrate followed by cross-linking of the top layer. Thus, the morphology of these membranes was TFC. CTA-700 was asymmetric in nature and was prepared by solution casting and phase inversion method.

#### 42.2.3.3 Description of Pilot-Scale Nanofiltration System

A pilot-scale membrane system (Figure 42.6) was assembled in-house with incorporation of a commercial spiral membrane module of 2.5 m<sup>2</sup> effective area in a stainless steel (SS316L) pressure housing. The system was skid mounted along with a polypropylene feed tank of 100 L capacity and constituted a low-pressure prefiltration pump (2 bar) for continuous transport of the feed through a micron filter cartridge of 0.2 μm pore size, installed upstream of the spiral NF membrane module to prevent entry of suspended particles that could damage the membrane. A high-pressure pump (run by a 1.5 HP single-phase motor) capable of maintaining pressure up to 25 bar and feed flow rate of 17 L/min was installed at the exit end of the micron filter to facilitate the transport of NaSCN feed solution through the membrane module and the entire NF system. A restricting needle valve was provided at the outlet of the concentrate (reject) pipeline to pressurize the feed liquid to a desired value indicated by the pressure gauge installed upstream of the needle valve. A coil-type heat exchanger was introduced in the reject line to minimize the heat generated by the reject stream due to continuous pressurization and recirculation during the batch operation. Though the membranes can withstand temperatures up to 45°C, long-term operation would reduce membrane life, while low temperatures (<15°C) could cause salt precipitation and low flux. The heat exchanger thus enables determination of percentage recovery by continuous removal of water until the flux remains within acceptable limits. Permeate and reject flow rates were measured by means of two glass rotameters containing metal floats. All other connections were made with ½" outer diameter stainless steel 316 piping in the high-pressure region, while the low-pressure lines comprised PVC braided tubing for permeate flow and reject recycle.

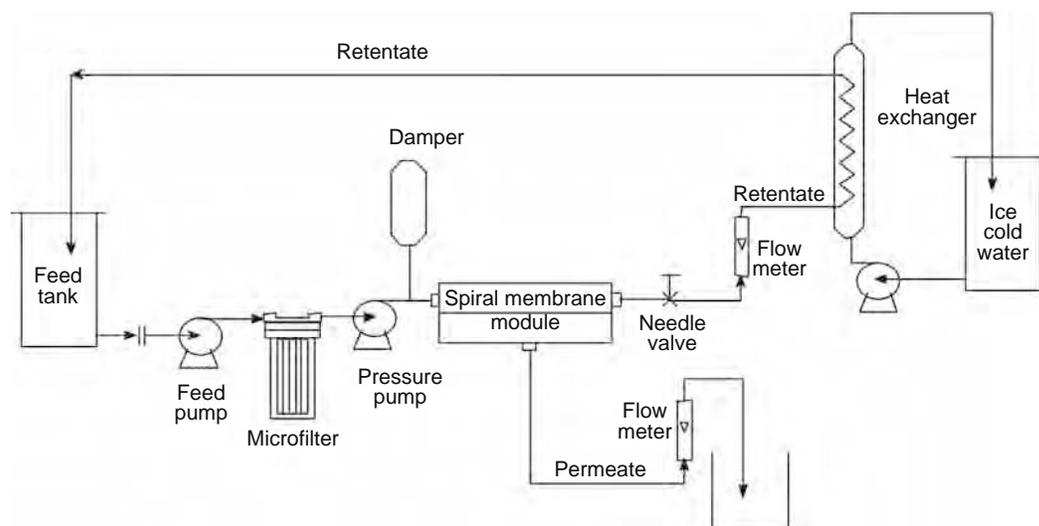

FIGURE 42.6 Schematic view of pilot-scale nanofiltration system.

#### 42.2.3.4 Nanofiltration Procedure

The plant was operated in batch mode with complete recycle of reject at a constant feed rate of 17 L/min. The description here focuses mainly on multistage batch operation with intermittent dilution of the feed (diafiltration) [185]. Initially 50–100 L of the original 10% NaSCN feed mixture containing 2%–4% total impurities was charged into the feed tank and initially pumped with complete recycle of reject and permeate for 5–10 min to ensure homogeneous concentration after which a sample was drawn to note the feed conductivity and temperature. The needle valve in the reject line is throttled to obtain a suitable pressure value in the range of 10–25 bar depending on the type of membrane module used and its MWCO. The initial permeate was recycled until a steady permeate flux was obtained. On the other hand, the reject was continuously circulated back to the feed tank through the heat exchanger. Permeate collection was then begun and conductivities of the feed and permeate were noted for every 5 L of permeate collected. The process was continued until a stage cut of 50%–60% was achieved. The system was stopped and 1 L sample each of the permeate and reject was collected for analysis of NaSCN, color, and other impurities. From the second stage onwards, the reject of the previous stage was diluted with known quantity of demineralized (DM) water and the procedure was repeated.

To obtain better fluxes, lower membrane fouling, and thereby longer membrane life another set of experiments were conducted where the original feed in the first stage (containing 10% NaSCN) was diluted with DM water and the stagewise process was repeated. Permeates for Stages I–III were mixed and the average concentration was noted. Material balance was carried out after thorough analysis to assess percentage recovery of NaSCN.

#### 42.2.3.5 Analytical

The collected feed, permeate, and reject samples were analyzed for sodium thiocyanate, sodium sulfate,  $\beta$ -SPA,  $\beta$ -SPN, Fe, and Ca concentrations and also the total impurity by procedures described in literature [186]. The chemical methods being too lengthy for instantaneous analysis during the course of the experiment, the approximate concentration of sodium thiocyanate especially in the permeate was determined by plotting a graph (Figure 42.7) between known concentrations of NaSCN in DM water and the respective conductivities. The conductivities of the various unknown samples were used to find the corresponding thiocyanate concentrations from the graph.

#### 42.2.3.6 Membrane Cleaning and Maintenance

*General cleaning:* At the end of the operation the membrane was initially washed everyday for 10 min with tap water to displace most of the sodium thiocyanate and impurities present in the pressure housing as well as feed, permeate, and reject lines. The system was operated at a pressure of about 10 bar with total disposal of permeate and reject for 5 min to flush out the dissolved solids present in the pipelines. For the remaining period the exiting streams were recycled back to the feed tank with repeated pressurizing and depressurizing to ensure efficient cleaning.

*Acid/Alkali wash:* To remove mineral scales and metal salt precipitates from the membrane surface, washing with a 1.0% solution of citric acid (or hydrochloric acid) prepared in 25 L of DM water was carried out at a pressure of 10 bar for a 10 min

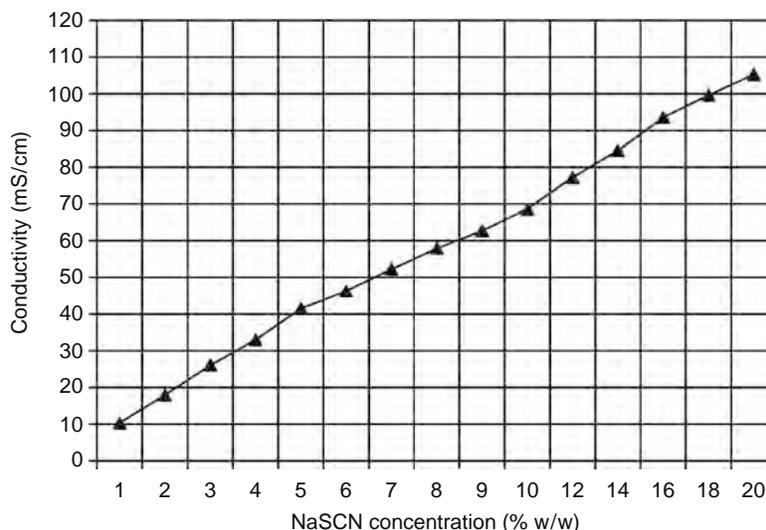

FIGURE 42.7 Concentration versus conductivity plot for sodium thiocyanate.

period everyday with complete recycle of permeate and reject streams after the tap water wash. This was followed by daily washing with a 1.0% solution of TSP for another 10 min at the same operating pressure.

1. *EDTA wash*: To remove organic foulants, a biweekly washing at 20 bar for 15 min with 1.0% aqueous solution of tetra sodium salt of EDTA is recommended. EDTA is a strong chelating agent, which has proven to be capable of flushing out very stubborn organic impurities.
2. *Membrane storage*: Finally at the end of washing, the membrane was stored in 0.5% solution of sodium metabisulfite (SMBS) preservative prepared in DM water. This helps to prevent biological fouling and irreversible destruction of the membrane.

It is worth mentioning that membranes affected by severe chemical fouling can be cleaned using aforementioned reagents but biological fouling causes permanent damage, which on most occasions requires membrane replacement [187]. The membrane is always stored in a horizontal position to prevent it from becoming dry. The above procedures were quite efficient in restoring flux and separation properties of the NF membranes to help them last their stipulated life span.

#### 42.2.4 RESULTS AND DISCUSSION

Table 42.4 exhibits the comparative performance of the four modules (PA-300, CTA-700, PERMA-400, and PERMA-250) in terms of average flux, rejection, NaSCN concentration, and enrichment factor. Operating conditions such as feed pressure, stage cut, and degree of dilution were varied to suit the MWCO of each membrane. From Table 42.4, it can be seen that although the highest pressure followed by initial dilution has been employed for PA-300, the overall flux is still poor, which meant that the commercial viability was quite poor. However, PA-300 gave the highest color and impurity rejections as well as maximum enrichment of NaSCN in permeate. The pore size distribution of CTA-700 was a bit too open for this particular process stream, which consisted of components having molecular weights in the range 50–200, which meant that impurity rejection would be poor in spite of high flux. To strike a balance, the PERMA NF membranes were then tested.

PERMA-400 yielded reasonable results in terms of separation at high flux, even without initial feed dilution. At 18 bar pressure and dilutions of 1:0.5 and 1:0.75 in the second and third stages, PERMA-400 gave high average flux of 43 L/m<sup>2</sup> h, an impurity rejection of 57.5%, and a color rejection of 64.3%, which meant that Fe compounds were rejected to a greater extent. However, the acrylic fiber spun from a concentrated permeate of PERMA-400 still possessed a light yellow tinge, which meant that further improvement in impurity rejection was to be achieved to make NF truly competitive to the conventional purification processes.

PERMA-250 was found to be ideal for this purpose as it gave excellent impurity and color rejections of almost 80% and 90%, respectively, along with a moderate average flux of 27.3 L/m<sup>2</sup> h at 21 bar, even without initial dilution. To further enhance its performance, dilution was introduced in the first stage itself, so that an improvement of the thiocyanate enrichment factor to 1.28 could be obtained. It is thus vivid that PERMA membranes comprised numerous polar moieties in the polymer matrix, which not only improves the water sorption but also its interaction with NaSCN rendering its enhanced transport. The bivalent salts Fe, Ca, and Na and organic impurities such as  $\beta$ -SPA and  $\beta$ -SPN could not penetrate the barrier to a larger extent. On the basis of optimum performance, PERMA-250 was considered as the right candidate for further studies. A five-stage process was employed to achieve the remaining objectives. Table 42.5 summarizes the five-stage process results for HPA-250 membrane. In Stage I, a batch time of 2.3 h was sufficient to obtain 60 L of permeate from a feed of 100 L. The initial flux was 45 L/m<sup>2</sup> h and at a stage cut of 60% the final flux was 7.6 L/m<sup>2</sup> h. High degree of

**TABLE 42.4**  
**Comparative Performance of Four Membranes Studied for Sodium Thiocyanate Extraction in Three Stages**

II	1:0.5	50	3.45	0.65	81.0	27.0
III	1:0.75	60	3.60	0.71	80.2	28.5
IV	1:3	70	2.01	0.17	91.5	30.5
V	1:5	80	1.03	0.05	95.0	54.3

Note: Membrane: PERMA-250, feed pressure 21 bar.

dilutions of 1:3 and 1:5 were applied in the last two stages to counter the effect of increasing impurity build up in the reject. To prevent substantial damage to the membrane, occurring due to fouling, the current five-stage process was made more commercially feasible by employing an initial dilution ratio of 1:0.5 in the first stage. From Table 42.5, it can be seen that the average concentration of NaSCN of 7.1% is achievable in three stages without dilution in Stage I. This reduces the evaporation cost, but leads to increased fouling on the membrane surface due to high TDS concentration in Stage I. Sufficient care was to be taken to avoid excessive dilution of the feeds to prevent a drop in the average concentration of NaSCN below the desirable value of 3.5% to match the conventional technology. Table 42.6 exhibits the performance of PERMA-250 over a five-stage process with initial dilution. Based on the results, a scheme was planned where the permeates of Stages I–III were collected and sent for concentration and spinning, while the permeates from Stage IV to V would be recycled back to the system to obtain 98% NaSCN recovery along with >3.5% NaSCN product concentration and <0.25% NaSCN in final reject (fifth stage) for disposal. It is, therefore, clear from the studies that higher degrees of dilutions produced greater flux as well as higher NaSCN enrichment factors. Figure 42.8 depicts the influence of feed impurity concentration on flux and rejection through PERMA-250 membrane at a constant pressure of 21 bar. Different concentrations of the feed were prepared by dilution with DM water as well as evaporation. As the impurity concentration increased from 0.6% to 3.64%, the flux reduced from 76.7 to 8.4 L/m<sup>2</sup> h for a single stage operation with 60% recovery. The corresponding impurity rejection lowered from 94.2% to 65.7%. Increasing feed concentration results in a rise in the osmotic pressure, which effectively reduces the transmembrane pressure gradient leading to reduced rate of mass transfer. It may be noted that though NaSCN is a permeable component, its presence definitely adds to the osmotic pressure value. The corresponding NaSCN concentration in the feed increased from 2.5% to 15.3%.

The influence of feed pressure on performance of PERMA-250 membrane is depicted in Figure 42.9. Increasing pressure caused enhancement of flux as well as NaSCN enrichment, due to exertion of increasing driving force on the movement of H<sub>2</sub>O and NaSCN molecules, which are preferentially sorbed by the hydrophilic membrane. The permeation rate of the noninteracting impurities remains relatively constant. Figure 42.9 shows that the flux increased from 8.7 to 34.2 L/m<sup>2</sup> h, while the impurity rejection improved from 72.1% to 77.4%. The NaSCN enrichment (not depicted in the figure) increased from 1.23 to 1.30. The effect of feed flow rate was also studied through PERMA-250 and better separation was observed at a feed rate of 17 L/min compared to 2 L/min since greater cross-flow minimizes concentration polarization of solutes near the membrane surface.

**TABLE 42.6**  
**Summarized Results for Five-Stage Process with Initial Dilution**

Stage	Dilution Ratio	Volume Recovery (%)	Feed Total Impurity (%)	Permeate Total Impurity (%)	Impurity Rejection (%)	Flux (L/m <sup>2</sup> h)

#### 42.2.5 PROCESS DESCRIPTION FOR OPERATION OF COMMERCIAL NANOFILTRATION PLANT

Figure 42.10 represents the process flow sheet consisting of membrane module equipment sufficient for one stage. The figure shows the 12 modules arranged in three pressure housings each containing four spiral modules. Two pressure housings are arranged in parallel and the third in series such that the feed is split into two streams while entering the parallel pressure housings and the rejects from these two parallel housings are again combined to form a single stream, which enters as the feed to the third housing. Such an arrangement is self-controlling and leads to constant input and output flow rates making the entire membrane assembly appear as one single membrane module.

The process operation involves five stages in a cycle that is to be completed in a total duration of 12 h; which includes 10 h for the five-stage operation, 1.5 h for reject recycle to feed tank, and 0.5 h for membrane cleaning and storage. The detailed explanation of the process in accordance is given below.

##### 42.2.5.1 Cycle 1

It is assumed that 8 m<sup>3</sup> of 10% sodium thiocyanate feed solution is available in the feed tank and DM water is available at a tapping source at a pressure of 1.5–2 bar. The feed is continuously drawn with the help of a centrifugal pump (feed transfer pump or prefiltration pump) at the rate of 4 m<sup>3</sup>/h, while the DM water for diluting the feed is drawn at a rate of 2 m<sup>3</sup>/h. Both the streams are forced through the static mixer to form a homogeneous solution, which then enters the prefilter assembly consisting

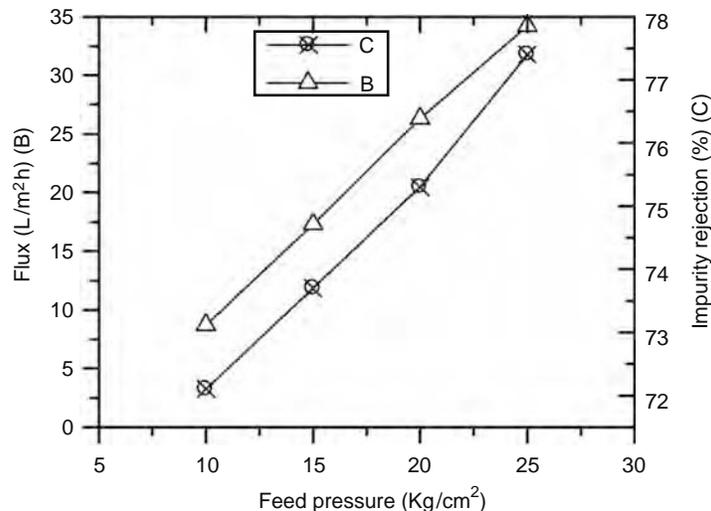

FIGURE 42.9 Influence of feed pressure on flux and rejection.

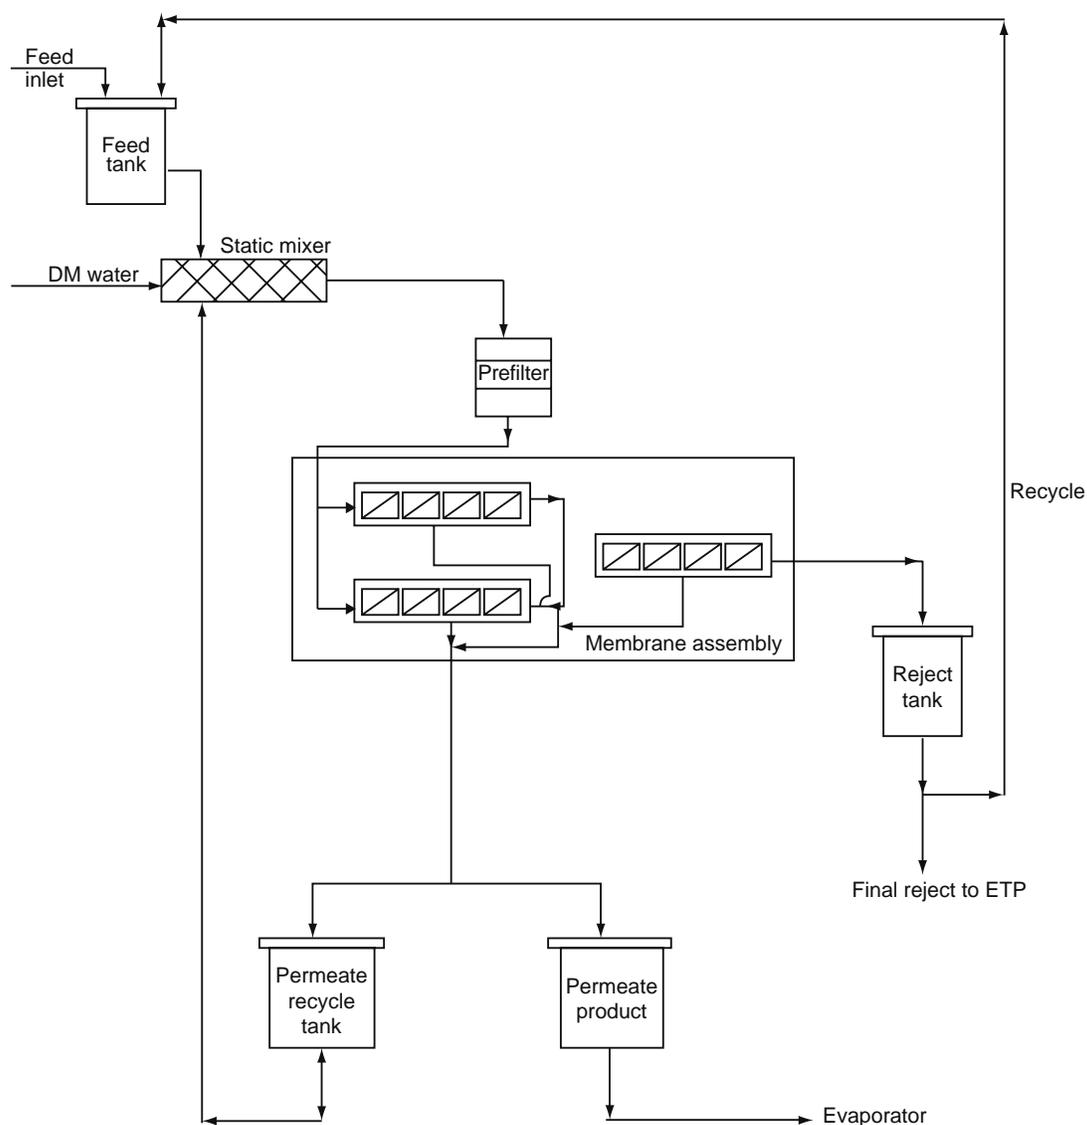

FIGURE 42.10 Process flow diagram for commercial nanofiltration plant of 8 m<sup>3</sup>/day capacity.

of iron filter, bag filter, and micron filter placed in series. The feed is then drawn by the high-pressure pump, and fed into the membrane assembly at 6 m<sup>3</sup>/h. The feed is recirculated for 10 min before the control valve placed on the reject line is throttled to obtain the desired operating pressure (15–25 bar), which signals the beginning of Stage I. The reject is now collected at 2.4 m<sup>3</sup>/h in the reject tank, while the product is collected at the rate of 3.6 m<sup>3</sup>/h in the permeate product tank. Stage I gets terminated in 2 h of operation during which a total feed quantity of 12 m<sup>3</sup> constituting 8 m<sup>3</sup> of original 10% feed is emptied from feed tank and 4 m<sup>3</sup> of DM water is consumed for dilution. A permeate quantity of 7.2 m<sup>3</sup> gets accumulated in product tank and a reject of 4.8 m<sup>3</sup> is separately collected.

Stage II is instantaneously started with 4.8 m<sup>3</sup> of feed (reject of Stage I) being drawn by a centrifugal pump at a decreased rate of 2.4 m<sup>3</sup>/h and DM water drawn at an increased rate of 3.6 m<sup>3</sup>/h. The fluid flow pattern is similar as in Stage I except for the fact that feed and DM water flow rates entering the static mixer are now different. However, the diluted feed flowing into the membrane assembly is once again maintained at 6 m<sup>3</sup>/h. The permeates and rejects are once again collected at rates and quantities similar to Stage I.

Stages III–V follow exactly the same pattern as Stage II. Permeates from Stage I to III constitute a total quantity of 21.6 m<sup>3</sup>, which is the product containing >3.5% sodium thiocyanate. This product is sent to the evaporator for concentration and spinning. However, the permeates for Stages IV and V are collected in the permeate recycle tank for use as diluting liquid from cycle 2 onwards. The reject after Stage V is sent for disposal. It may be noted that the dilution ratio for Stage I is 1:0.5, while it is 1:1.5 for all the subsequent stages. This holds good for all the cycles of operation.

### 42.2.5.2 Cycle 2

The process for cycle 2 is similar to that of cycle 1 except for the fact that initially the 14.4 m<sup>3</sup> of recycle permeate available in the permeate recycle tank is used for feed dilution during a couple of stages. The recycle permeates are used for diluting feeds in Stages II and III, while DM water is tapped for the other stages.

### 42.2.5.3 Membrane Cleaning and Storage

A tank of polypropylene make of 200 L capacity is generally provided along with the membrane system for cleaning in place (CIP). Tap water is collected in the CIP tank and the NaSCN feed present as dead volume in the system is displaced using high-pressure pump. A 200 L of DM water is then filled in the CIP tank to which 2 kg of one of the cleaning agents is added and dissolved. The membrane is thus washed in two or three separate steps using citric acid and TSP on a daily basis and EDTA on a weekly basis for a duration of 10 min each. The membrane is finally stored in 1% sodium metabisulfite (SMBS) aqueous solution prepared in DM water. At the beginning of a fresh cycle of operation the dead volume of 1% w/v SMBS solution present in the membrane and pipeline is removed by displacement with NaSCN feed solution.

### 42.2.6 SIMULATION AND DESIGN

A simulation program was prepared using excel functions based on the results obtained with PERMA-250 membrane in a five-stage process scheme with initial and intermittent dilution. The purpose of simulation [188] was to determine the material balance, membrane area requirement, and compositions of the exiting permeate and reject streams in response to different feed inputs comprising NaSCN concentration, impurity concentration, enrichment factors, quantity of demineralized water required for dilution and permeate percentage recovery in each stage (stage cut). For this study, Table 42.7 describes the base case operating conditions and membrane specifications considered for designing a commercial NF system capable of processing 8 m<sup>3</sup>/day of 10% sodium thiocyanate feed containing 2%–4% of impurities including color, which must be processed to an output product solution containing at least 3.5% NaSCN besides negligible color and other impurities (<0.8%).

**TABLE 42.7**  
**Base Case Operating Conditions for Process Design and Membrane Specifications for Commercial Nanofiltration Plant**

Operating Condition/Parameter	Specification
Feed capacity	8 m <sup>3</sup> /day
Feed concentration	10% NaSCN + 3% total impurity
Feed pressure	21 bar
Feed temperature	Ambient
Number of stages	5
Initial feed dilution ratio	1:0.5
Subsequent dilution ratios	1:1.5
Total feed quantity per stage	12,000 L
Stage cut	60% (7,200 L)
Duration of operation per stage	2 h
Total time of operation/day	12 h
Minimum NaSCN recovery	98%
Minimum NaSCN concentration in product	3.5%
NaSCN concentration in final reject	<0.25%
Recommended range of flux	20–45 L/m <sup>2</sup> h
Membrane type	PERMA-250
Modular configuration	Spiral wound
Total membrane area requirement	90 m <sup>2</sup>
Dimension of each module	4" dia × 40" length
Effective area in each module	7.5 m <sup>2</sup>
Total number of spiral modules	12
Number of FRP housings	3

TABLE 42.8

Optimized Five-Stage Process Scheme for Feed Capacity of 8 m<sup>3</sup>/day (Second Cycle of Operation Onwards [Steady State])

Stage	Feed Solution (Liters) and Source	Demineralized Water Added (L)	Total Feed Volume	Permeate Volume (L) and Recovery	Reject Volume (L)	Flux (L/m <sup>2</sup> h)
I	8,000 Fresh feed	4,000 Fresh DM water	12,000	7,200 60%	4,800	40
II	4,800 Reject of Stage I	7,200 Permeate of Stage IV, cycle 1	12,000	7,200 60%	4,800	40
III	4,800 Reject of Stage II	7,200 Permeate of Stage V, cycle 1	12,000	7,200 60%	4,800	40
IV	4,800 Reject of Stage III	7,200 Fresh DM water	12,000	7,200 60%	4,800	40
V	4,800 Reject of Stage IV	7,200 Fresh DM water	12,000	7,200 60%	4,800	40

The design (for the first cycle of operation) was made as simple as possible to enable easy understanding and effortless operation as shown in Table 42.8. The total membrane area required for processing a feed of 12 m<sup>3</sup> in 2 h was also stipulated from the simulation program. It is a well-known fact that the area required is a function of the flux [14]. Figure 42.11 shows the variation of area with the average flux for a five-stage process. Flux between 20 and 45 L/m<sup>2</sup> h is within the acceptable range, while a rate below 20 L/m<sup>2</sup> h would be uneconomical and a value higher than 45 L/m<sup>2</sup> h is preferentially avoided to minimize membrane fouling. The membrane area required for every two hourly stage, in the present case, was found to vary from 180 to 80 m<sup>2</sup> as the flux increased from 20 to 45 L/m<sup>2</sup> h. Thus, the area required to obtain a permeate of 7.2 kg in 2 h at a flux of 40 L/m<sup>2</sup> h is 90 m<sup>2</sup>. Five stages would require a total operation time of 10 h. It may be noted that the same membrane area of about 90 m<sup>2</sup> can be utilized to operate each stage individually. As per the standard modular configurations (Table 42.7) available with the supplier (Permionics Membranes Pvt. Ltd., Baroda, India), the spiral membrane module of 4" diameter × 40" length was chosen, which gives an effective area of 7.5 m<sup>2</sup> each. Hence 12 such modules would provide an area of 90 m<sup>2</sup>.

## 42.2.6.1 Material Balance

The material balance for the first cycle of operation in the present study is shown in Figure 42.12. The present material balance shows a total input of 12 m<sup>3</sup> of 10% NaSCN feed containing 3% impurities. A total amount of 18.4 m<sup>3</sup> of DM water is added for dilution of feeds during the five stages from cycle 2 onwards. The output product is 21.6 kg of 3.6% NaSCN, which is free of color and contains only 0.06% of impurities since a dilution of 1:1.5 is employed from Stage II onwards. The other output is a final reject quantity of 4.8 m<sup>3</sup> containing <0.1% NaSCN and 4.7% impurities for disposal. The total NaSCN recovery is 99.4% and impurity rejection 94.2%.

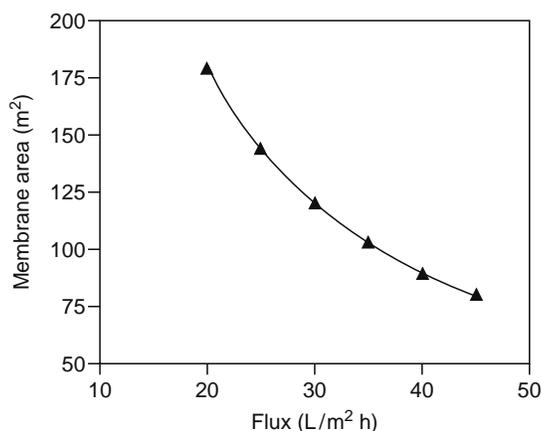

FIGURE 42.11 Variation of membrane area requirement per stage with average flux.

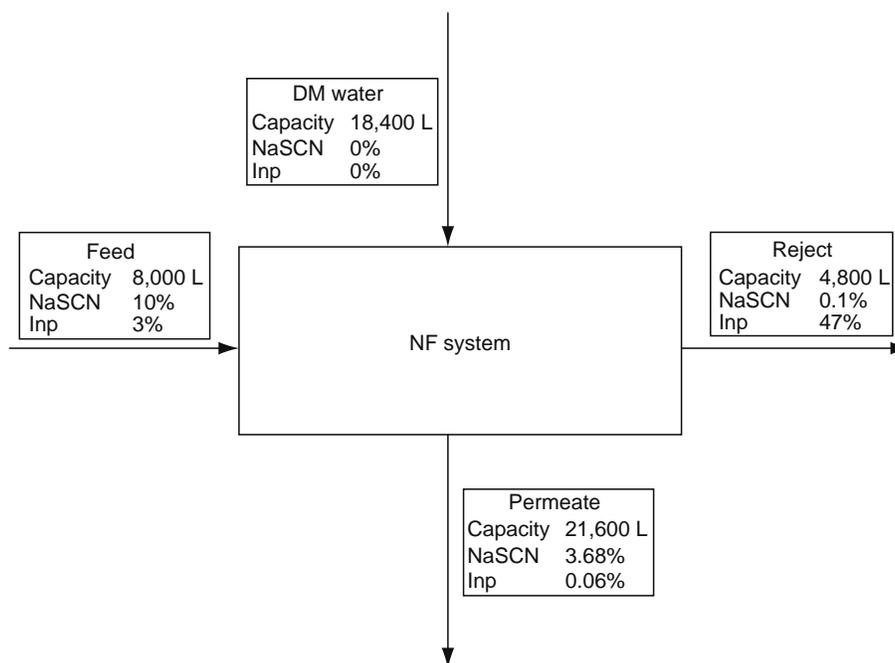

FIGURE 42.12 Overall material balance diagram for commercial nanofiltration system.

## 42.2.7 ECONOMIC ESTIMATION

### 42.2.7.1 Capital Investment

The two most important as well as expensive equipments in an NF system are the membrane assembly and the high-pressure system pump [189]. Most of the equipment shown in Figure 42.10 are listed in Table 42.9. These include membrane assembly, static mixer, prefilter assembly, besides fiber-reinforced plastic (FRP) tanks for storage of feed, permeate, and reject. The accessories that are not shown in Figure 42.10, but which form an integral part of the NF system are the low- and high-pressure pumps besides piping and instrumentation. The cost of each equipment was estimated in Indian rupees, but presented in U.S. dollars assuming an exchange rate of Rs 50 per U.S. dollar.

NaSCN solution being highly corrosive, the material for tanks and membrane housings was FRP, while piping and other contacting parts were made from stainless steel 316 L. The FRP feed tank (1 no.), permeate tanks (2 nos), and reject tank (1 no.) of 15 m<sup>3</sup>, 25 m<sup>3</sup>, and 15 m<sup>3</sup>, 5 m<sup>3</sup> capacities respectively, were purchased at the rate of \$216 per cubicmeter. The total capital investment for the NF system came to \$38,000 excluding expenditure for site preparation. The space required for installation of the NF system was 10 × 8 m.

TABLE 42.9

List of Equipment and Capital Cost for Commercial Nanofiltration Plant

Description	Capacity/Size	Quantity	Material of Construction	Unit Price (\$)
Prefilter assembly	75 L/min	01	MS epoxy	1,600
PERMA-250 membranes, pressure vessels, piping and skid	4" × 40"	01 set	—	9,700
Static mixer	2 m long	01	SS316L	800
System pump (high pressure)	50 L/min	01	SS316L	6,000
Feed transfer pump	75 L/min	01	PP	700
Permeate recycle pump	100 L/min	01	PP	1,000
Reject recycle pump	200 L/min	01	PP	1,200
Storage tanks for feed, permeate, and reject	5–25 m <sup>3</sup>	05	FRP	13,000
Piping, instrumentation	—	01 set	SS316L	4,000
Total				38,000

### 42.2.7.2 Operating Cost

Power cost for running a high-pressure pump of reasonable capacity and periodic membrane replacement account for a major proportion of the operating costs in NF [190]. Other contributors to the operating cost include consumables such as dosing chemicals for pretreatment of feed before NF, cleaning chemicals and utilities such as DM water, etc. The basis for calculation was a membrane life span of 2 years taking into consideration a 11 h/day period of operation. The number of working days per annum was assumed to be 325. From calculations, the power consumed by the high-pressure pump was 3,1736.25 kWh per year amounting to \$2540 per annum. The feed transfer pump, permeate, and reject recycle pump were expected to incur annual power consumptions of 6303.7, 1212.25, and 775.8 kWh, respectively. Hence the total power consumed was 40,028 kWh, which costs \$10 per day and \$3200 per year.

#### 42.2.7.2.1 Membrane Replacement

The cost of 12 modules (1 module of 7.5 m<sup>2</sup> effective area costing \$600) was \$7200. The membrane life is expected to be 2 years for 11 h duration of operation per day.

#### 42.2.7.2.2 Dosing Chemicals for Feed Pretreatment

The dosing chemicals such as antiscalant, SMBS (to consume free chlorine), and HCl used cost \$3 on a daily basis.

#### 42.2.7.2.3 Cleaning Chemicals

Cleaning agents, such as citric acid, EDTA, and TSP, and preservatives such as sodium metabisulfite costed \$2 per week.

#### 42.2.7.2.4 Utilities

Demineralized water for feed dilution and membrane storage, besides raw water for cleaning purpose, constitutes the main utilities. Raw water costs \$0.18 per cubicmeter while DM water is three times costlier. The quantity of raw water required is 0.5 m<sup>3</sup>/day and that of DM water is 19 m<sup>3</sup>/day. Other consumables, such as pump oil and spares, were negligible compared to the above costs and are not included. Existing Labor for conventional purification equipment was expected to operate NF plant. The total operating cost was determined to be \$11,700 per annum. Table 42.10 gives the total operating cost for the commercial NF plant.

## 42.2.8 CONCLUSIONS

Nanofiltration appears to be a promising process to recover impurity-free sodium thiocyanate from aqueous industrial process solution due to removal of color and most impurities in a single step at a reasonably high rate. Among the membranes tested, PERMA-250 was found to exhibit the optimum performance in terms of flux and impurity rejection with the permeate generated being practically colorless. PERMA-250 also showed sufficient affinity for sodium thiocyanate, which enabled the permeate to be enriched in NaSCN and the feed to be completely stripped off the same compound. Under the same operating conditions PERMA membranes gave 5–6 times higher flux compared to ordinary polyamide membrane of similar MWCO owing to greater sorption of water. A five-stage process design involving initial and intermittent dilution of the feed with recycle of the fourth and fifth stage permeates was ideal in achieving objectives including >98% NaSCN recovery in the permeate and <0.25% NaSCN in the final reject for disposal. Simulation using Excel functions enabled determination of output characteristics such as overall material balance, permeate and reject compositions, percentage recovery, expected fluxes, and most significantly the membrane area requirements for input characteristics such as feed capacity, stage dilution ratio, NaSCN

**TABLE 42.10**  
**Operating Cost Estimate for Commercial NF Plant**

Type of Cost	Details	Cost/Day (\$)	Cost/Year (\$)
Power	2 Pumps-1 Hp 1 Pump-2 Hp 1 Pump-12.5 Hp	10	3,200
Dosing chemicals	Anti-scalant, SMBS HCl	3	1,150
Cleaning chemicals	EDTA, citric acid TSP	2	400
Membrane replacement	PERMA-250 spiral modules (9 nos)	10	3,600
Utilities	DM water Raw water	10	3,350
Total		35	11,700

enrichment factor, and feed pressure. The commercial plant incurred a capital investment of \$38,514, while the operating cost was \$11700 per annum. The life of the PERMA-250 membrane was expected to be 2 years for a 12 h period of operation per day. Maintenance of the NF membrane through daily washing with citric acid and TSP followed by storage in aqueous solution of sodium metabisulfite was necessary to extract maximum life.

## ACKNOWLEDGMENTS

The authors acknowledge the encouragement given by Dr. J.S. Yadav, director and Dr. K.V. Raghavan, former director of Indian Institute of Chemical Technology (IICT), Hyderabad, India during the course of this project. The constant support of Dr. A.A. Khan, Dr. M. Ramakrishna, Dr. D.H.L. Prasad, and Dr. K. Babu Rao, scientists of the Chemical Engineering Division of IICT, Mr. Satyajai Mayor, managing director of Permionics Membranes Pvt. Ltd., Vadodara, India, is gratefully acknowledged. Mr. K.B.S. Saibabu of Chemical Engineering Design group and Mr. Murthy of Mechanical Engineering Division are thanked for their help during process design. The authors would like to thank Elsevier publications for granting permission to use a figure and few lines from one of their publications. The authors would like to extend their thanks to Dr. Chakravorty, Genesis Membranes Pvt. Ltd. for having enabled us to reproduce the figure pertaining to the module configurations. Finally, the efforts of Mr. G. Suryanarayana Murthy and Ms. D. Suhanya, Research Assistants at Membrane Separations Group, IICT are acknowledged.

### 43.1 MEMBRANE ENGINEERING FOR PROCESS INTENSIFICATION

It is well understood today that our society has to face the challenge of modifying the traditional industrial growth to a sustainable growth, if we want to continue developing for generations. In principle, adverse environmental impact can be notably reduced by optimizing the existing activities. Present design methods are effectively devoted, in most cases, to manage wastes better, to introduce methods for pollution abatement, and to realize cleaner processes for cleaner products. Nevertheless, these positive effects are expected to be offset by the ongoing growth. Traditional environmental management and pollution prevention will not suffice in the long run; newer approaches, which are radically innovative and integrated, are needed. The chemical and engineering community are already paying significant attention to the quest for technologies that would lead us to the goal of technological sustainability.

A promising example with a lot of interest by process engineers is the strategy of process intensification. It consists of innovative equipment, design, and process development methods that are expected to bring substantial improvements in chemical and any other manufacturing and processing, such as decreasing production costs, equipment size, energy consumption, waste generation, and improving remote control, information fluxes, and process flexibility.

In this frame, an interesting and important case is the continuous growth of modern membrane engineering whose basic aspects satisfy the requirements of process intensification [1]. Membrane operations, with their intrinsic characteristics of efficiency and operational simplicity, high selectivity and permeability for the transport of specific components, compatibility between different membrane operations in integrated systems, low energetic requirement, good stability under operating conditions and environment compatibility, easy control and scale-up, and large operational flexibility, represent an interesting answer for the rationalization of chemical productions.

Many membrane operations are practically based on the same hardware (materials), only differing in their software (methods). The basic properties of membrane operations make them ideal for industrial production: they are simple in concept and operation; they are modular and easy to scale-up; and they are low in energy consumption with a remarkable potential for a more rational utilization of raw materials, and recovery and reuse of by-products.

Practically, there is a lot of opportunities for membrane separation processes in all areas of the modern industry. The most interesting developments for industrial membrane technologies are related to the possibility of integrating various membrane operations in the same industrial cycle, with overall important benefits in terms of product quality, plant compactness,

environmental impact, and energetic aspects. At present, redesigning important industrial production cycles by combining various membrane operations suitable for separation and conversion units, thus realizing highly integrated membrane processes, is an attractive opportunity because of the synergic effects that can be attained [2].

### 43.2 FUNDAMENTAL STUDIES ON MEMBRANES ENGINEERING

A continuous research work on membrane properties and fundamental aspects of transport phenomena in the various membrane operations is important for the future of membrane science and technology. There is a need for both basic and applied research to develop new membranes with improved properties and new membrane processes. These research efforts must take into account the studies done in other areas such as supramolecular chemistry, molecular imprints materials, nanotechnology, nonlinear optics, studies on biological membranes and biological phenomena, etc.

Progress in better understanding of fouling phenomena and their prevention, improving of membrane selectivity, and development of new enantioselective membranes, are some examples of sectors where basic research can contribute.

More progresses on anticipating and predicting relationship between membrane chemical properties, their morphology and configuration, with the overall membrane phenomena, are still necessary, as well as, the role of interfacial phenomena and the influence of the properties and phenomena in the solution upstream and downstream the membrane surfaces.

Computational strategies will be key tools for the understanding of properties and behavior of materials to exploit the potential use of novel highly complex composite systems, new molecules and new multifunctional materials, also in membrane technology.

The possibility to design, using molecular dynamics tools, new organic or inorganic materials having selectivity for different chemical species similar to the palladium for hydrogen or to the perovskite for oxygen, might be an interesting area for future research activities.

### 43.3 REVERSE OSMOSIS IN SEAWATER AND BRACKISH WATER DESALINATION

Desalination of seawater and brackish water has been at the origin of the research efforts on reverse osmosis (RO). Today, the scarcity of potable water resource is in fact one of the main worldwide problem. Membrane technology had contributed and can further contribute in the future for the resolution of water scarcity emergency. Membrane technology is nowadays well recognized as the most convenient approach in desalination, producing daily more water than any thermal systems. More progresses can be anticipated in terms of overall costs reduction and quality improvement, by the growing integration of different membrane operations in the same desalination system. Microfiltration (MF) and ultrafiltration (UF) are becoming standard in the feeds pretreatment alternative to the traditional sand filters, active charcoal, and similar.

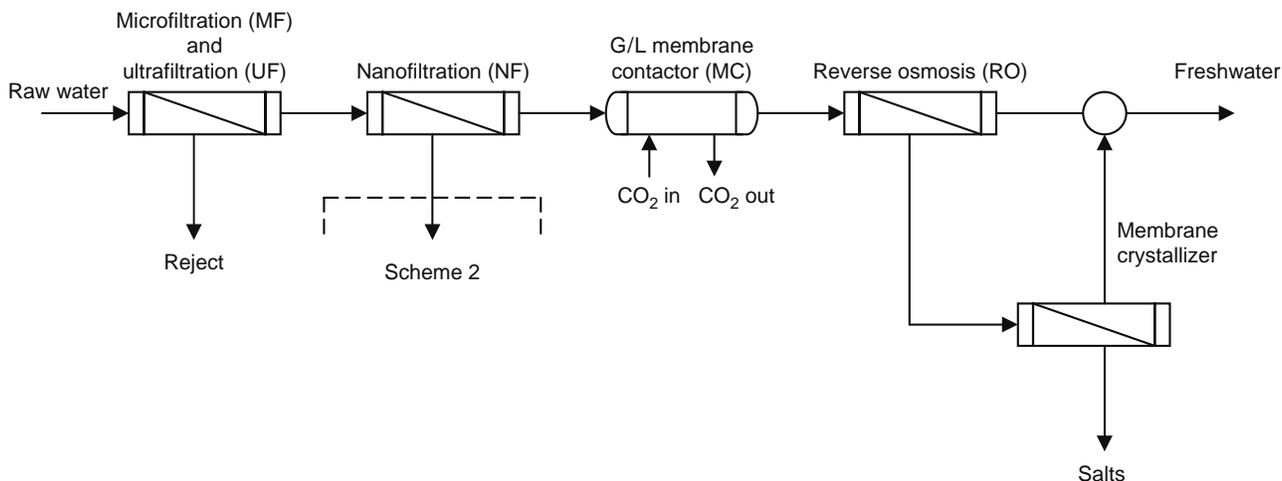

MF is a low energy-consuming technique that can be used to efficiently remove suspended solids and to lower COD/BOD (chemical oxygen demand/biological oxygen demand) and silt density index (SDI) [3,4]. UF is able to retain suspended solids, bacteria, macromolecules, and colloids thus reducing the potential of fouling and biofouling; despite of the larger pressure gradient with respect to MF, this membrane separation method remains competitive against conventional pretreatments. The introduction of nanofiltration (NF) pretreatment step leads to significant improvement in the reliability of RO; hardness is strongly reduced, as well as the most part of multivalent ions; monovalent species are also retained by 10%–50% depending on the membrane properties. As consequence, the osmotic pressure of the RO feed stream is decreased, thus allowing the unit to operate at high recovery factors without scaling problems.

Membrane contactors (MCs) represent another interesting frontier in the application of membrane technology in seawater desalination. Gas–liquid application for addition/extraction of selected gasses or operation like membrane crystallization has been recognized in some new experimental works, as important ways for improve efficiency and get some advantages for the overall desalination processes [5,6].

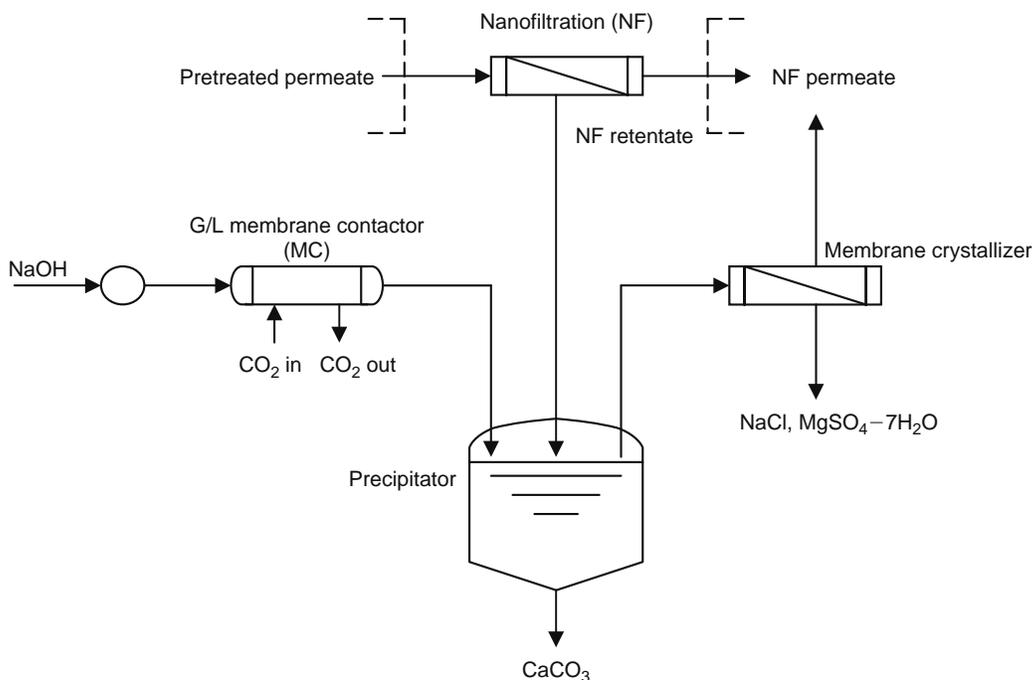

The increase of the low values of the recovery factor in the RO step by the introduction of membrane contactors stages on the brines of both NF, if used, and RO, has been recently proposed in literature (Figure 43.1). The use of gas–liquid membrane contactors can lead to a better and specific control of the gases dissolved in the feeds, thus preventing corrosion problems, reducing posttreatment operations, and providing optimal conditions for possible selective crystallization. Membrane contactors, in the form of membrane crystallizers, have been also recently tested as an innovative application in reducing the polluting charge and recovery some valuable salts of commercial relevance from the high concentrated brine of NF or RO plants in desalination installations (Figure 43.1) [5,6].

Presently, about 48% of all desalination facilities discharge their concentrate waste stream into surface waters or the ocean. This disposal method represents currently the most-effective and less-expensive option for both smaller and larger systems located near coastal regions. However, the promulgation of more and more stringent environmental protection regulations will reduce progressively this opportunity. In particular, the study of alternative design pathways for brine concentration is encouraged as viable opportunity to obtain value from saline waste streams, with consequent benefits in terms of overall costs reduction. In this respect, a membrane crystallization step for recovery of commercial solid substances that are present in

Scheme a

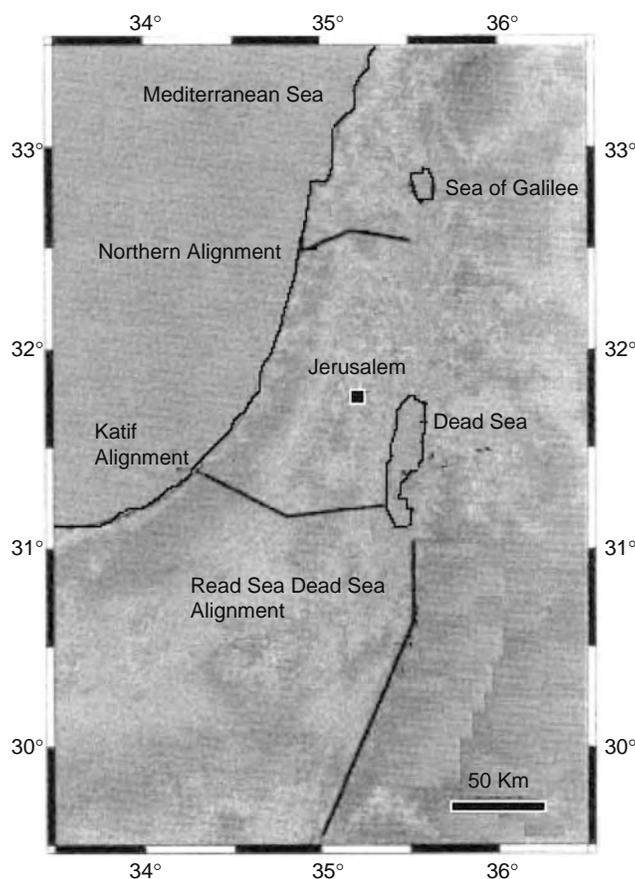

Scheme b

**FIGURE 43.1** Integrated membrane system proposed for seawater desalination. (Adapted from Drioli, E., Curcio, E., Criscuoli, A., and Di Profio, G., *J. Membr. Sci.*, 239, 27, 2004.)

the concentrated streams of the desalination plants, can improve the whole desalination process. The spontaneous precipitation of calcium carbonate from NF retentate has resulted in the formation of both NaCl and MgSO<sub>4</sub> · 7H<sub>2</sub>O salts using a membrane-based crystallization unit. In particular, it has been showed that 8.4 kg of MgSO<sub>4</sub> · 7H<sub>2</sub>O can be obtained per cubic meter of NF reject. When a membrane crystallizer follows an RO stage, the highly concentrate brine does not represent waste but rather the mother liquor in which sodium chloride crystals could nucleate and grow. The presence of the NF as pretreatment allows increasing the water recovery of the RO unit up to 50%. Moreover, introduction of a membrane crystallizer leads to a 100% recovery and elimination of the brine disposal problem, representing the pure crystals produced a valuable product (Figure 43.1).

The progress made in membrane-based desalination has lead to the substitution of evaporation plants with RO systems in different part of the world. For example, the United States holds the second position in worldwide desalination capacity (15.2% of the world production) and the 78% of their production come from RO treatments. Mediterranean countries, including Spain, Malta, Cyprus, and Israel, have also reverted from traditional multistage flash (MSF) to RO during the past two decades. The water production by reverse osmosis desalination plants passed from 36% of the global desalting capacity in 1996 to 42%

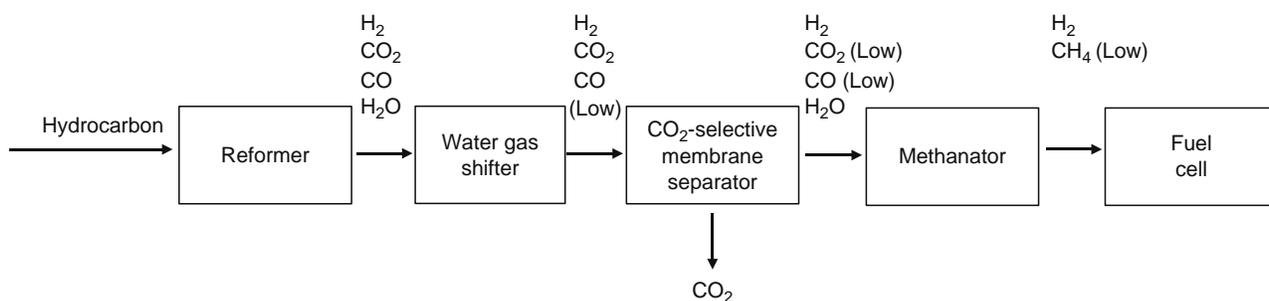

**FIGURE 43.2** The three alignments suggested for the realization of a seawater reverse osmosis (SWRO) desalination plant between Israel and the Hashemite Kingdom of Jordan. (From <http://www.mfa.gov.il/mfa>.)

in the 2000; the opposite trend was evident for the thermal plants. In particular, MSF processes passed from the 54% in 1996 to the 44% in 2000. In 2002, total installed or contracted desalting capacity based on RO processes reached the value of MSF-based plants at 43.5% of the world-installed capacity [7]. Currently the water production by membrane techniques has exceeded that of the traditional thermal systems, thanks to the construction of new systems. One of the Europe's largest seawater reverse osmosis (SWRO) plant was realized in the 2002 at Carboneras in Spain; this plant has a capacity of 120,000 m<sup>3</sup>/day. Moreover, many large plants are under construction. Particularly, in April 2003 began the realization on the South Israel (Ashkelon) of a SWRO plant which, once fully completed, will be the largest in the world. This plant alone will contribute to 100 million m<sup>3</sup>/year; the design will use advanced SWRO technology and state-of-the-art energy recovery systems to reduce operating costs and achieve one of the lowest water prices for this kind of operation (\$0.527/m<sup>3</sup>). A more ambitious project is the realization of a desalination plant between Red Sea and Dead Sea, using the process of hydrostatically supported reverse osmosis to provide a desalinated seawater (Figure 43.2). Hydrostatic energy potential of 300 m elevation difference between Red Sea and Dead Sea will be used for desalination by hydrostatically supported SWRO. On completion, this plant will produce 26 m<sup>3</sup>/s of water.

The need for even more cost-effective and efficient systems for water recovery was, and continues to be, the driving force for the research and development in RO technology.

#### 43.4 MEMBRANE-BASED GAS SEPARATION

The membrane-based gas separation (GS) processes are characterized by lower energy consume and capital investments compared to traditional gas separation systems. Both porous and nonporous membranes can be used in GS. Generally, porous membranes exhibit high level of gas flux but low selectivity. On the contrary, dense membranes generally provide high selectivity and low flux values compared to porous ones [8]. In a porous membrane, gas with different size can be separated; in a dense membrane, even gas having similar size can be separated. Membrane-based gas separation can be used as a single separation unit, or as part of an integrated separation system.

**FIGURE 43.3** One of the integrated system proposed in a U.S. Patent, ExxonMobil property. (Adapted from U.S. Patent No. 6 579 331 B1.)

Theoretical infinite selectivity can be achieved for hydrogen separation by Pd or Pd-alloy membranes. Hydrogen is one of the most important gases for industrial applications and its production is principally based on steam reforming of methane. The reaction is carried out at high temperature, about above 1000 K, because of the equilibrium of the endothermic reactions involved in the process:

and

Many studies demonstrate that Pd-based membranes with ideally infinite selectivity for H<sub>2</sub> can be used to increase the equilibrium conversion of steam reforming of methane by H<sub>2</sub> removal [10,11]. The driving force in this process is the partial pressure difference.

The high cost, limited lifetime, and low permeability are relevant limits of Pd and Pd-alloy membranes. To overcome these drawbacks, many studies have been carried out for the preparation of supported metallic membranes in which a thin metallic layer is supported on a thicker sublayer. However, the preparation technology of metallic membranes is still today not sufficiently mature and more work is necessary to produce defect free and stable membranes at acceptable costs.

Hydrogen separation can also be carried out using electrochemical method in an electrolysis cell. By applying a direct current to a proton-conducting membrane, hydrogen can be electrochemically dissociated at the anode, transported through the membrane as hydrated and protons, and recovered at the cathode. In this process, the electrochemical potential difference provides the driving force, and the separation rate can be easily controlled acting on the applied current [12].

In fuel cells systems, as reported in recent patents [13,14], membranes will be present not only as PEM (proton-exchange membrane), which allows protons to pass from the anode to the cathode where they are combined with oxygen and electrons to produce water, but also for the production and purification of the H<sub>2</sub> (Figure 43.3). This system provides a CO<sub>2</sub>-selective membrane process for the purification and water gas shift reaction of a reformed gas, generated from on-board reforming of a fuel, e.g., hydrocarbon, gasoline, diesel, methanol, or natural gas, to hydrogen for fuel cell vehicles.

Membranes have interesting application also in oxygen separation. In many gas-fired power plants for electricity generation, the oxygen for combustion is produced by very expensive cryogenic air separation techniques. This technology requires large plants to cool air to several 100° below zero to separate the component gases. Nitrogen and oxygen are then distributed to customers in liquid form by tanker trucks. About noncryogenic air separation, membrane technology offers interesting opportunities. Recent advances in the development of ion-transport membranes using dense mixed-conducting ceramic membranes to separate oxygen from air [15] will contribute to the complete replacing of cryogenic air separation techniques.

Perovskite-structured oxides with high electronic and oxygen ion conductivities could be used as a membrane alternative to solid electrolytes for oxygen separation. In such materials, both oxygen ions and electronic defects are transported in an internal circuit in the membrane material.

Perovskite membranes are interesting systems not only for their possible applications (e.g., fuel cells, oxygen generators, oxidation catalysts) but also for the fundamental fascination of fast oxygen transport in solid-state ionic.

### 43.5 CATALYTIC MEMBRANE REACTORS

Catalytic membrane reactors (CMRs) are an interesting example of integrated system in which molecular separation and chemical conversions are combined in one unit.

The heterogenization of catalysts in membrane is particularly suitable for catalyst design at the atomic and molecular level. One of the main advantages of the membrane reactors, compared to traditional reactors, is the possibility to recycle easily the catalyst. Moreover, the selective transport properties of the membranes can be used to shift the equilibrium conversion (e.g., esterification reaction), to remove selectively products and by-products from the reaction mixture, to supply selectively the reagents (e.g., oxygen for partial oxidation reactions).

The scientific literature on CMRs is significant today; however, practically only few large-scale industrial applications have been reported so far because of the relatively high price of membrane units. However, current and future advancements in membrane engineering might significantly reverse this trend. CMRs are today successfully applied in small-scale operations, but for their use on large industrial scale, additional efforts mainly related to the optimization of membrane materials, modules manufacturing and reactors design, are required.

The application of CMRs appears of particular interest in several areas such as hydrogen production, oxidation reactions, and enantiomeric productions.

A special category of membrane reactors exists when the membrane defines the reaction volume, e.g., by providing a contacting zone for two immiscible phases (phase-transfer catalysis) excluding solvents and thus making the process environmentally more attractive.

The first applications of CMRs have concerned high temperature reactions. The employed inorganic membranes, characterized by higher chemical and thermal stability with respect to polymeric membranes, still today suffer from some important drawbacks: high cost, limited lifetime, difficulties in reactor manufacturing (delamination of the membrane top-layer from the support due to the different thermal expansion coefficients).

On the other hand, the use of polymeric membranes in CMRs is increasing in interest [16]. The cost of polymeric membranes is generally lower in comparison with inorganic ones, and the preparation protocols allow a better reproducibility; moreover, the relatively low operating temperatures are associated with a less stringent demand for materials used in the reactor construction [16].

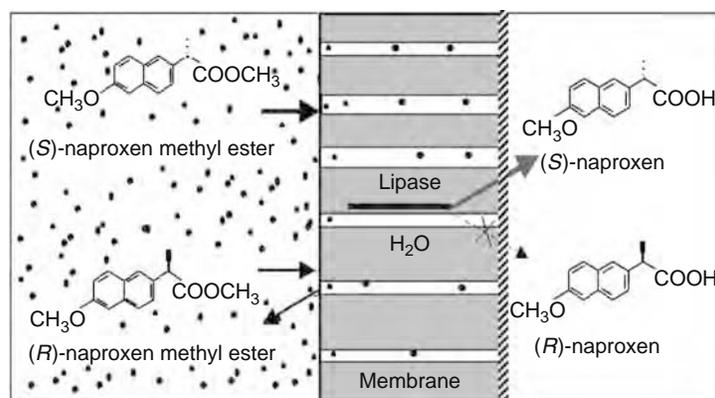

In general, polymeric membranes are less resistant to high temperatures and aggressive chemicals than inorganic or metallic membranes. However, polymeric materials resistant under rather harsh conditions, namely polydimethylsiloxane, Nafion, Hyflon, polyvinylidene fluoride, are today available. Moreover, many reactions of relevant interest in fine chemical synthesis or in water treatment take place under mild conditions.

For biological applications, synthetic membranes provide an ideal support for catalyst immobilization due to their wide available surface area per unit volume; enzymes that are retained in the reaction side do not pollute the products and can be continuously reused. Biocatalytic membrane reactors can also be used in production, processing, and treatment operations. The trend toward environmentally friendly technologies makes these units particularly attractive because of their ability to operate at moderate temperature and pressure, and reduce the formation of by-products. Enzymes, compared to inorganic catalysts, generally permit greater stereospecificity, and higher reaction rates under milder reaction conditions. Relevant applications of biocatalytic membranes reactors include production of new or better foodstuffs, in which desired nutrients are not lost during thermal treatment; novel pharmaceutical products with well-defined enantiomeric compositions; wastewater treatment. The catalytic action of enzymes is extremely efficient, selective and highly stereospecific when compared with chemical catalysts; moreover, immobilization procedures have been proven to enhance the enzyme stability. In addition, membrane bioreactors are particularly attractive in terms of eco-compatibility because they do not require additives, are able to operate at moderate temperature and pressure, and reduce the formation of by-products. Potential applications have been at the origin of important developments in various technology sectors, mainly concerning: induction of microorganisms to produce specific enzymes, techniques of enzymes purification, bioengineering techniques for enzyme immobilization, and design of efficient productive cycles.

One of the most interesting aspects of catalyst heterogenization in membranes is the effect of the membrane environment on the catalyst activity. Membrane composition (hydrophobic or hydrophilic characteristics of the membrane material, presence of chemical groups with acid or basic properties, etc.) and membrane structure (dense or porous, symmetric or asymmetric) can positively influence the catalyst performance, not only by the selective sorption and diffusion of reagents or products, but also influencing the catalyst activity by electronic (electron-donating and electron-withdrawing groups) and conformational effects (stabilization of the transition states). These effects are similar to those occurring in biological membranes.

A membrane-induced structure-reactivity trend that may be exploited to achieve selective processes has been recently observed in polymeric catalytic membranes prepared embedding polyoxotungstates, W(VI)-oxygen anionic clusters having interesting properties as photocatalysts, in polymeric membranes [17]. These catalytic membranes have been successfully applied in the photooxidation of organic substrates in water providing stable and recyclable photocatalytic systems.

Membrane reactors using biological catalysts can be used in enantioselective processes. Methodologies for the preparation of emulsions (sub-micron) of oil in water have been developed and such emulsions have been used for kinetic resolutions in heterogeneous reactions catalyzed by enantioselective enzyme (Figure 43.4). A catalytic reactor containing membrane immobilized lipase has been realized. In this reactor, the substrate has been fed as emulsion [18]. The distribution of the water organic interface at the level of the immobilized enzyme has remarkably improved the property of transport, kinetic, and selectivity of the immobilized biocatalyst.

**FIGURE 43.4** Scheme of the *S*- and *R*-naproxen isomer production in the enzyme-emulsion membrane reactor. (From Li, N., Giorno, L., and Drioli, E., *Ann. N.Y. Acad. Sci.*, 984, 436, 2003.)

An innovative potential application of membrane technology in catalysis and in CMRs might be the possibility to produce catalytic crystals with a well-defined size, size distribution, and shape by membrane crystallization [19,20] (Figure 43.5). Membrane crystallization is particularly attractive for the preparation of heat-sensitive catalysts such as enzymes.

#### 43.6 MEMBRANE-BASED ARTIFICIAL ORGANS

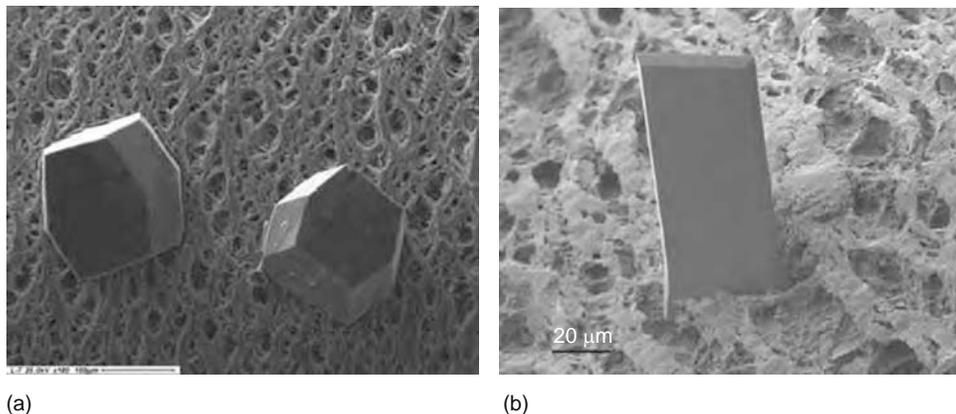

The progress made in the last years in membrane science and technology has a positive fall out, not only in separation industrial processes but also in biotechnology and medical applications.

In particular, membrane bioartificial organs are promising means of treating acute organs failure in alternative to transplantation this is not an option for many patients.

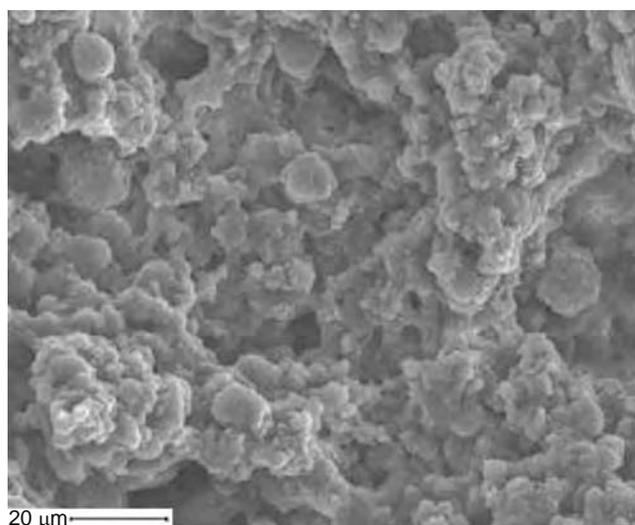

Membrane, with appropriate permeability characteristics, as well as, physicochemical properties, is used in bioartificial organs as selective barriers to compartmentalize isolated cells while allowing the transport of nutrients and metabolites to cells and the transport of catabolites and specific metabolic products to blood. Moreover, the membrane avoids the contact between immune system components with xenogenic cells to prevent immunological response and rejection of xenograft.

Currently, the main areas of interest in membrane bioartificial organs include the bioartificial kidney, the bioartificial pancreas, and the bioartificial liver. Very interesting is also the study of artificial membrane retina, where an artificial membrane is used to convert the light signals to electric signals through the structural change of the membrane [21]. Membrane technology has also relevant potentiality in neural engineering [22] for the development of brain-implantable biomimetic devices.

Cytocompatibility is a key issue for membrane in bioartificial organs. In this respect, the development of new materials with physicochemical properties that provide improved blood/cell compatibility is strictly related to the progress in this promising

**FIGURE 43.5** Lysozyme (a) (Reprinted from Di Profio, G., Curcio, E., and Drioli, E., *J. Cryst. Growth*, 257, 359, 2003. Des.*, 83(A3), 223, 2005.) crystals grown on PP microporous hydrophobic membrane.

**FIGURE 43.6** Liver cells after 48 h of culture on microporous PEEK-WC membranes. (Reprinted from De Bartolo, L., Morelli, S., Rende, M., Gordano, A., and Drioli, E., *Biomaterials*, 25, 3621, 2004. With permission from Elsevier.)

area. Polymer-based materials have numerous applications in medicine for their relative inertness and possibility of controlled degradation to harmless by-products.

A recent study has shown that membranes made of a modified polyetheretherketone (PEEK-WC) are interesting materials for biomedical applications [23,24]. The cytocompatibility of PEEK-WC membranes was evaluated by culturing hepatocytes isolated from rat liver (Figure 43.6). The properties of PEEK-WC membranes were compared to polyurethane membranes prepared using the same technique, and commercial membranes (made of Nylon, polyethersulphone, and polyester). The results have shown that PEEK-WC membranes promoted hepatocyte adhesion most effectively and metabolic activities of cells cultured on these membranes improved significantly.

The interesting results obtained, not only with PEEK-WC but also with other materials, encourage further research work to better understand and improve the potentialities of membranes in biomedical applications.

In cell encapsulation, ultrathin polymeric membranes microcapsules are used for the immunoprotection of transplanted cells. The membrane must allow the selective passage of some molecules but must act as a barrier to others. As a consequence, a careful material design is fundamental.

Membrane capsules containing dopamine-secreting cells have been investigated for treating of Parkinson's disease. Immunoprotective membrane cell transplants are also being used in the treatment of other nervous system disorders [25].

Although the interesting results obtained in many studies, the lack of clinical-grade polymers and the difficulties in the production of uniform capsules with excellent repeatability and reproducibility, still limits the clinical applications of this technology [26].

Membrane emulsification has been recently proposed for the preparation of stable and uniform-sized microcapsules [27]. Membrane emulsification is a technology that allows to obtain uniform emulsions at low energy input compared to the emulsion prepared using high-pressure homogenizers and rotor/stator systems; therefore, it is very useful for the preparation of emulsions containing labile compounds such as bioactive molecules sensitive to shear stress [28].

Membranes have been also used in the antisolvent solidification process wherein a liquid medium containing organic or inorganic compounds which have to be solidified, is forced through a membrane into one or more antisolvent. Alternatively, one or more antisolvent can be forced through a membrane into a liquid medium containing the compounds, which are to be solidified, yielding a composition comprising these organic or inorganic compounds [29].

For many industrial applications, the particle size of the solidified compounds is very important. This issue is of particular interest in the area of pharmaceutical product development. For example, in low dosage forms it might be difficult to obtain a good homogeneity if the particle size is too large. Moreover, a large particle size can make the pharmaceutical compound difficult to process into a pharmaceutical end product. The particle size also influences the ease of segregation in a mixing process, which takes place before tableting. The controllability of the particle size is also important because a wide variation in particle size of the pharmaceutical compounds can lead to insufficient control of its concentration. Moreover, if the pharmaceutical compounds are prepared in a crystalline form, the purity, crystal size distribution, and polymorphy of the crystals can be very important. For example, differences in crystal structure can lead to a difference in physicochemical parameters such as stability, rate of dissolution, melting point, etc., which frequently are strongly influenced by the crystal forms of a polymorphous compound.

By using a membrane for the dosing of the antisolvent to the liquid medium containing the compounds of interest or vice versa for dosing the liquid medium in the antisolvent, an improved solidification process can be obtained.

This patented device allows to obtain a controlled solidification process, in many cases crystallisation, yielding a composition comprising solid particles which are in general nonagglomerated and which have an improved quality (e.g., an improved shelf life) [29]. Moreover, with this process higher product yields can be achieved. In other words, the antisolvent solidification process can allow a more efficient use of (starting) materials or solvents and, therefore, a decrease in energy consumption can be achieved compared to conventional evaporative or antisolvent processes [29]. Furthermore, the process can easily be scaled-up to a higher volume and enables a robust control of the particle size [29].

### 43.7 CONTRIBUTIONS OF MEMBRANE TECHNOLOGIES TO THE LIFE IN THE SPACE AND IN OTHER PLANETS

Membrane technology is also an ideal technology for application in the space because process intensification strategy is a more imperative request in the space than on the Earth, today. Volumetric efficiency, optimal remote control, energy, and waste saving are fundamental aspects in the space. Membranes could efficiently solve some of the problems of life in the space such as energy production and water and air purification, fulfilling these requirements.

Recently different research projects on membrane technology have been funded by NASA. In one of these, researchers are working for the production of rocket fuel from the Martian atmosphere using membrane-based gas separation [30]. The Martian atmosphere is composed mainly of 95% CO<sub>2</sub> (95%) that mixed with H<sub>2</sub> yields, when heated, methane, a useful propellant for rockets or rovers. This process, called Sabatier process, gives water as by-product that can be electrolyzed into oxygen, for breathing, and hydrogen, which can be used to produce another round of methane. However the Martian atmosphere is not pure enough for the Sabatier process, and CO<sub>2</sub> must be separated from the other atmospheric components, mostly nitrogen and argon, before its processing. In this project, specialized polymers engineered to increase CO<sub>2</sub> solubility are used for membrane preparation, and tested in a special chamber that simulates the Martian environment. The researchers want to design a device that produces CO<sub>2</sub> pure at 99.8% at a rate of 2.5 L/min.

These membranes could be also used to remove CO<sub>2</sub>, which is a waste product of human metabolism, from the atmosphere of a self-contained spacecraft. Moreover, these or similar membranes could also offer possible solutions to the problem of the CO<sub>2</sub> control emission also in the Earth.

Another important international project in which membranes are proposed as interesting tools for space life-support systems is the Space2Tex [31]. The Space2Tex project has been originally conceived within the framework of the European Space Agency's Technology Transfer Program, inspired by the MELiSSA (Micro-Ecological Life Support System Alternative) research activities on membrane bioreactors. MELiSSA has been conceived as a microorganisms and higher plants-based ecosystem intended as a tool to gain understanding of the behavior of artificial ecosystems, and for the development of the technology for a future regenerative life-support system for long-term manned space missions, e.g., a lunar base or a mission to Mars [32].

The Space2Tex project aims at developing a novel concept of compact high efficiency and cost-effective wastewater treatment plant for water recycling in textile finishing. The project final objective is the application of membrane bioreactors for the biodegradation of textile-finishing pollutants, often hardly biodegradable, in small wastewater system plants to be inserted end-of-pipe of textile-processing plants, with the final aim of 100% water recycling in micro-ecological space life-support systems.

It is important to note that the new membranes and membrane systems that have been, or will be developed for the life in the space in the next years could also help people to live in the Earth. Because of the more and more rapid growth of the worldwide population, the Earth is becoming a sort of big spacecraft where billions of people live together, and the problems of the life in the Earth are becoming very similar to the problem of the life in the space.

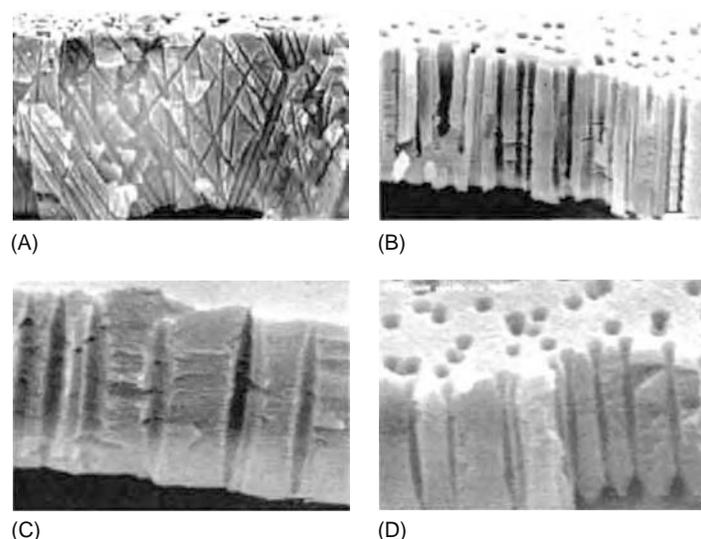

### 43.8 NANOSTRUCTURED MATERIALS

Development of innovative materials with improved properties is a key issue for the application of membrane technology in industrial processes. Significant progresses have been made in the study and realization of new organic and inorganic membranes with controlled structure.

The ability to control pore sizes is an important topic for membrane technology development. Membranes with controlled morphology can be used not only in separation process but also in chemical conversion supplying highly ordered and confined geometries for chemical reactions.

Nanoscale control of membrane architecture can further extend the field of application of membrane technology. With regard to this aspect, nanotechnologies have been used to create membrane structures by the typical methods used for electronic component construction using lasers and etching. Track etch membrane technology is an example of industrial application of track etching technique (Figure 43.7) [33].

In these membranes, pore size, shape, and density can be varied in a controlled way and, as a consequence, a membrane with the required transport and retention characteristics can be produced.

**FIGURE 43.7** Examples of porous structures produced in thin polymeric films using various methods of irradiation and chemical treatment. (Reprinted from Apel, P., *Radiat. Meas.*, 34, 559, 2001. With permission from Elsevier.) (A) Cross section of a polycarbonate membrane with cylindrical nonparallel pore channels; (B) polypropylene membrane with slightly conical parallel pores; (C) polyethylene terephthalate membrane with cigar-like pores; and (D) polyethylene terephthalate membrane with “bow-tie” pores.

Microporous alumina membranes electrochemically grown by anodizing of aluminium can be also produced with an excellent controlling of pore size distribution and porosity [34].

Membrane made of precisely sized nanotubes also hold great potential for filtration and separation processes. The nanometer-scale sized and hollow-, cylindrical-shaped nanotubes suggest that they may be used as membranes with pores on the order of 1–100 nm.

Nanotube membranes prepared via the template method are also of particular interest [35]. For example, gold nanotube membranes have been successfully synthesized using a template-based electroless plating technique [36] (Figure 43.8). Human serum albumin, which acts as an enantiomer selector, was immobilized on the inner surface of the nanotubes through a reactive thiol, obtaining a bio-nano device for chiral resolution. However, for large-scale application of nanotubes membranes improving in their preparation technique are request (lower costs, higher stability and reproducibility, etc.).

Preparation of membranes by phase separation performed on mould having a micrometer-sized surface profile has been also reported for the production of membranes with microstructure structure [37].

Self-assembling is another innovative research field in membrane technology. Self-assembly process consists in the regular assembly of small molecular entities into larger supramolecular structures exhibiting new functions that can not be exhibited by

**FIGURE 43.8** Gold nanotube synthesized by using a 50 nm polycarbonate membrane template. (Reprinted from Shao, P., Ji, G., and Chen, P., *J. Membr. Sci.*, 255, 1, 2005. With permission from Elsevier.)

the isolated units. The interaction between subunits is generally due to noncovalent bonds, such as hydrogen bonds, van der Waals interactions, and electrostatic forces. Recently, Massachusetts Institute of Technology researchers have patented stable macroscopic membranes formed by the self-assembly of amphiphilic peptides, peptides with alternating hydrophobic and hydrophilic residues [38]. The membranes result stable in aqueous solution, serum, ethanol, and are highly resistant to heat, alkaline and acidic pH, chemical denaturants, and proteolytic digestion. They are also noncytotoxic. Potential uses include biomaterial applications such as slow-diffusion drug delivery systems and artificial skin and separating filters. The invention further provides scaffolds comprising the self-assembling peptides and methods of using the scaffolds including for cell culture, tissue engineering, and tissue repair.

### 43.9 MEMBRANES IN ELECTRONIC DEVICES

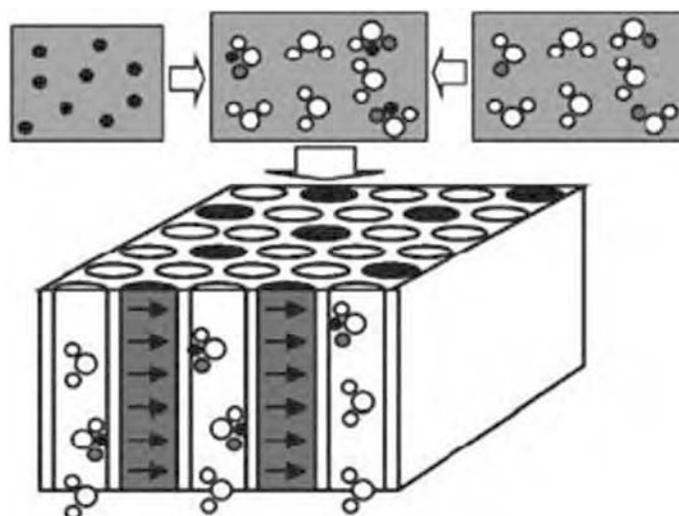

Membranes applications in sensors and microelectromechanical systems (MEMS) are increasing in importance in our society. The development of new device able to give rapid detection of chemical and biological species is central to many areas of life science and industrial production. In particular, conducting polymeric materials show major potentiality in this field, and are replacing classical inorganic semiconductor materials because of their better selectivity and rapid measurements, low cost, and easy manufacture for their preparation as films [39]. Moreover, appropriate molecular design of polymer properties can increase the efficiency of the system.

Membrane technology has enormous potentiality in gas detection, ion-selective sensors, biochemical analyzes, medical applications, and quality control on industrial manufacturing processes, food and beverages. Polymeric membranes are used in sensor device, either participating in sensing mechanism or immobilizing the substance responsible for sensing. Membranes are applied today also for mimic natural sense organs. An electronic tongue using membranes based on conducting polymers (polypyrrole and polyaniline) and a lipid-like material components (stearic acid) has been already realized [40]. The device is able to distinguish salt, sweet, bitter, and acidic solutions.

Very promising can be the use in sensors field of molecular imprinted membrane [41,42], where the memory of a specific substance is imprinted in a polymeric material.

Membranes fabricated using the MEMS technology are finding an increasing number of applications in sensors, actuators, and other sophisticated electronic device. However, the new area of application of MEMS is creating new materials demands that traditional silicon cannot fulfill [43]. Polymeric materials, also in this case, are the optimal solution for many applications. Microfabrication of polymeric films with specific transport properties, or micromembranes, already exists, and much work is in progress [44–50].

Membranes made or filled with ferromagnetic materials have special features making them useful to MEMS applications. In a recent work [51] a micro-magnetic membrane for biological separation has been proposed. Magnetic beads have been engineered to bind to specific biological system (molecules, proteins, viruses, bacteria) and mixed with the biological solution of interest (Figure 43.9). After the binding process, the solution is passed through a nanoporous membrane with cylindrical pores partially filled with ferromagnetic material. An external magnetic field is applied parallel to the membrane surface to magnetize the ferromagnetic cylinders perpendicular to the wires' long axis. Inside the pores, the biological system, bound

**FIGURE 43.9** Magnetic membrane proposed for biological separation. (Reprinted from Barbic, M., *J. Magn. Magn. Mater.*, 249, 357, 2002. With permission from Elsevier.)

to the magnetic bead, is trapped on the walls of the capillaries while the unbound units are passed through. The trapped particles can later be released simply by removing the external magnetic field. The magnetic forces depend inversely on the diameter of the ferromagnetic wires, and, therefore, smaller the pore diameter, stronger the magnetic field gradients and magnetic forces will be [52].

This method is well suited to be implemented into the microfluidic and MEMS designs.

### 43.10 MEMBRANE CONTACTORS

In the field of membrane technology, membrane contactors (MCs) represent a very important branch of new devices having a wide range of applications with a high charge of innovation. Membrane contactors are expected to play a decisive role in the design of alternative production systems appropriate for a sustainable growth [53,54]. Membrane contactors are systems where the membrane function is to facilitate diffusive mass transfer between two contacting phases (liquid–liquid, gas–liquid, gas–gas, etc.) without dispersion of one phase within another. This is accomplished by passing the fluids on opposite sides of a microporous membrane. By controlling the pressure difference between the fluids, one of them is immobilized in the pores of the membrane so that the fluid–fluid interface is located at the mouth of each pore (Figure 43.10).

In a membrane contactor, generally, microporous hydrophobic membranes are used to promote mass transfer between phases.

These membrane systems, mainly provided in the form of low cost hollow fibres, offer a high interfacial area, significantly greater than most traditional absorbers, between two phases to achieve high overall rates of mass transfer. Furthermore, whereas the design of the conventional devices is restricted by limitations in the relative flows of the fluid streams, membrane contactors give an active area which is independent of the liquid fluid dynamics.

Membrane crystallization has been recently proposed as one of the most interesting and promising extension of the membrane contactors concept [19,20]. This innovative technology uses the evaporative mass transfer of volatile solvents through microporous hydrophobic membranes to concentrate feed solutions above their saturation limit, thus attaining a supersaturated environment where crystals may nucleate and grow (Figure 43.5) [19,20]. In addition, the presence of a polymeric membrane increases the probability of nucleation with respect to other locations in the system (heterogeneous nucleation).

Membrane distillation	Contacting phases Phase I: Liquid Phase II: Liquid gas vacuum	Driving force $X_1^I$ $X_1^{II}$ $\Delta X_1 = \Delta T_1 - \Delta P_1$ (Partial pressure gradient)	Limit to mass transfer $T^I$ $T^{II}$ Temperature polarization
Osmotic membrane distillation	Contacting phases Phase I: Liquid Phase II: Liquid	Driving force $X_1^I$ $X_1^{II}$ $\Delta X_1 = \Delta T_1 - \Delta P_1$ (Partial pressure gradient)	Limit to mass transfer $c^I$ $c^{II}$ Concentration polarization
Membrane crystallization	Contacting phases Phase I: Liquid solid Phase II: Liquid	Driving force $X_1^I$ $X_1^{II}$ $\Delta X_1 = \Delta T_1 - \Delta P_1$ $\Delta X_1 = \Delta C_1 - \Delta P_1$	Limit to mass transfer $T^I$ $T^{II}$ $c^I$ $c^{II}$ Temperature polarization Concentration polarization
Gas–liquid membrane contactors	Contacting phases Phase I: Gas Phase II: Liquid	Driving force $X_1^I$ $X_1^{II}$ $\Delta X_1 = P_1 - HC_1$	Limit to mass transfer $p^I$ $c^I$ $c^{II}$ Resistance in liquid or in membrane phase
Membrane emulsifiers	Contacting phases Phase I: Liquid Phase II: Liquid	Driving force $X_1^I$ $X_1^{II}$ $\Delta X_1 = \Delta P$	Limit to mass transfer $c^I$ $c^{II}$ Resistance in liquid or in membrane phase
Phase–transfer catalysis	Contacting phases Phase I: Liquid Phase II: Liquid	Driving force $X_1^I$ $X_1^{II}$ $\Delta X_1 = \Delta C_1$	Limit to mass transfer $c^I$ $c^{II}$ Resistance in liquid or in membrane phase

FIGURE 43.10 Different examples of membrane contactors.

Membrane contactor offers potential solution in a wide range of gas/liquid and liquid/liquid applications: gas adsorption and stripping, liquid/liquid extraction, dense gas extraction, fermentation and enzymatic transformation, pharmaceutical applications, protein extraction, wastewater treatment, chiral separations, semiconductor manufacturing, carbonation of beverages, metal ion extraction, protein extraction, and VOCs removal from waste gas [55].

Membrane crystallizers, membrane emulsifiers, membrane strippers and scrubbers, membrane distillation systems, membrane extractors, etc. can be devised and integrated in the production lines together with the other existing membranes operations for advanced molecular separation, and chemical transformations conducted using selective membranes and membrane reactors, overcoming existing limits of the more traditional membrane processes (e.g., the osmotic effect of concentration by reverse osmosis).

A number of commercial applications of MCs have been already successfully realized. A bubble-free membrane-based carbonation line, using Liqui-Cel equipment, is in operation by Pepsi in West Virginia since 1993. MCs are also used in beer production: the CO<sub>2</sub> removal stage is followed by nondispersive nitrogenation to obtain a dense foam head. Another important field of application of MC is the production of ultrapure water for semiconductor manufacturing.

### 43.11 CONCLUSIONS

Membrane science and technology is expected to play an increasingly important role in the future for various industrial sectors. The availability of new membrane with tailor-made properties and new membrane processes offers important tools for the design of alternative production systems appropriate for a sustainable growth.

The traditional membrane separation processes (reverse osmosis, micro-, ultra- and nanofiltration, electrodialysis, pervaporation, etc.), already largely used in many different applications, are today combined with new membrane systems such as CMRs and membrane contactors. Membranes are applied not only in traditional separation processes such as seawater desalination but also in medicine, bioengineering, microelectronics, the life in the space, etc.

The biological systems well represent what are the new trends in membrane technology. The integration of membrane operations allows in prospective the possibility to redesign important industrial processes. Petrochemical plants, complex artificial organs such as the brain, etc. can be more and more conceived as based on integrated membrane systems simulating the analogous biological ones. The possibility to produce self-repairing membranes is also an interesting possibility.

Despite its success and undoubtedly great potential, membrane technology is still quite far from fulfilling all the expectations of its role in intensification of a large variety of processes. Actually, membrane-based hybrid separation methods cannot be proven to be significantly better than conventional techniques, and the use of catalytic membranes is just recently becoming effective for large-scale industrial applications. To overcome these barriers, more systematic analyzes of possible advantages or drawbacks due to the introduction of a membrane stage instead of a conventional unit, clear protocols and comparison indexes for the choice of the best membranes and optimal operative conditions, accurate modelling for an easy scale-up or scale-down, and significant multidisciplinary research efforts are needed.

However, these efforts need to be combined with new research works in the process dynamics and in the study of advanced control systems applied to integrated membrane systems. These multidisciplinary studies will offer interesting opportunities for the future development of membrane engineering.

**COLOR FIGURE 24.5** Enantioseparations. (A) 3-Dimensional structures of the RS enantiomer (left) and the SR enantiomer (right) of the drug FTB. The black, white, blue, red, and yellow balls are carbon, hydrogen, nitrogen, oxygen, and fluorine, respectively, and \* denotes the chiral centers. The geometry optimization was done by ab initio calculation with minimal basis set in HyperChem 6.03. The drug is in clinical trials by Hormos Medical Corp., Turku, Finland. (From Lee, S.B., Mitchell, D.T., Trofin, L., Li, N., Nevanen, T.K., Söderlund, H., and Martin, C.R., *Science*, 296, 2198, 2002. With permission.) (B) Chiral HPLC chromatograms for racemic mixtures of FTB before (I) and after (II, III) extraction with 18 mg/mL of 200-nm Fab-containing nanotubes. Solutions were 5% dimethylsulfoxide in sodium phosphate buffer, pH 8.5. (From Mitchell, D.T., Lee, S.B., Trofin, L., Li, N., Nevanen, T.K., Söderlund, H., and Martin, C.R., *J. Am. Chem. Soc.*, 124, 11864, 2002. With permission.)

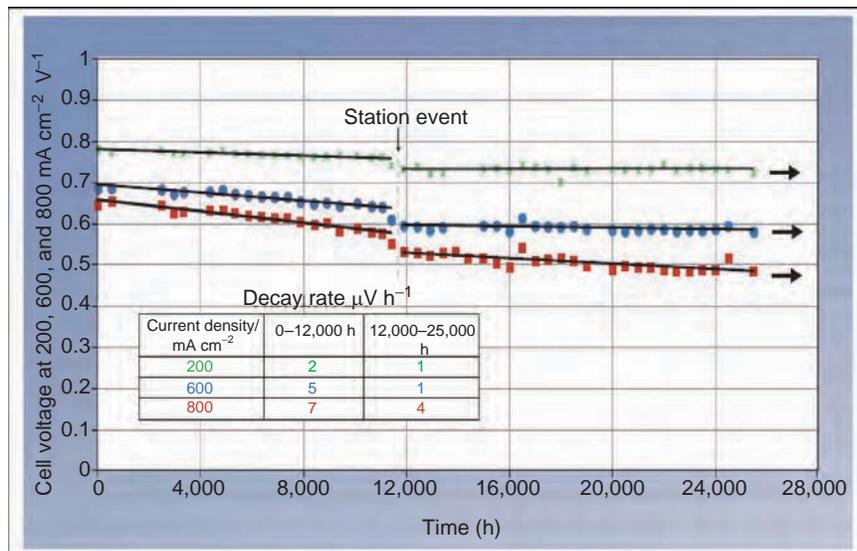

**COLOR FIGURE 24.13** (A) I–V curves for nanotubes with mouth diameter 40 nm containing no DNA (black) and attached 12-mer (blue), 15-mer (red), 30-mer (green), and 45-mer (orange) DNAs. (B,C) Schematics showing electrode polarity and DNA chain positions for on (B) and off (C) states. (From Harrell, C.C., Kohli, P., Siwy, Z., and Martin, C.R., *J. Am. Chem. Soc.*, 126, 15646, 2004. With permission.)

(From the Foreword) “... *comprehensive discussion of membrane applications in the chemical, food, and pharmaceutical industries, in biotechnology, and in the treatment of toxic industrial effluents. The applications of membranes in different areas are described by scientists and engineers who not only are experts in membrane science and technology, but also have extensive experience in the specific field of membrane application...*”

—Heiner Strathmann, University of Stuttgart, Germany

During the past two decades, membrane technology has grown into an accepted unit of operation for a wide variety of separations in industrial processes and environmental applications. Written by prominent researchers and professionals from all over the world, the **Handbook of Membrane Separations: Chemical, Pharmaceutical, Food, and Biotechnological Applications** covers the full spectrum of membrane technology and discusses its advancement and applications.

#### Features

- Explores chemical, pharmaceutical, food processing, and biotechnological applications of membrane processes ranging from selective separation to solvent and material recovery
- Presents in-depth knowledge of membrane separation mechanisms, transport models, membrane permeability computations, membrane types and modules, and membrane reactors
- Provides background information on the various membrane components and processes to evaluate their potential application
- Deals with membrane applications in industrial waste management and environmental engineering
